## ABSTRACT

Parabasalia is a phylum of flagellated protists with a large range of cell sizes, spanning from as little as 7  $\mu\text{m}$  in length (e.g. *Pentatrichomonas hominis*) to well over 300  $\mu\text{m}$  (e.g. *Pseudotrichonympha grassii*). Many Parabasalia are associated with animals in mutualistic, parasitic, or commensal relationships. The largest Parabasalia species are obligate mutualists of termites, which help to digest lignocellulose. While the specific digestive roles of different protist species are mostly unknown, Parabasalia with different cell sizes are known to inhabit different regions of the termite hindgut. It is currently unclear whether these size differences are driven by selection or drift, but it is well known that cell size correlates with genome size in eukaryotes. Therefore, in order to gain insight into possible selection pressures or mechanisms for cell size increase, genome sizes were estimated for the five Parabasalia species that inhabit the hindgut of *Coptotermes formosanus* Shiraki. The cell volumes and C-values for the five protist species are 89,190  $\mu\text{m}^3$  and 147 pg in *Pseudotrichonympha grassii*, 26,679  $\mu\text{m}^3$  and 56 pg in *Holomastigotoides hartmanni*, 8,985  $\mu\text{m}^3$  and 29 pg in *Holomastigotoides minor*, 1,996  $\mu\text{m}^3$  and 12 pg in *Cononympha leidyi*, and 386  $\mu\text{m}^3$  and 6 pg in *Cononympha koidzumii*. The positive correlation between genome size and cell size was maintained in this group ( $R^2 = 0.76$ ). These genome sizes are much larger than the previously estimated genome sizes of non-termite associated Parabasalia, which spanned 2-fold ranging from 0.088 pg (in *Tetratrichomonas gallinarum*) to 0.181 pg (in *Trichomonas foetus*). With these new estimates, the range now spans over 1,500-fold from 0.088 pg to 147 pg in *P.*

*grassii*, implying potential differences in the level of selective pressures for genome size in termite-associated Parabasalia compared to other protists.

## 1. INTRODUCTION

Genome size has large variation across eukaryotes, most of which is unexplained. It has long been noted that some organisms considered less complex than humans had larger genome sizes; this disconnect between perceived organismal complexity and genome size is known as the C-value enigma (Gregory 2002). Many attempts have been made to correlate genome size to cell characteristics such as metabolic rate, rate of development, and body size which have occasionally revealed weak lineage-specific relationships. The only characteristic that has a consistent correlation to genome size across eukaryotes is cell size (Gregory 2001; Cavalier-Smith 1980). Despite knowing these relationships exist and many of the factors that can contribute to genome changes, the evolutionary forces behind genome expansion and reduction are highly debated. These forces are generally explained through ‘mutational pressure’ or ‘optimal DNA’ types of theories. In mutational theories, genome size is explained by the balance between constant mutational pressure to accrue insertions and selective pressures to keep the genome size in check (Pagel and Johnstone 1992). Under this view, any correlation between C-value and cell size or other cell characteristics is merely coincidental. Examples of mutational pressure theories include the junk DNA theory, in which non-genic regions or transposable elements (TE) accumulate over time until replication is strained, and selfish DNA theories, in which transposable elements propagate themselves within the DNA sequence (Doolittle and Sapienza 1980; Orgel and Crick 1980; Gregory 2001). Conversely, optimal DNA theories consider the quantity of DNA to affect an organism’s fitness, such that genome sizes and other cell characteristics, such as cell volume or metabolic rate can coevolve (Gregory 2001; Cavalier-Smith 1980). In the

nucleo-skeletal optimal DNA theory, cell volume may be the primary target of selection but changes in nucleus volume accompany those changes and modulation of DNA content is necessary to alter the nucleus envelope size (Cavalier-Smith 1978).

This study aims to estimate the genome size of *Coptotermes formosanus* symbionts and place their cell and genome sizes in context of both the evolution of Parabasalia as well as the generalized context of the evolution of eukaryotes as a whole. Regardless of the explanation as to why, this study recognizes the positive correlation that cell size has with DNA content and hypothesizes that due to the relatively large size of *C. formosanus* symbiont protists they are expected to display relatively large genome sizes. Of the *C. formosanus* symbionts, the smallest is similar in size to and the largest is about 30 times larger than *Trichomonas vaginalis*, a well-studied model parabasalid (Jasso-Selles et al. 2020). Although the protist community of *C. formosanus* has recently been characterized by newly identifying two species using molecular and phylogenetic means and discovering species specific functional roles, there is still a lot that needs to be done to get a better understanding of their role in the symbiotic relationship with termites and their evolution (Jasso-Selles et al. 2020; Nishimura et al. 2020).

In this study, C-value and genome size both refer to the amount of DNA in the nucleus of the dominant life cycle stage, for example the soma of an animal or the vegetative phase of a protist. This can be further specified as 2C for predominantly diploid organisms or 1C for predominantly haploid organisms (or the gametes of diploid organisms). Genome size is usually given in the units of mega- or giga-bases (Mbp, Gbp) while C-value is given in picograms (pg); 1 pg = 978 Mbp (Doležel et al. 2003).

Through karyotype testing, it has recently been determined that trichomonads are haploid (1C). This paper will calculate the genome sizes of the *C. formosanus* symbionts as if they were haploid as well (Zubáčová et al. 2008).

### **1.1 Parabasalia**

Recent advances have brought relative stability to the eukaryotic tree of life, resulting in a number of super-kingdom level lineages called supergroups. While most of the supergroups remain relatively stable in the tree, the Metamonada, to which Parabasalia belong, have uncertain placement. Metamonada was previously grouped with Discoba and *Malawimonas* in the supergroup Excavata but the phylogenetic support has been mixed (Hampl et al. 2009; Brown et al. 2018). Within Metamonada are the phyla Preaxostyla, Parabasalia, and Fornicata, which mainly include species that form symbiotic relationships with animals. Symbiosis refers to the relationships between two different organisms that is either parasitic, commensal, or mutualistic (Paracer and Ahmadjian 2000). Parasitic symbiosis occurs when one organism benefits from the relationship at the cost of the other. This describes the relationship between pathogens and their hosts, such as *T. vaginalis* mentioned earlier. Commensal symbiosis occurs when one organism benefits while the other neither benefits nor is harmed by the presence of the other. A large portion of Metamonada species fall into this category. Finally, mutualistic symbiosis describes the relationship between two organisms when both benefit from the presence of the other. Symbiont refers to the organisms within such relationships, in this paper it refers to the group of Parabasalia protists that reside in the hindgut of *C. formosanus*.

Of the three Metamonada phyla, Preaxostyla and Parabasalia have species known to reside in certain termites and wood-eating roaches in the genus, *Cryptocercus*. Within Preaxostyla, the order Oxymonadida, which is comprised of roughly 140 species, contains all of the termite and *Cryptocercus*-associated species of Preaxostyla (Hampl 2016). The order also contains some species that can be found elsewhere besides the termite or cockroach gut, such as *Monocercomonoides* which can be found in a wide variety of terrestrial animals, such as guinea pigs, crickets, and lizards (Hampl 2016).

There are approximately 450 described Parabasalia species grouped into six classes: Trichomonadea, which is divided into two orders (Trichomonadida and Honigbergiellida) and four families; Tritrichomonadea, which has one order (Tritrichomonadida) and four families; Hypotrichomonadea, which has one order (Hypotrichomonadida) and one family; Cristamonadea, which has one order (Cristamonadida) and one family; Spirotrichonymphaea, which has one order (Spirotrichonymphida) and one family; and Trichonymphaea, which has two orders (Trichonymphida and Lophomonadida) and a total of six families (Figure 1; Čepička et al. 2017). Parabasalia are mostly anaerobic and symbiotic, having parasitic, mutualistic, or commensal relationships. The orders Trichonymphida, Spirotrichonymphida, and Cristamonadida are only found in termites and *Cryptocercus* and have an obligate mutualistic relationship to their hosts (Cleveland 1925; Čepička et al. 2010). Members of the other four orders are often found in the digestive tracts of various animals although some have been found outside their hosts digestive tract, such as *T. vaginalis* which is a

human sexually transmitted infection. Some are host specific while others, such as *Trichomitus batrachorum* and *Pentatrichomonas hominis*, can infect multiple host species (Honigberg 1953; Čepička et al. 2005; Smejkalová et al. 2011). A few species are free-living, such as *Pseudotrichomonas keilini* and *Monotrichomonas carabina* (Honigbergellidae), and can be found in freshwater, brackish, and marine anoxic or microoxic environments (Bishop 1935; Bishop 1939; Bernard et al. 2000; Yubuki et al. 2010). Across these classes there is a lot of variability in cell size and complexity as well as number of flagella. Parabasalia is informally divided into two groups based on these character differences: trichomonads are mostly small cells with few flagella while hypermastigotes tend to be large and have many flagella, from around 20 to more than ten thousand.

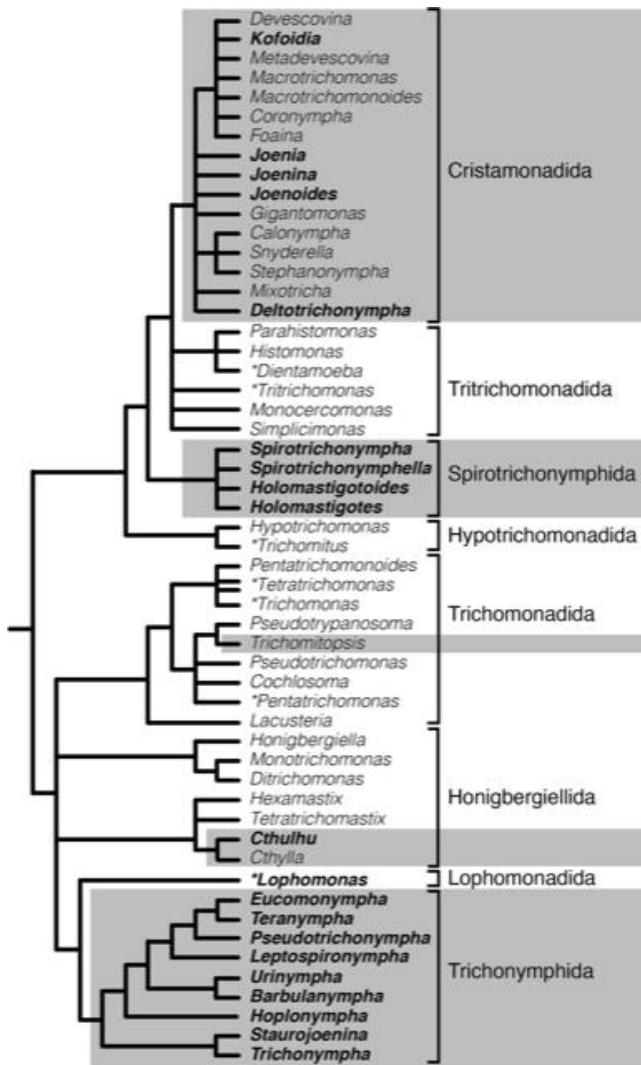

The informal term “trichomonad” describes the smaller pleiomorphic species belonging to Trichomonadida, Honigbergellida, Tritrichomonadida, and Hypotrichomonadida as well as some larger uni-nucleate species belonging to Cristamonadida (Čepička et al. 2010; Gile and Slamovits 2012; James et al. 2013). They range from 10 – 100  $\mu\text{m}$ ; those found in vertebrates tend to be closer to 10  $\mu\text{m}$  while those that inhabit termites tend to be closer to the 100  $\mu\text{m}$  end of the range. Trichomonads are primarily uninucleate, although two lineages of Cristamonadida have developed multiple nuclei (Cleveland et al. 1964; Brugerolle 2004; Harper et al. 2009; Gile et al. 2011). They have up to six flagella per nucleus including a recurrent flagellum that runs posteriorly along the cell, (Kirby 1942; Hollande and Valentin 1969; Brugerolle and Lee 2000). Hypermastigotes include all species from the orders Trichonymphida,

Lophomonadida, and Spirotrichonymphida and a few species from Cristamonadida and Honigbergiellida (Čepička et al. 2010; Gile and Slamovits 2012; James et al. 2013).

Although they share many of the same cell structures as the trichomonads, the cells tend to be larger, measuring in the hundreds of  $\mu\text{m}$ , and can have more than ten thousand flagella. The Trichonymphida hypermastigotes have an anteriorly positioned rostrum while Spirotrichonymphida hypermastigotes lack a rostrum.

Parabasalids and oxymonads share many characteristics, such as anaerobic metabolism and ecto- and endosymbiotic relationships with bacteria. They differ in certain aspects as well, like in mitochondria and Golgi (Čepička et al. 2017). Both groups are anaerobic, being intolerant of oxygen, which allows them to survive in the guts of animals. Both groups also experience symbiotic relationships with bacteria and protists inside and outside their cell such as with spirochetes which are attached to the outside of the cell of some species (Ohkuma et al. 2015; Čepička et al. 2017). There is also a trend of larger species of oxymonads that reside in the gut of termites to increase in flagella number, though not as drastic an increase as in Parabasalia (Čepička et al. 2017). In contrast, Preaxostyla have a range of mitochondria types from present to reduced to absent. Reduced mitochondria called hydrogenosomes are present in *Trimastix* and *Paratrimastix* (similar to Parabasalia) while mitochondria tend to be absent, with no homologous or modified organelle, in Oxymonadida (Tachezy 2008; Karnkowska et al. 2016; Čepička et al. 2017). Oxymonads also differ in their Golgi complex. In Parabasalia, there is a distinctive and characteristic Golgi complex that is part of their parabasal body. In contrast, the Golgi complex in Oxymonadida is not identified

(Karnkowska et al. 2016). There are Golgi specific genes in oxymonads indicating its presence but is too discreet to identify in electron microscopic images (Karnkowska et al. 2016).

**Figure 1.** Schematic phylogeny of Parabasalia, including about half of the approximately 100 described genera, modified from Čepička et al. 2017. Gray boxes indicate exclusively termite-associated genera. Asterisks indicate genera for which at least one species has been reported to inhabit or infect humans. Bold type indicates hypermastigotes.

## 1.2 The Termite *Coptotermes formosanus* Shiraki

With the help of their gut endosymbionts, termites are one of the few groups of animals that can break down the cellulose in wood. This ability makes them both ecologically important and economically destructive, as they are major contributors to plant decomposition but can also severely damage human-made wooden structures (Rust and Su 2011). Termites form a clade along with the *Cryptocercus* wood roaches within the cockroach class Blattodea. Termites are divided into two groups informally referred to as “lower” and “higher” termites. Gut protists were acquired in the ancestor of this clade and helped establish eusocial behavior along with shifts from parental to alloparental brood rearing in the termites (Nalepa 2015). In later-diverging host lineages these protists were lost, and this loss is what distinguishes “lower” and “higher” termites. “Lower” termites include the deeper-branching, more plesiomorphic termites who have retained gut protist communities while “higher” termites, which comprise the majority of termite species, have a more recent origin and do not harbor specialized wood-feeding protist symbionts (Chouvenc et al. 2021). The loss of protists and acquisition of new bacteria and archaea to replace and perform new digestion-related function in “higher” termites allowed for increased diversity and specialization of those termites (Chouvenc et al. 2021). Although it is not clear how diversification effected the loss of protists or vice versa, it is known that there is an increase in diversity of feeding modes and other colony characteristics in “higher” termites. Rather than feeding strictly on wood, the “higher” termites can feed on wood, soil, leaf litter, and fungi (Bignell 2016). The change in

symbiont community composition also accompanied increased complexity of nesting patterns and caste differentiation.

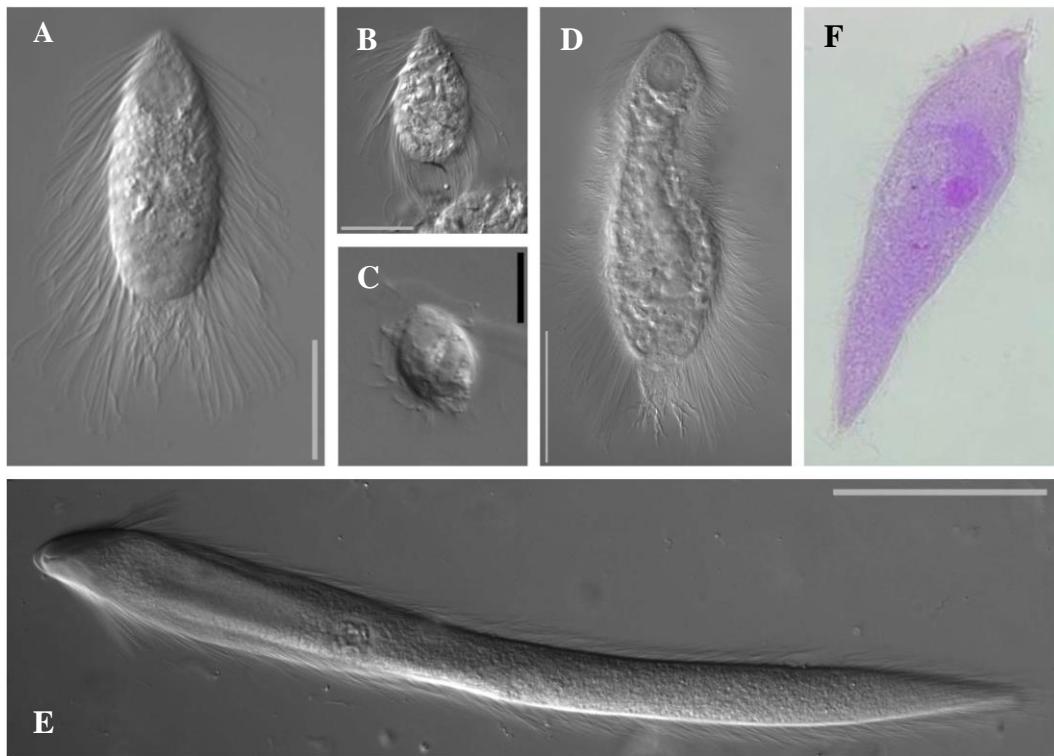

*Coptotermes formosanus* Shiraki (Blattodea: Rhinotermitidae) is a subterranean “lower” termite (Krishna et al. 2013). It lives in warm to temperate subtropical climates and is native to China and Taiwan but has also been found in the United States, specifically in Florida, Louisiana, and Hawaii (Li et al. 2009; Chouvenc, Li, et al. 2016). *Coptotermes formosanus* was most likely first established in Florida in the 1970s. By the 2000s, it was causing minimal localized damage within the South Florida Metropolitan Area and it is projected that by 2040 roughly 50% of the South Florida Metropolitan Area will experience termite infestation (Chouvenc, Scheffrahn, et al. 2016). As of 2010, the annual global cost of termite pest management and damage repair was estimated to be \$40 billion. Of the termite species considered pests, subterranean termites (belonging to the “lower” termite family Rhinotermitidae) contribute to about 80% of the costs (Rust and Su 2011).

All “lower” termites possess a protist community hosted in their gut which aid in the digestion of wood particles. Protist identification from selected termite species hindguts have been performed through morphological and molecular methods. Morphological identification methods have tended to under-estimate the number of species compared to molecular methods although the use of both methods is preferable (Harper et al. 2009; Duarte et al. 2018). Initial investigations into the *C. formosanus* hindgut microbiota using morphologic identifiers revealed three protist species: *Pseudotrichonympha grassii*, *Holomastigotoides hartmanni*, and *Cononympha*

*leidyi* (previously named *Spirotrichonympha leidyi*) (Koidzumi 1921). Recent studies using 18S rRNA gene sequence and single-cell PCR have identified five parabasalian species within the *C. formosanus* hindgut, adding *Holomastigotoides minor* and *Cononympha koidzumii* (Jasso-Selles et al. 2020; Nishimura et al. 2020) (Figure 2).

*Cononympha leidyi* cells are small to medium, ranging about 15-60 µm long, cone shaped, have a centrally positioned nucleus, and spiral flagellar bands that cover the entire cell (Koidzumi 1921; Jasso-Selles et al. 2020). *Cononympha koidzumii* has a shorter, more blunt, apex and rounder posterior due to spiral flagellar bands extending only half way down the cell body (Jasso-Selles et al. 2020). They are small cells that range from about 10-35 µm long (Jasso-Selles et al. 2020). *Holomastigotoides hartmanni* are large cells, measuring 50-170 µm in length and 30-105 µm in width, with a somewhat irregular oval shape (Koidzumi 1921; Jasso-Selles et al. 2020). They have tight spiral flagellar bands that cover the entire cell and spirochetes at the posterior of the cell (Koidzumi 1921; Jasso-Selles et al. 2020). The recently described *Holomastigotoides minor* cells are medium in size, measuring from 23-117 µm in length. They tend to have a flattened bell shape from a front view or a narrow ovoid shape in side view with spiral flagellar bands that cover the entire cell and spirochetes at the posterior (Jasso-Selles et al. 2020; Nishimura et al. 2020). *Pseudotrichonympha grassii* cells are long and narrow, covered in flagella, and measure 150-400 µm long with

distinctive an apical rostrum with a nose cone and longer flagella around the base of the rostrum (Grassi and Foà 1911; Koidzumi 1921).

**Figure 2.** Symbiont community of *C. formosanus*. (A-E) Differential interference contrast light microscopy of live cells; (F) Light microscopy of fixed and Feulgen stained cells. (A) *Holomastigotoides minor* Nishimura, (B) *Cononympha leidyi* Koidzumi, (C) *Cononympha koidzumii* Jasso-Selles & Gile, (D) *Holomastigotoides hartmanni* Koidzumi, (E,F) *Pseudotrichonympha grassii* Koidzumi. Scale bars: (A,B) 20 µm, (C) 10 µm, (D) 50 µm, (E) 100 µm.

### 1.3 Symbiotic Digestion in “Lower” Termite Hindguts

The “lower” termites’ ability to digest lignocellulose comes from their symbiotic relationships with the microbiota of their hindgut which includes diverse protists and bacteria (Cleveland 1923; Cleveland 1924). The wood-eating protists all belong to the phylum Parabasalia or the order Oxymonadida (phylum Preaxostyla). They are vertically inherited from parent to offspring in newly established colonies and later between the

workers, soldiers, and reproductives of established colonies through proctodeal trophallaxis (Eggleton 2010; Bourguignon et al. 2015; Nalepa 2015). Due to this vertical inheritance, the host termites and their hindgut symbionts have co-evolved together into an obligate mutualistic association. Certain symbiont genera are restricted to specific termite families and each of the lower termite species contains a unique assortment of protists within its hindgut which, to a certain degree, can be used to identify the termite species (Kirby 1949). The various protist species tend to reside in specific areas of the hindgut; the regional differentiation of the protists may be related to each species' oxygen requirements (Lai et al. 1983). In *C. formosanus*, *Cononympha* often reside in the more posterior portions of the hindgut, *Holomastigotoides* reside in the middle, and *Pseudotrichonympha* in the anterior hindgut regions (Lai et al. 1983; Tsunoda 2016). Different protists also perform differentiated enzymatic activities to aid in lignocellulose digestion. For example, in *C. formosanus*, *Cononympha leidyi* has been found to perform functions related to chitin degradation and *Pseudotrichonympha grassii* has been found to produce enzymes that aid in the initial degradation of cellulose at the beginning of the hindgut (Watanabe et al. 2002; Nishimura et al. 2020).

#### **1.4 Genome Size Variation in Eukaryotes**

Genome size across eukaryotes span 200,000-fold. Some groups such as birds and echinoderms have relatively low variation with a C-values spanning 2-fold and 8-fold respectively while other taxa have very large variation such as angiosperms which can span over 1,000-fold (Gregory 2001; Gregory 2005). C-values have been found to correlate with several characteristics in specific lineages. For example, there is a

negative correlation between rate of development and genome size in some arthropods and between metabolic rate and genome size of birds (Wyngaard et al. 2005; Ji and DeWoody 2017). Across all eukaryotes, only cell size consistently correlates with genome size (Gregory 2001; Gregory 2002; Gregory 2005). The variation in genome size is a result of mutations that can drive genome expansion or reduction. The primary drivers of this change include mobile elements and whole genome duplication events although there are smaller factors such as intron expansion and pseudogene accumulation that can also contribute to genome expansion (Gregory 2004).

Mobile elements have been linked to genome expansion throughout eukaryotes (Zubáčová et al. 2008; Hebert et al. 2019). Mobile elements, sometimes referred to as TEs or selfish DNA, are DNA segments that can insert into other DNA regions. They are divided into two main classes: class I retrotransposable elements that use RNA as an intermediate template before reverse transcribing into DNA that can then be inserted at DNA nicks, and class II transposable elements that use copy-and-paste mechanisms to insert directly into the DNA. Mobile elements mostly insert randomly into the genome and can change gene expression if inserted into regulatory regions or genes, causing frame shift mutations or gene truncation (Bennetzen 2000; Bennetzen et al. 2005; Grover et al. 2008). The proliferation of mobile elements is not constant but happens in bursts that make periodic quantum gains in genome size possible (Neumann et al. 2006; Piegu et al. 2006; Hawkins et al. 2007; Vitte et al. 2007). Proliferation rates are controlled by recombination rates, insertion location, epigenetics, and population genetics. Recombination rate has been shown to positively correlate with TE removal and can

therefore aid in genome size reduction (Wright et al. 2003; Tian et al. 2009). While many TEs insert randomly, certain TE families have a bias to insert themselves into pericentromeric or centromeric regions which experience lower recombination rates (Choo 1998; Jiang et al. 2003). RNA interference (RNAi) can check uncontrolled proliferation of TEs: as TE families increase in the cell small interfering RNAs that target the TEs also increase, upregulating the RNAi process and enhancing the silencing of the TEs (Hollister and Gaut 2009). However, in small populations or populations experiencing bottlenecks, selection to purge mobile elements based on environmental pressures is expected to be less effective so genome size can expand more rapidly in those populations (Lynch 2007; Grover et al. 2008; Lockton et al. 2008; Ross-Ibarra et al. 2008). Recently it has been observed that within the largest known gypsy moth species, *Lymantria dispar*, the subspecies *L. dispar asiatica* and *L. dispar japonica* experienced TE proliferation associated with their genome expansion. Their genomes range between 865 and 999 Mbp with 60% of their total genomes being comprised of TEs and sequence repeats (Hebert et al. 2019).

In contrast to mobile element proliferation, whole genome duplication (WGD) can cause rapid quantum shifts in the quantity of DNA by replicating entire chromosomes or genomes. Whole genome duplication is often associated with quick bursts of genomic expansion between closely related species, although such expansions have also been found to be caused by mobile element proliferation (Blommaert et al. 2019). Although WGD can occur in any eukaryote, it is most common in plants, which can have multiple duplications (Woodhouse et al. 2009). Recent WGD events will result in

polyploidization, although over time the duplication may be reduced with some of the duplication being lost while others are retained in the genome. Those genome sections that remain may evolve novel functions, thus it can be difficult to detect past WGD events as they can be obscured through deletions or rearrangements, but long colinear duplication spans of genes or chromosomes are often thought to be indicators of past WGD events (Lynch 2007; Gerstein and Otto 2009; Marburger et al. 2018). Post-duplication TE proliferation can occur due to the WGD event interrupting the RNAi's ability to silence the mobile elements resulting in even more drastic genomic shifts (Oliver and Greene 2009).

### **1.5 Feulgen Densitometry as Best Method for Estimating Genome Sizes in Mixed Protist Samples**

Genome size data are valuable when considering future genome sequencing projects and can provide comparisons for genome structure and evolution studies. There are several genome databases for eukaryotes but there is currently not a detailed database for protists, which is an under-sequenced group compared to other eukaryotic groups (Kullman et al. 2005; Leitch et al. 2019; Gregory 2021). Genome sizes can be quantified through several methods including fluorometry, Feulgen densitometry, and k-mer analysis. Fluorometry measures fluorescence to detect, measure, and identify molecule concentrations. The most common fluorometry technique used to estimate genome size is flow cytometry in which extracted and stained nuclei (usually DAPI or propidium iodide) from samples of interest are suspended in fluid that flows through a laser beam of a specific wavelength. The stimulated light emission by the fluorochrome is measured

and the genome size can be inferred by comparing the unknown sample to a known standard (Hardie et al. 2002). This process can provide rapid and accurate results but requires expensive equipment that may not be readily available and large quantities of sample nuclei which can be difficult to obtain if the samples are not able to be cultured.

Genome sizes can also be estimated using bioinformatic approaches, such as k-mer counting. K-mers are strings of unique DNA sub-sequences of a specific length. Any sequence, even unassembled short reads, can be broken down into its k-mer units. K-mers of about 20 nucleotides in length are usually best for estimating genome size. Traditionally, this method has worked best with sequence coverage greater than 10X but newer methods can get decent estimations with coverage as low as 0.5X (Hozza et al. 2015). In a given sequence, all unique k-mers are identified and it is determined how many times each unique k-mer appeared in the sequence. From there, a k-mer frequency distribution is generated and the peak should represent the average sequencing depth for the genome sequence (Li and Waterman 2003). These distributions are then analyzed using varying models that can determine genomic characteristics such as size, coverage, or heterozygosity (Hozza et al. 2015). Compared to flow cytometry, k-mer counting tends to underestimate genome sizes; in most cases it is only a slight underestimation although there is an instance where the reported k-mer genome size was half that of the flow cytometry reported size (Pflug et al. 2020).

Densitometry is the measurement of optical density (OD) using microscopy in the quantification of genome size. The DNA is stained and OD calculations are performed comparing the stained DNA to background. Feulgen densitometry is one of the most

common staining procedures for quantifying DNA. In this process, fixed tissue preparations or cells are stained through stages of hydrolysis which depurinates the DNA and creates open aldehyde groups. Schiff's reagent, which contains fuchsin decolorized by SO<sub>2</sub>, can interact with the DNA and the fuchsin will bind to the aldehyde groups, releasing the SO<sub>2</sub> and resulting in a pink coloration of the DNA (Hardie et al. 2002). It is important to note that this is not a true stain but rather a series of chemical reactions. The quantity of the stain bound to the DNA should be proportional to the amount of DNA present in the nucleus. The stain quantity is determined by its OD in the nucleus, since OD is the amount of light absorbed it cannot be measured directly but must be measured indirectly through transmittance (the difference between the light intensity of the target nuclei from an empty space on the slide). As DNA content is not consistent throughout the nucleus, many point measurements must be made throughout the nucleus to get a good estimation of the DNA content. In the past, such point measurements have been performed using a flying spot or scanning microscopy and would be very time consuming. With modern image analysis techniques, the entire microscope field can be captured with a microscope mounted camera connected to a computer. In this case, each pixel in the image could act as a point measurement. The target nuclei can be outlined using microscope image software and the mean light intensity for all the pixels in the selected area can be automatically calculated. This drastically reduces the time and effort to compute the OD and makes this method a rapid, cost effective, and user-friendly method to estimate genome size. Comparisons between Feulgen densitometry image

analysis and flow cytometry have shown that flow cytometry using propidium iodide provides comparable results to Feulgen densitometry (Doležel et al. 1998).

Feulgen densitometry has been the most common method for estimating genome size, being first implemented in the 1950s (Hardie et al. 2002). As technology advanced, flow cytometry has become more common and is widely used in genome size estimation. Feulgen densitometry is still used quite frequently for tissue samples where it is more difficult to isolate single cells and extract nuclei, such as is the case with these samples. All five of the protist species reside together in the same guts, and as of yet, these species have not been able to be cultured singly or together. Due to the benefits, flow cytometry would have been the preferable method but deciphering the results of a mixed-species flow run would be difficult. Since flow cytometry uses extracted nuclei, multiple peaks that represent genome size would be present but there would be no way to directly confirm which peak corresponds to which species. Due to these issues, this study used Feulgen densitometry image analysis because it allowed morphological identification of the cells as their genome sizes were calculated, which is not possible using flow cytometry.

## **1.6 Objectives**

Recognizing the known positive correlation cell size has with genome size and the relatively large cell size of the *C. formosanus* protist symbionts, this study aimed to estimate the C-values of *P. grassii*, *H. hartmanni*, *H. minor*, *C. leidyi*, and *C. koidzumii* to see if they also have relatively large genome sizes. This was accomplished through Feulgen densitometry image analysis to estimate the C-value in picograms for each of the

five species. The study also aimed to place their cell and genome sizes in context of the evolution of Parabasalia and Eukaryotes. This was achieved through comparisons of these findings to other Parabasalia with known genome sizes, specifically certain trichomonas belonging to the Tritrichomonadida, Hypotrichomonadida, and Tritrichomonadida, and by comparison of the Parabasalia genome size range to those of other other eukaryotic taxa.

## 2. METHODS AND MATERIALS

### **2.1 Termite Collection and Care**

The *C. formosanus* termites are from a lab colony originating from the University of Florida, Ft. Lauderdale Research and Education Center Subterranean Termite Laboratory, Broward County, Florida, USA (26.10, -80.17). Termite alate collection and laboratory colony rearing conditions followed the protocol previously described (Chouvenc and Su 2017; Jasso-Selles et al. 2020).

### **2.2 Genome Size Estimation**

#### **2.2.1 Reagent Preparation**

Fixation Solution (500 µL): in a 1.5 mL tube, 418 µL milliQ water, 50 µL 10x PBS, and 32 µL 32% paraformaldehyde were combined and vortexed for 30 seconds to mix.

Schiff's Reagent (30 mL): 0.55 g basic fuchsin was dissolved in 5 mL 1.0 N HCl in a glass bottle. In a separate beaker, 0.5 g sodium bisulfite ( $\text{Na}_2\text{S}_2\text{O}_5$ ) was dissolved in 50 mL dH<sub>2</sub>O then combined with the fuchsin and HCl solution. The reagent was a dark

purple to red color. The bottle was tightly capped and stored in a room temperature dark area for 72 hours, mixed every eight hours to ensure no precipitate formed. The solution was decolorized through a series of incorporating and then filtering out activated charcoal. Activated charcoal (1.75 g) was added in 0.25 g increments to the solution, shaken for two minutes, and filtered through 8  $\mu\text{m}$  pore size filter paper using a Buchner funnel. The resulting solution was a clear light pink and the final volume was 30 mL. Reagent was stored at 4 °C in the dark. Schiff's reagent was used within a month of preparation and discarded once white precipitate formed. The same batch was used on all samples being compared.

Bisulfite solution (16 mL): 750  $\mu\text{L}$  of 10% sodium metabisulfite solution was combined with 15 mL dH<sub>2</sub>O then 750  $\mu\text{L}$  1.0 N HCl was added and the solution was vortexed for 30 seconds to mix. Solution was prepared fresh for every use.

### **2.2.2 Feulgen Densitometry Image Analysis**

Feulgen densitometry uses a series of chemical reactions to “stain” the nucleus. There is a proportional relationship between the amount of DNA and the amount of stain bound to the nucleus which allows the C-value to be quantified. This study followed a protocol modified from “From pixels to picograms: a beginners' guide to genome quantification by Feulgen image analysis densitometry” as follows (Hardie et al. 2002).

Roughly 200 *C. formosanus* termites were removed from their colony and placed in a separate container with a damp paper towel and placed in an incubator at 28 °C for three days to allow the protists to digest ingested wood particles that can interfere with staining and image analysis. One hundred whole guts from the *C. formosanus* starved

workers were extracted using fine-tipped forceps. To fix protist cells, 10 guts were placed in each 1.5 mL tube with 500  $\mu$ L fixation solution (milliQ water, 10x PBS, 32% paraformaldehyde) and opened using the forceps to release the gut contents into the solution. Fixed samples were stored in the fridge for 24 to 48 hours at 4 °C. The samples were then stained using Feulgen reactions and Schiff's reagent.

First, the samples were rinsed three times by adding 400  $\mu$ L tepid water, inverting the tube ~20 times to mix, centrifuging at 4,400 rcf for 5 minutes, and discarding the supernatant. Samples were hydrolyzed with 400  $\mu$ L 5.0 N HCl for 15 minutes at room temperature, then rinsed three times with 400  $\mu$ L 0.1 N HCl, inverting the tube ~20 times to mix, centrifuging at 4,400 rcf for 5 minutes, and discarding the supernatant each time. Schiff's reagent (fuchsin, 1.0 N HCl, sodium metabisulfite ( $\text{Na}_2\text{S}_2\text{O}_5$ ), dH<sub>2</sub>O) was prepared and 400  $\mu$ L was added to the pellet to stain the sample nuclei. Each sample with Schiff's reagent was placed in the dark for 90 minutes and inverted 10x every fifteen minutes to ensure the contents were well mixed. The Schiff's reagent was rinsed with 400  $\mu$ L of the bisulfite solution (1.0 N HCl, sodium metabisulfite ( $\text{Na}_2\text{S}_2\text{O}_5$ ), dH<sub>2</sub>O) three times. Samples were then rinsed with 400  $\mu$ L tepid water and resuspended in 300  $\mu$ L water. Samples were stored in the fridge at 4 °C and used within a week. Trout nuclei (BioSure Controls TEN Cytometry Control) standard was prepared similarly but with a hydrolysis and stain time of 120 minutes. Trout was chosen as the standard because it is a commonly and reliably used standard in genome estimation and had the largest genome size of all readily available nuclei standards.

The stained samples were mounted on a slide and Kohler illumination was established using an AxioImager upright compound light microscope with an AxioCam 503 monochrome camera (Zeiss). The Zeiss AxioCam 503 camera response was tested for linearity before image data were gathered. Using the camera and software, brightfield images of the stained protists were taken at a magnification of 400x and exposure of 1/125 seconds. The nuclei were outlined and area ( $\mu\text{m}^2$  and pixel) and foreground intensity mean (IF) measurements for the nuclei were taken. Background intensity mean (IB) measurements were also taken from an empty space on the slide for comparison. For each cell, an integrated optical density (IOD) was calculated using the following equation where  $n$  = the total number of pixels within the nucleus:

$$IOD = \sum_{i=1}^n -\log_{10} \left( \frac{IF_i}{IB_i} \right)$$

and the C-values (CV) for the protists were calculated using the equation:

$$CV_u = CV_s \times \left( \frac{IOD_u}{IOD_s} \right)$$

where the subscript  $u$  indicates the unknown and  $s$  indicates the standard (Hardie et al. 2002). The  $IOD_s$  used to calculate the  $CV_u$  was the mean of all trout nucleus IODs. Cells were then identified as one of five protist species (*C. leidyi*, *C. koidzumii*, *H. hartmanni*, *H. minor*, and *P. grassii*) according to morphological criteria including flagella type and location, cell size and shape, and nucleus location (Jasso-Selles et al. 2020). A total of 586 protists were imaged, 66 *P. grassii*, 41 *H. hartmanni*, 158 *H. minor*, 119 *C. leidyi*, and 202 *C. koidzumii*.

## 2.3 Cell and Nucleus Volume Estimates and Their Correlation to Genome Size

The measurements of the cells and nuclei were taken from digital micrographs of the stained cells from the AxioImager upright compound light microscope fitted with an AxioCam 503 camera. The nuclei were outlined and length (anterior to posterior) and width (longest measurement perpendicular to the length) measurements ( $\mu\text{m}$ ) were taken for each of the cells and nuclei. The five species fall under three shape categories which were used to approximate their cell volume: cone-like, ellipsoid, or cylindrical. *C. koidzumii*, *H. hartmanni*, *H. minor*, and all the nuclei are all ellipsoid, *C. leidyi* is cone-shaped, and *P. grassii* is cylindrical. The nucleus and cell volumes ( $V$ ) were approximated using the following equations:

$$V_e = \frac{3}{32}\pi ab^2$$

$$V_{cs} = \frac{1}{6}\pi ab^2$$

$$V_c = \frac{1}{4}\pi ab^2$$

where the subscript  $e$  indicates ellipsoid,  $cs$  indicates cone-shaped, and  $c$  indicates cylindrical and “ $a$ ” is the cell or nucleus length and “ $b$ ” is the cell or nucleus width. The mean, median, and interquartile range (IQR) were calculated for each of the species and outliers were determined as any value that falls outside  $Q1 - 1.5 \times IQR$  or  $Q3 + 1.5 \times IQR$ . Linear regression analyses were completed to test for relationships between cell volume and genome size and nucleus volume and genome size.

### 3. DATA ANALYSES AND RESULTS

#### 3.1 Cell and Nucleus Sizes

The cell and nucleus volumes were calculated from the imaged cell measurements and approximate cell shape (Table 1). All species had large ranges for cell volumes, often having large outliers that inflated the mean to be quite larger than the median. The ranges for the nucleus volume were narrower across the five species and their mean and median values were closer together, but the median values were still considerably lower than the mean due to large outliers. There was a similar pattern with the distribution of genome sizes (Figure 3). Because of this, the median and IQR are better descriptors of the data. The cell shapes for these five species were approximated as either cone-like, ellipsoid, or cylindrical, and their volumes were calculated based on that descriptor. *Cononympha koidzumii* is a small ellipsoid cell with a median cell volume of  $386 \mu\text{m}^3$  and nucleus volume of  $5 \mu\text{m}^3$ . *Cononympha leidyi* is a small to medium cone-shaped cell with a median cell volume of  $1,996 \mu\text{m}^3$ , about five times larger than *C. koidzumii*, and nucleus volume of  $13 \mu\text{m}^3$ . *Holomastigotoides minor* is a medium ellipsoid cell and has a median cell volume of  $8,985 \mu\text{m}^3$  and nucleus volume of  $54 \mu\text{m}^3$ . *Holomastigotoides hartmanni* is a large irregular ellipsoid shaped cell with a median cell volume about three times larger than the *H. minor* cells,  $26,679 \mu\text{m}^3$ , and nucleus volume of  $178 \mu\text{m}^3$ . *Pseudotrichonympha grassii* is the largest species with a cylindrical cell shape and a median cell volume of  $89,190 \mu\text{m}^3$  which is over 200 times larger than the smallest symbiont, *C. koidzumii*, and nucleus volume of  $378 \mu\text{m}^3$  which is over 70 times larger than *C. koidzumii*.

### 3.2 Genome Sizes

A total of 586 cells from the five protist species and 105 extracted trout nuclei were imaged. All measurement data collected for the five protist species are recorded in Appendix A and summarized in Table 1 and Figure 3. All measurement data for the standard IOD (IOD<sub>s</sub>) is recorded in Appendix B. The optical densities from Feulgen staining, which correspond to DNA content, revealed large C-values compared to other Parabasalia. The largest C-values were found in *P. grassii*. From 66 *P. grassii* nuclei, the mean C-value was determined to be 153±50 pg with a median value of 147 pg and a single outlier of 330 pg. The C-values of the *Holomastigotoides* species were the second largest. From 41 *H. hartmanni* nuclei, the mean C-value was determined to be 81±51 pg with a median value of 56 pg. For *H. minor*, the mean and median values were 34±22 pg and 29 pg (n=158 nuclei). In this case there were 12 outliers ranging between 72 and 140 pg. The *Cononympha* species had the smallest C-values, around ten times smaller than that of *P. grassii*. *Cononympha leidyi* was measured (n=119 nuclei) and its mean was 12±5 pg and the median was 12 pg with four outliers ranging between 25 and 30 pg. *Cononympha koidzumii* is the smallest of the cells, 202 cells were collected and had a mean C-value of 9±7 pg and median value of 6 pg with eight outliers ranging from 24 to 39 pg.

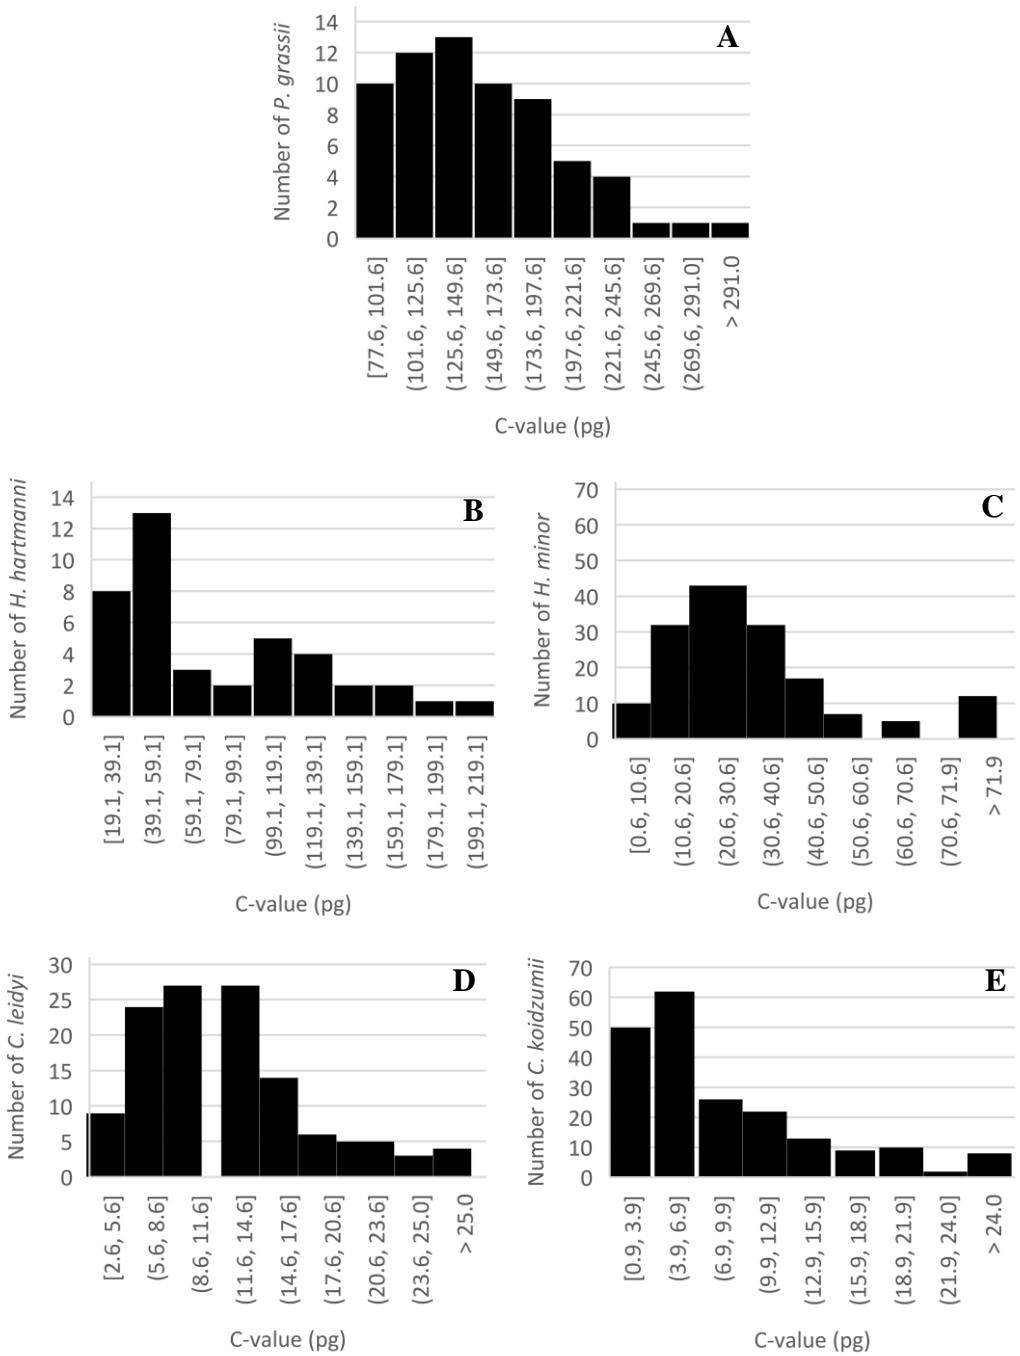

**Table 1.** Cell and Nucleus Volumes and C-values of *C. formosanus* Symbiont Species

Cell				
	Length (μm) mean ± S.D. (n)	Width (μm) mean ± S.D.	Volume <sup>a,b,c</sup> (μm <sup>3</sup> ) mean ± S.D.	Volume (μm <sup>3</sup> ) median (Q1, Q3)
<i>Cononympha koidzumii</i>	16.96 ± 7.97 (199)	11.64 ± 5.91	1195.28 ± 1662.09	385.70 (155.77, 1679.82)
<i>Cononympha leidyi</i>	25.61 ± 9.13 (119)	13.78 ± 4.99	3463.96 ± 3726.56	1996.44 (976.49, 4804.30)

Genome Size				
	C-value (pg) mean ± S.D. (n)	C-value (pg) median (Q1, Q3)		
<i>Cononympha koidzumii</i>	8.76 ± 6.94 (202)	6.32 (3.99, 12.03)		
<i>Cononympha leidyi</i>	12.36 ± 5.51 (119)	11.57 (8.35, 15.07)		
<i>Holomastigotoides minor</i>	34.35 ± 22.19 (158)	28.56 (20.40, 41.01)		
<i>Holomastigotoides hartmanni</i>	80.59 ± 51.45 (41)	56.12 (39.99, 106.52)		
<i>Pseudotrichonympha grassii</i>	152.88 ± 50.08 (66)	146.77 (113.50, 184.51)		

<sup>a</sup> All nucleus and cell volumes for *C. koidzumii*, *H. hartmanni*, and *H. minor* were calculated using the formula  $V=(3/32)\pi ab^2$

<sup>b</sup> Cell volumes for *C. leidyi* were calculated using the formula  $V=(1/6)\pi ab^2$

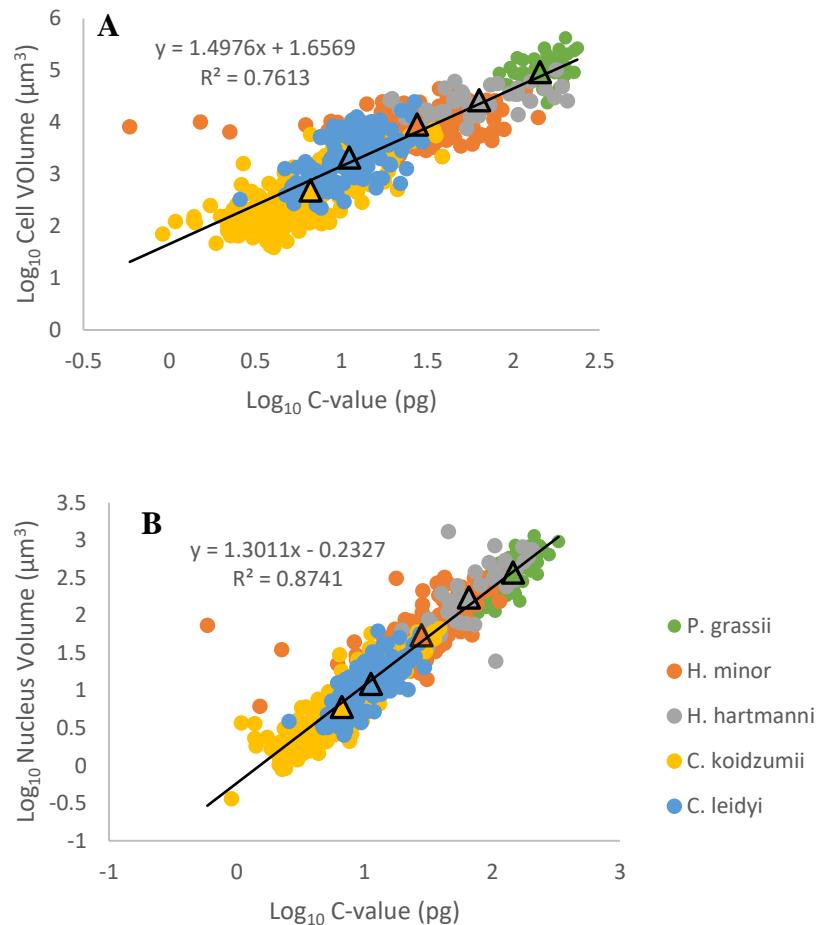

<sup>c</sup> Cell volumes for *P. grassii* were calculated using the formula  $V=(1/4)\pi ab^2$ ; "a" is the length and "b" is the width.

**Figure 3.** Distribution histogram of the C-values for the five *C. formosanus* Parabasalia symbiont species. (A) Distribution of 66 *P. grassii*, median: 147 pg, (B) Distribution of 41 *H. hartmanni*, median: 56 pg, (C) Distribution of 158 *H. minor*, median: 29 pg, (D) Distribution of 119 *C. leidyi*, median: 12 pg, (E) Distribution of 202 *C. koidzumii*, median: 6 pg. Bin size: (A) 24 pg, (B) 20 pg, (C) 10 pg, (D,E) 3 pg; last bin contains all the outliers for each species.

### 3.3 Correlation Between Cell and Nuclei Sizes and Genome Sizes

The cells with the largest cell, nucleus, and genome sizes were represented by *P. grassii* (Table 1). Those with the smallest genome sizes, *C. koidzumii*, also had the smallest cell and nucleus volumes. The calculated log C-values were positively correlated with both the log cell volume ( $R^2 = 0.76$ ) and the log nucleus volume ( $R^2 = 0.87$ ), with a stronger correlation to nucleus volume (Figure 4).

**Figure 4.** Correlation between log C-value and log cell volume and log C-value and log nucleus size of *C. formosanus* protist symbiont species. The dots represent individual measurements from each species and the triangles represent the median values for each species. (A) Positive correlation between log C-value and log cell volume,  $R^2=0.76$ . (B) Positive correlation between C-value and nucleus volume,  $R^2=0.87$ .

## 4. DISCUSSION

### 4.1 Sources of Error

Compared to other studies estimating genome sizes in plants, crustaceans, Oomycota, and insects using Feulgen densitometry, these data showed larger C-value ranges with larger standard deviation relative to mean C-value (Michaelson et al. 1991; Voglmayr and Greilhuber 1998; Jeffery et al. 2016; Kelly 2018). Genome size of each individual cell within a species should be fairly consistent but our results show an abnormal amount of variation. There are several potential sources of error related to Feulgen densitometry, especially in relation to these symbiont samples which could be causing this level of variation.

Size and shape of these nuclei could be a cause of potential error. Along with there being large variation with the genome size, there is also large variation of the nucleus volumes for each species. Since the size of the nucleus goes into the calculation for the genome size, it seems reasonable to think if there is variation in one of the calculation components there would also be variation in the calculation results. There may also be issues getting accurate outlines of the nucleus. Due to the large size of these nuclei, small deviations outlining the nuclei can lead to larger deviation in the calculated nucleus area which would affect the C-value calculations. C-values at the extremes of the ranges are potentially caused by anomalies in the nucleus, such as folding or improper nucleus orientation, or minor staining abnormalities (Hardie et al. 2002).

Some of the variation may be caused by the cell exterior still being intact. Since the cell exterior was required in order to identify the cells to determine which genome

sizes corresponded to which species, the protist samples estimated were whole cells. However, the standard used was extracted nuclei which may have biased the genome size estimation. This may have resulted in the nucleus area of the symbiont samples to have greater light absorption due to flagella, cell membrane, and cytoplasm being in the light path. This could potentially result in higher IOD and C-values.

Another possible source of error is the large range of genome sizes across the species. When performing genome size estimations in which a standard is used for comparison, it is best practice to use a standard with a genome size no more than three times smaller or larger than the genome size of the sample (Vindeløv et al. 1983; Doležel and Bartos 2005). In this case, one standard was used as comparison for all the symbiont cells. The standard was chosen because it is one of the larger standards available and is considered a reliable reference for genome size estimation. C-value for the standard (5.2 pg) was close to the *Cononympha* species but much smaller than the *Holomastigotoides* and *Pseudotrichonympha* species. This would have made the species with C-values closer to the trout value more likely to be accurate. Regardless of the potential sources of error, there remains support for the large range of genome sizes across these five species, the ratios of the genome sizes of the symbiont species relative to each other, and the large difference between these species compared to other Parabasalia.

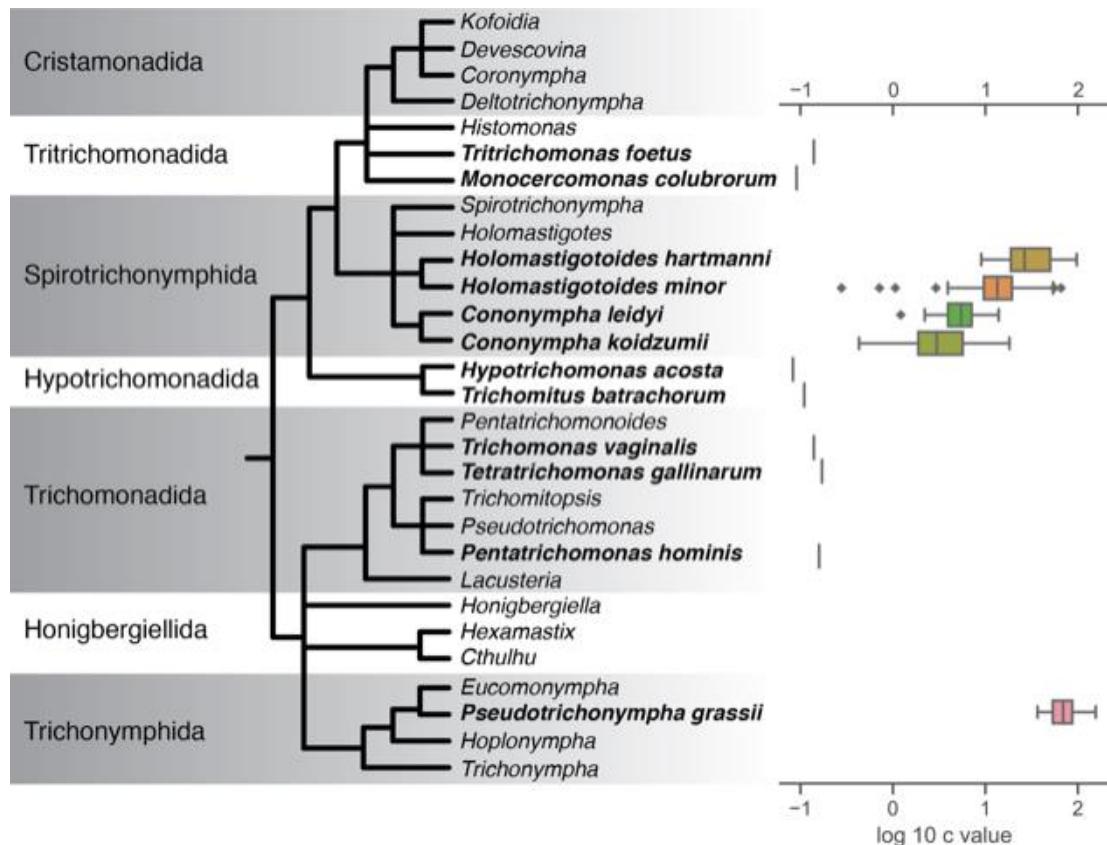

#### **4.2 *C. formosanus* Symbionts in Relation to Parabasalia and Eukaryotes**

Genome sizes have been estimated for several Parabasalia species across five orders. Two have been estimated from the order Tritrichomonadida, four from Spirotrichonymphida, two from Hypotrichomonadida, three from Trichomonadida, and

one from Trichonymphida (Figure 5). The *Holomastigotoides* and *Cononympha* species estimated in this paper belong to Spirotrichonymphida and the *Pseudotrichonympha grassii* belongs to Trichonymphida. The species whose genomes sizes were previously estimated are in the orders Tritrichomonadida, Hypotrichomonadida, and Trichomonadida. These species are all parasites or commensals of vertebrates and all have estimated genome sizes less than 0.2 pg (Zubáčová et al. 2008). This highlights a difference in genome size between Parabasalia that are parasitic or commensal and those that are mutualistic in termites, which leads to the enquiry: can the relationship between protists and their hosts have some sort of effect on their genomes' tendency to expand, compress, or maintain size? To explore this notion further, more genomes across Parabasalia need to be estimated, including those that are free-living, to compare those with different host – protist relationships and to those outside of such relationships.

Prior to this study, Parabasalia had a narrow range of variation of known genome sizes, having a 2-fold difference from 0.088 pg found in *Tetratrichomonas gallinarum* to 0.181 pg found in *Tritrichomonas foetus* (Zubáčová et al. 2008). These genome sizes were estimated using flow cytometry. The reference standard used was *T. vaginalis* and the nuclei were stained with Hoechst 33342 for flow cytometric size estimation (Zubáčová et al. 2008). The genome size of the reference standard used was estimated from sequence data (~160 Mbp  $\approx$  0.16 pg), but the assembly was highly fragmented due to large amounts of repeat sequences and its genome size was most likely under-reported (Carlton et al. 2007). This would cause the other trichomonad genome size estimations to be smaller than the actual size. The study showed consistent genome sizes of different

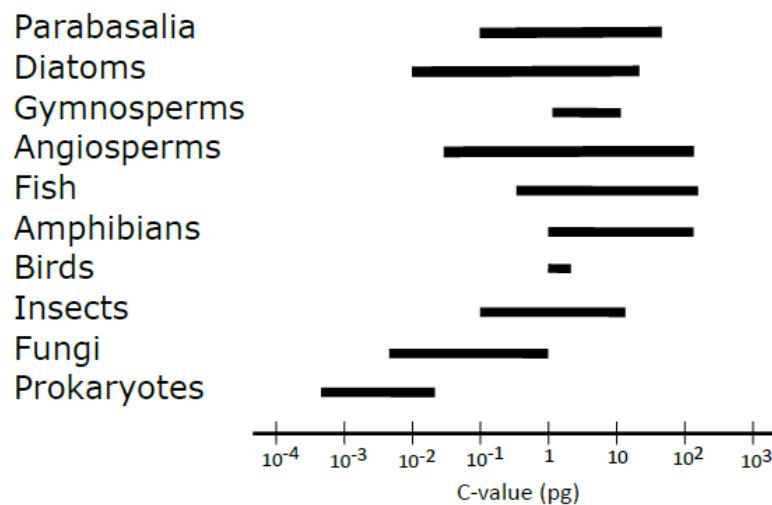

strains of the same species, even between the sequenced reference *T. vaginalis* strain and the additional *T. vaginalis* sample strain, indicating the methods used were most likely effective (Zubáčová et al. 2008).

**Figure 5.** Phylogenetic relationships between Parabasalia with corresponding log c-value. The taxa used in this genome size comparison are in bold and those whose genome sizes were estimated in this study have their full species name given and a box plot of their log c-values (pg).

Although this range seems narrow, it is similar to the range found in birds (Gregory 2005). With these new genome size estimates, Parabasalia now spans over 15,000-fold range with the largest known Parabasalia genome size now being 146.8 pg in *P. grassii*. This large range is not uncommon as similar ranges can be found in such

differing groups of eukaryotes as diatoms and angiosperms (Figure 6). More studies are needed to assess whether these *C. formosanus* symbiont species are representative of all Parabasalia – termite symbionts or if they are uncommonly large for Parabasalia symbionts.

**Figure 6.** Overview of C-value variation across groups of organisms. Parabasalia genome sizes measured so far span three orders of magnitude. Adapted from several publications, (Connolly et al. 2008; Zubáčová et al. 2008; Gregory et al. 2004).

#### 4.3 Adaptive Role of Variation

As previously mentioned, mobile elements and whole genome duplication events can have a large impact on the variation of genome sizes. Whether the genomes experience expansion or compaction has a lot to do with whether there is active selection occurring or not. There are two types of theories that explain the governing forces of genomic change: mutational pressure theories and optimal DNA theories (Gregory 2001). Mutational pressure theories rely on the natural tendency of genomes to accumulate mutations, resulting in genome expansion, and require selective pressures to reduce

genome size (Pagel and Johnstone 1992). Optimal DNA theories assert that genome size is a selectable trait which can be governed by environmental pressures by having a direct link to traits such as cell and nucleus sizes (Orgel and Crick 1980; Cavalier-Smith 1982).

Looking at the genome size expansion in the *C. formosanus* symbionts through the optimal DNA lens it can be hypothesized that their genome expansion could be due to selective pressures favoring larger cells in order to digest large wood particle, which according to nucleo-skeleton theories would require larger nuclei and genomes to support the larger cells. The location differentiation in which small cell species tend to be at one end of the hindgut and larger species at the other suggests there may be something about the environments at the different gut pouches that may apply selective pressure towards cells of a certain size.

On the other hand, bottleneck effects can reduce the efficacy of selection and have been shown to allow species to undergo and maintain genome expansions (Lynch 2007; Gerstein and Otto 2009). Looking through the mutational pressure lens it can be argued that since these species experience repeated bottlenecks as part of their relationship with termites, they may have had the opportunity to expand their genomes with weak selective pressure for compaction. This has also been suggested as a possible contributing factor to the genome size increase in *T. vaginalis* compared to other parasitic protists as well as to the genome size expansion in *Helianthus* hybrid species (Baack et al. 2005; Carlton et al. 2007).

Now that the genome sizes for the *C. formosanus* Parabasalia symbionts have been determined, the next step in understanding the symbiotic relationship between the

termites and their symbionts is to estimate the genome sizes of the symbionts of other termite species to see if they follow the same pattern. It would also be interesting to examine protists within and outside of Parabasalia that have either mutualistic, parasitic, or commensal symbiotic relationships to animals to see if certain relationships are more likely to result in genome expansion or compaction of symbionts.
