## **Abstract**

The Grenville Province represents a complex, highly metamorphosed orogenic belt at the southeastern margin of the Canadian Shield that is composed of different lithotectonic domains of various ages that have all been affected by the 1.0 Ga Grenville Orogeny. The present study focuses on one of the youngest regions, the Quebecia terrane, and through reconnaissance neodymium isotope mapping, investigates the extent of an old crustal block that predates the Grenville Orogeny.

The Quebecia Terrane is found within Central Quebec and is a Mesoproterozoic arc terrane that was constructed around 1.5 Ga. Utilizing the Samarium-Neodymium dating method, previous research had identified a few isolated neodymium signatures of older crustal ages, and through reconnaissance mapping, several of these Paleoproterozoic crustal blocks are suggested to represent a single fragmented crustal panel. The study focused on more detailed mapping of these blocks in the areas of Baie Comeau, Forestville, Labrieville and Pipmuacan in Central Quebec.

The full extent and connection between the fragments has been mapped as a series of Paleoproterozoic crustal blocks extending longitudinally through the Quebecia terrane. These blocks are embedded within the younger terrane, suggesting that the old panel was incorporated sometime during the accretion of Quebecia to Laurentia. It is possible that the old panel broke off from older Laurentian crust and reattached during the accretion of the Quebecia terrane via strike slip tectonics, implying that the Quebecia terrane itself consists of more than one accreted unit. The present study found that the older neodymium isotope signatures were consistent with the Berthe Terrane in the

Manicouagan region to the north, providing evidence for the origin of the older panel within Quebecia. However, by invoking a division of Quebecia into a north and south segment, this implies a Composite Arc Belt model for the Central Grenville Province.

## **Acknowledgements**

I would first like to express my sincere gratitude to my supervisor, Dr. Alan P Dickin, for taking me on as his B.Sc undergraduate and M.Sc student, and for showing me the beautiful province of Quebec through our many exciting field work excursions. Thanks to his guidance, support and unwavering patience with me (and many, many coffee breaks), I successfully made it to where I am today in academia.

I would also like to thank my lab family who helped me learn and grow these past four years: First to my predecessor, Dr. Rebecca Moumblow, who served as both my role model and good friend, for influencing me to go farther in my degree, and teaching me the ropes of graduate student life. Second, to Gabriel Arcuri, for the Starbucks dates and vent sessions, and for keeping me calm and level headed when writing got stressful. Lastly, to Jacob Strong, for being a GIS master and helping me with my interpolations, and always providing a good laugh in the lab. Thank you all so much for your support, smiles and guidance.

A special thank you to my parents, Kelly and Garth Vautour, who although may not have understood many of the geologic terms as I anxiously practiced my presentations in front of them, consistently gave me amazing support, understanding and love throughout this whole journey. I could not have done it without you all!

## **List of Tables**

**B-1:** Nd isotope analysis results for Quebecia samples (1.46-1.64 Ga) in the study area.

**B-2:** Nd isotope analysis results for BC Block samples (1.7-2.0 Ga) in the study area.

**B-3:** Nd isotope analysis results for intermediate aged samples (1.65-1.69 Ga) in the study area.

**B-4:** Major and Trace Element Analyses

**B-5:** La Jolla Standard Analyses

## **List of Figures**

- 1.1:** The first proposed Rodinia assembly, surrounded by superocean Mirovia (McMenamin and McMenamin, 1990).
- 1.2:** Possible craton assembly of Nuna around 1.54 Ga (Pesonen et al., 2012).
- 1.3:** Possible craton assembly of Rodinia around 1.04Ga (Pesonen et al., 2012).
- 1.4:** Paleomagnetic reconstruction of Nuna at the beginning of its break-up phase, showing age provinces in the GPAO using detrital zircon ages (Condie, 2013).
- 1.5:** Worldwide zircon ages from igneous rocks preserved in the Laurentian portion of the GPAO in Ma (Condie, 2013).
- 1.6:** Geologic divisions of the North American Shield with the Grenville Province highlighted in green (after Rivers, 1997).
- 1.7:** The tectonic divisions of the Grenville Province (after Rivers et al., 1989).
- 1.8:** The Grenville Province and its terrane divisions based on identified crustal formation ages (Thomson et al., 2011).
- 1.9:** Crustal formation age map for the Quebecia Terrane (Published data from Thompson et al., 2011).
- 1.10:** Proposed extent of old crust within the Quebecia terrane (Hynes, 2010).
- 1.11:** Sm-Nd isochron diagram comparing the Berthe Terrane in relation to surrounding terranes (Modified from Thomson et al., 2011).
- 1.12:** A sample transect map for the study area.
- 2.1:** Nd isotope evolution diagram (Dickin, 2005).
- 2.2:** Diagram of Nd isotope evolution against time (DePaolo and Wasserburg, 1976b).
- 2.3:** Plot of  $\epsilon$  Nd against time (After DePaolo, 1981).
- 3.1:** A numbered map for all the sample data found in tables B-1, B-2 and B-3.
- 3.2:** An isochron diagram comparing the published data for the current study and the surrounding terranes

- 3.3:** Distribution of Tdm age for the BC block compared with surrounding terranes
- 3.4:** AFM Ternary diagram for samples in the present study compared with reference suites from Laurentia and the Kohistan Arc
- 3.5:** QP Petrochemical grid for samples in the present study compared with reference suites from Laurentia and the Kohistan Arc
- 3.6:** TAS diagram for samples in the present study compared with reference suites from Laurentia and the Kohistan Arc
- 3.7:** R<sub>1</sub>-R<sub>2</sub> diagram for samples in the present study compared with reference suites from Laurentia and the Kohistan Arc
- 3.8:** Petrochemical chart comparing potassium oxide and zirconium
- 3.9:** Model age/distance transect graph
- 4.1:** An inverse distance weighted interpolation of the Baie Comeau area in Central Quebec.
- 4.2:** Possible configuration of the BC Block fragments overlaying the regional geology (geologic mapping by Energie et Ressources naturelles, Québec)
- 4.3:** Continental tectonic blocks in Southeast Asia (Barber and Crow, 2009).
- 4.4:** Distribution of the stratigraphic and tectonic units in Sumatra (Barber and Crow, 2009).
- 4.5:** Paleogeography of NE Gondwana and SE Asian terranes in the Early Permian (Barber et al., 2005).
- 4.6:** Paleogeography of NE Gondwana and SE Asian terranes in the Late Permian (Barber et al., 2005).
- 4.7:** Paleogeography of NE Gondwana and SE Asian terranes in the Early Triassic (Barber et al., 2005).
- 4.8:** Comparisons of the sediment sequences in Sibumasu and Western Sumatra (Barber et al., 2005).
- 4.9:** Proposed tectonic model for placement of the old block within the Quebecia Terrane (After Barber and Crow, 2003).

**5.1:** Map of the NE Grenville Province and the BC Block fragments

**5.2:** A histogram summary of the model ages for this study

**5.3:** Enlargement of area around Baie Comeau, showing the boundary samples (X's) in relation to the surrounding blocks of old and young crust

## **Chapter 1: Geological History**

### ***1.1 Introduction***

The Canadian Shield is the oldest portion of the North American crustal plate. It is largely comprised of exposed Precambrian rock and covers much of the eastern half of Canada and part of the northern United States. The shield is divided into several provinces of various geologic ages, where the Grenville Province is not only the youngest, but also the most complex. The Grenville Province records about one billion years of crustal growth, from 2 Ga – 1 Ga, culminating with the formation of the supercontinent Rodinia.

The concept of supercontinents was first developed by Alfred Wegener, based on his theory of continental drift (Wegener, 1929). He proposed that prior to their present day distribution, Earth's continents were once assembled into one large supercontinent 300 million years ago, which he named Pangaea. Canadian geologist J. Tuzo Wilson was one of the first scientists to suggest that there may have been ancient oceans that were destroyed by the formation of Pangaea, leading to suspicions that this could only be true if there were also ancient supercontinents prior to Pangaea (Wilson, 1966).

The configuration of Pangaea is well established based on patterns of fossil evidence, oceanic magnetic anomalies, and the fit of modern continents to each other. However, because of the older age of the ancient pre-Pangaea supercontinents, the evidence is less certain, making it more difficult to propose configurations.

## ***1.2 Precambrian Supercontinents***

Evidence began to surface in the early 1970's for a ~1 Ga supercontinent, variously called "proto-Pangaea" (Sawkins, 1976) or simply, "the Late Proterozoic Supercontinent" (Piper, 1987). While studying the Cambrian explosion and the environmental conditions prior to Pangaea, McMenamin and McMenamin (1990) noted that paleomagnetic evidence, Precambrian bedrock geology and paleobiogeography supported the existence of a pre-Pangaea supercontinent and they named it Rodinia. The first proposed assembly for Rodinia is shown in Figure 1.1.

### **THE RIFTING OF RODINIA**

*Figure 1.1: The first proposed Rodinia assembly, surrounded by the superocean Mirovia (McMenamin and McMenamin, 1990)*

After the acceptance of this new supercontinent, studies showed that similar processes had occurred to create and destroy the two ancient supercontinents Pangaea and Rodinia. It was therefore suggested that the timeline of supercontinent growth followed three

stages: (1) an initial period of accretion, (2) an intermediate period of accretion in some areas until the achievement of maximum ‘packing’, while rifting began in others, and (3) a final period of complete fragmentation due to rifting (Rogers and Santosh, 2002).

After a decade of studies providing more solid evidence for Rodinia’s existence, it began to seem likely that Rodinia formed from accretion of fragments from an even older Paleoproterozoic supercontinent, with the addition of several juvenile crustal blocks. In 2002, Rogers and Santosh proposed an older supercontinent called Columbia.

In the Paleoproterozoic, it is proposed that Columbia, more commonly referred to today as Nuna, was formed from a linear arrangement of older cratons, Laurentia, Baltica and Amazonia (Figure 1.2).

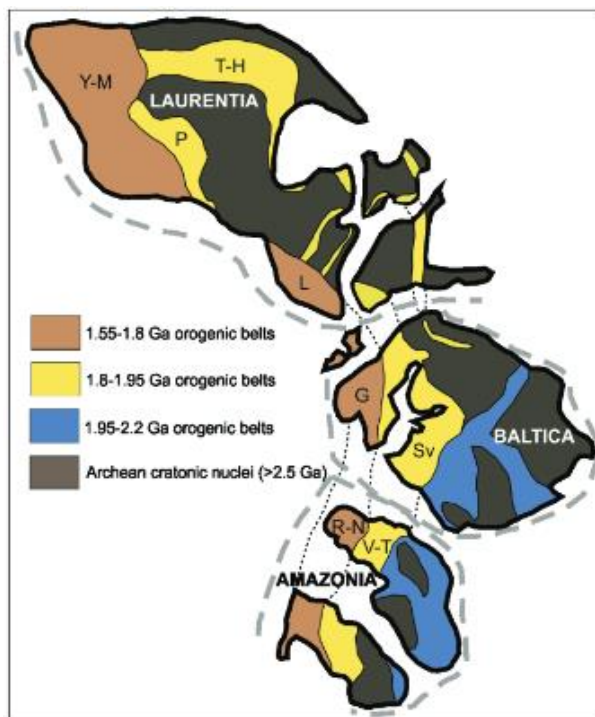

Figure 1.2: Possible craton assembly of Nuna around 1.54 Ga; Y-M: Yavapai-Mazatzal, T-H: Trans-Hudson, P: Penokean, L: Labradorian, G: Grenvillian, Sv: Svecofennian, R-N: Rio Negro-Juruena, V-T: Ventuari-Tapajós (Pesonen et al., 2012).

During the Mesoproterozoic around 1.6 Ga, Nuna had reached its maximum size (Rogers and Santosh, 2002), after which its component parts, Laurentia, Baltica and Amazonia, with the addition of the West African craton, would later be the basis for the Neoproterozoic supercontinent, Rodinia (Figure 1.3, Pesonen et al., 2012).

Figure 1.3: Possible craton assembly of Rodinia around 1.04 Ga; Y-M: Yavapai-Mazatzal, T-H: Trans-Hudson, P: Penokean, L: Labradorian, G: Grenvillian, Sv: Svecofennian, Sn: Sveconorwegian, S: Sunsas, R-N: Rio Negro-Juruena, V-T: Ventuari-Tapajos (Pesonen et al., 2012).

After the amalgamation of the supercontinent Nuna, and before the formation of the supercontinent Rodinia, there were five long-lived > 500 Myr accretionary orogenic events between the two supercontinent assemblies. However, Condie (2013) grouped four of these, Penokean-Yavapai-Mazatzal, Makkovikian-Labradorian, Baltica, and Amazonia, into the Great Proterozoic Accretionary Orogen (GPAO). This is said to possibly be the

long-lived orogen of all time, and contributed to much of the Rodinia supercontinent (Condie, 2013).

Condie (2013) summarized zircon ages from igneous rocks preserved in the Laurentian portion of the GPAO – Figure 1.4 is a distribution map of the zircon ages within the Laurentian portion of the GPAO, and Figure 1.5 is the histogram of the age data.

*Figure 1.4: Paleomagnetic reconstruction of Nuna at the beginning of its break-up phase showing age provinces in the GPAO using detrital zircon ages. Double red lines: rifting of cratons (Condie, 2013).*

Figure 1.5: Worldwide zircon ages from igneous rocks preserved in the Laurentian portion of the GPAO in MA (Condie, 2013) P=Pinwarian age, L=Labradorian age, M=Makkovikian age

Several of the maxima he identified correlate directly with North American orogenic events, such as the 1.5 Ga Pinwarian, 1.7-1.63 Ga Labradorian, and 1.92-1.86 Ga Makkovikian (Figure 1.5). However, an unexplained minimum at 1.6-1.5 Ga was observed between Labradorian and Pinware orogenic events. Condie (2013) suggested this gap in Uranium-Lead (U-Pb) dating between Labradorian and Pinware orogenic events could be explained by three scenarios: (1) rocks of this age never formed, (2) rocks of this age are covered with younger rocks, (3) rocks of this age were recycled into the mantle; where the latter is Condie's preferred explanation for the gap. The Grenville Province provides the largest exposure of Mesoproterozoic basement in North America,

therefore further study of Mesoproterozoic crustal formation in the Grenville Province may offer a chance to solve this problem.

### 1.3 The Grenville Province

The Grenville Province forms a longitudinal belt 2000 km long and 400 km wide, extending through Ontario and Quebec, from Georgian Bay to Labrador. The province represents a complex, highly metamorphosed orogenic belt at the southeastern margin of the Canadian Shield. The Grenville province is bounded to the north by the Grenville Front, which is juxtaposed against the Archean aged Superior Province (Figure 1.6).

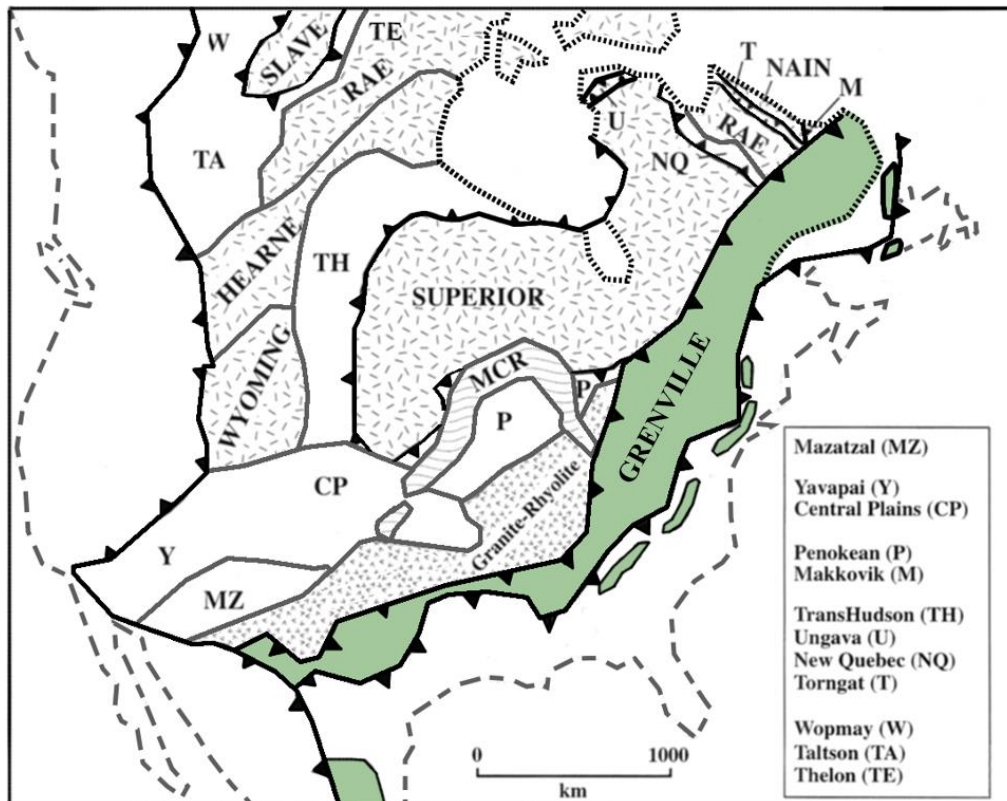

Figure 1.6: Geologic divisions of the North American Shield with the Grenville Province highlighted in green; dashed lines indicating coastlines (after Rivers, 1997)

There have been several different divisions of the Grenville Province; Wynne-Edwards (1972) had presented seven broad divisions based on metamorphic grades when little else was known about the province, but this was superseded by the model of Rivers et al. (1989), who divided the province into three tectonic structural belts based on geologic, geophysical and geochronological evidence (Figure 1.7).

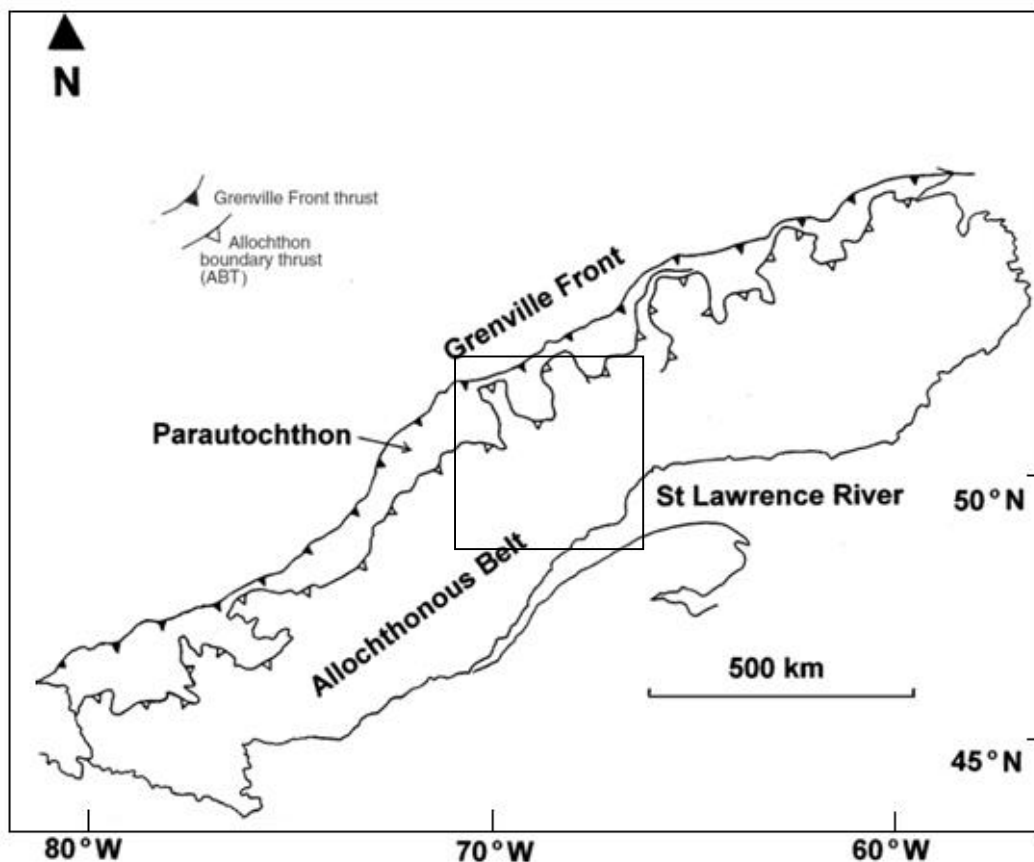

Figure 1.7: The tectonic divisions of the Grenville Province (after Rivers et al., 1989). The black box indicates the study area.

Rivers et al. (1989) defined these belts in terms of Grenvillian orogenic cycles of transposition and overprinting, each with their own tectonic boundaries: the Parautochthon in the north, the Allochthonous Polycyclic Belt in the south, and the Allochthonous Monocyclic Belt, a restricted portion in the far east and far west (not

shown). The Parautochthon is bounded to the north by the Grenville Front and contains reworked Archean and Paleoproterozoic crust. The Allochthon Thrust Boundary (ABT) separates the Parautochthon from the largely Mesozoic Allochthonous Belt that tectonically overlays it. The present study area lies fully within the central part of the Allochthonous Polycyclic Belt (APB), characterized by multiple orogenic cycles that overprinted the belt with a high metamorphic grade of amphibolite to granulite facies (Rivers et al., 1989). However, because the present study area is smaller in scale and lies completely within the APB and deals with pre-Grenvillian tectonics, this tectonic model is not suitable for explaining the tectonics of smaller accreted terranes.

Studies of Mesoproterozoic crustal evolution must be carried out in the context of Grenvillian belts and terranes; however a detailed understanding of the pre-Grenvillian evolution of the Laurentian margin depends on the identification of accreted terranes with distinct ages of crustal formation. Hence, Dickin (2000) proposed that the Grenville Province could also be explained in terms of several large accreted terranes with distinct crustal formation ages: Laurentia 2.7 Ga, Barilia and Makkovikia 1.9 Ga, Labradoria 1.7 Ga, and Quebecia 1.5 Ga (Figure 1.8).

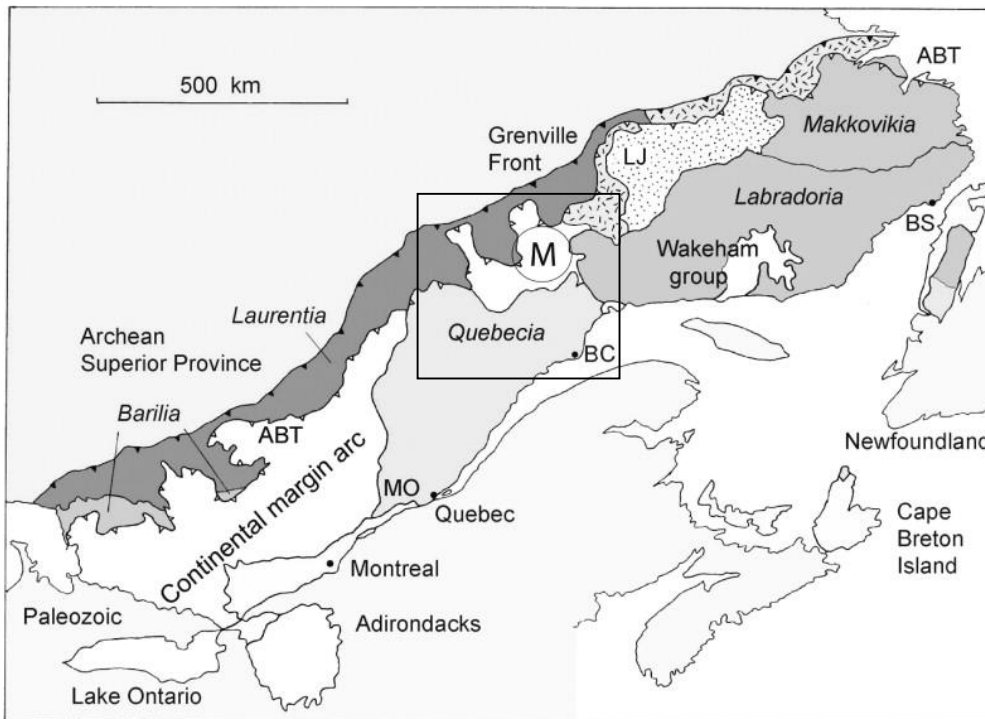

Figure 1.8: The Grenville Province and its terrane divisions based on identified crustal formation ages (Thomson et al., 2011). M: Manicouagan Impact Crater, BC: Baie Comeau, ABT: Allochthon Boundary Thrust., LJ: Lac Joseph allochthon, largely composed of Makkovik-age sedimentary rocks. Coarse stipple: Trans-Labrador batholith. The black box indicates the study area.

#### 1.4 The Study Area

Among the terranes proposed by Dickin (2000), the Quebecia terrane is the largest Mesoproterozoic accreted terrane, and was first identified by Dickin and Higgins (1992) as a Mesoproterozoic arc that was accreted to the Laurentian craton within 100 Ma of its formation. Figure 1.9 shows the Quebecia Terrane in relation to the Manicouagan Reservoir, the Makkovikian-age terranes to the north, and the Labradoria Terrane to the east.

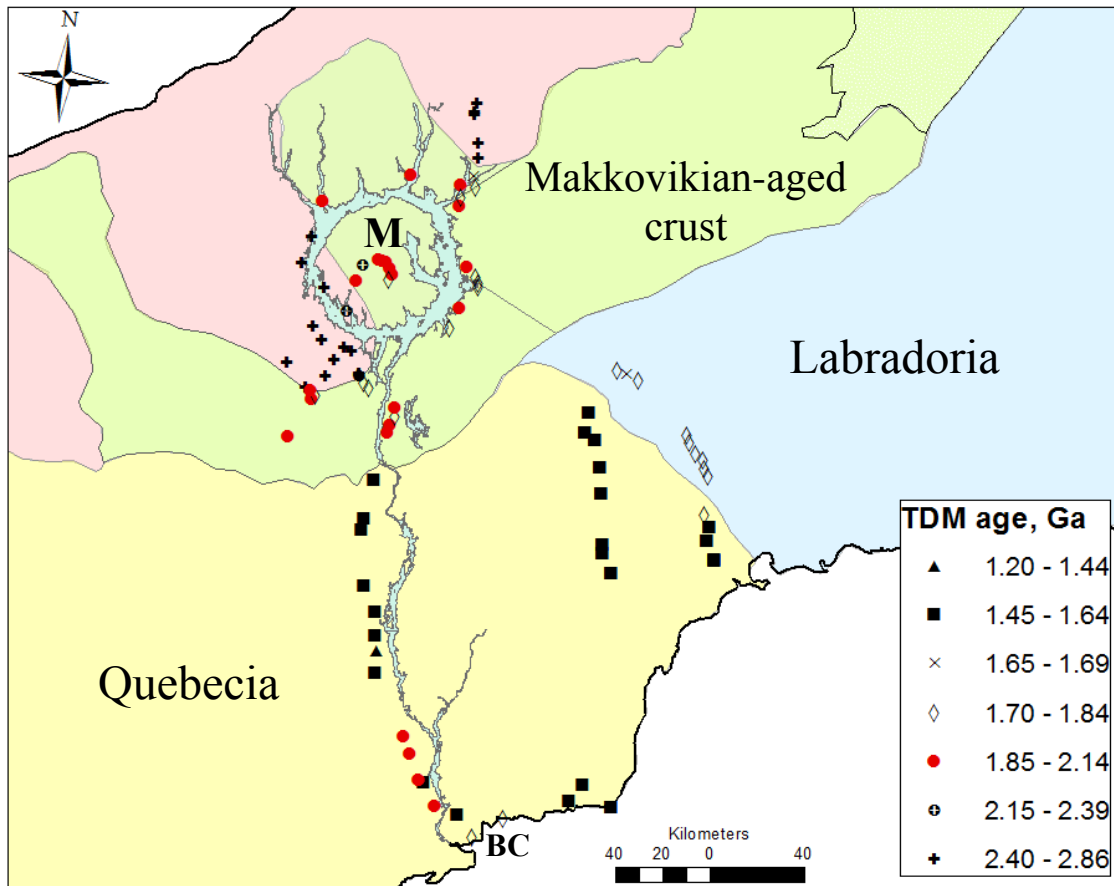

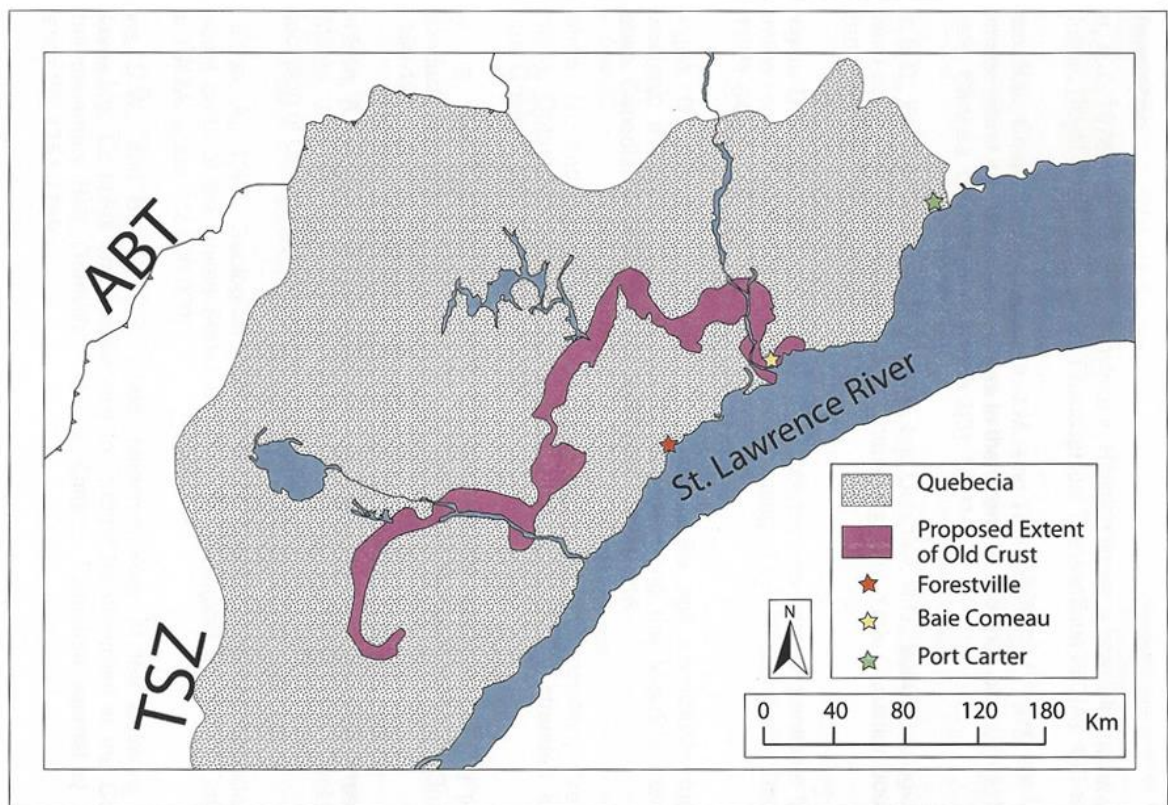

Figure 1.9: Crustal formation age map for the Quebecia Terrane (yellow) in relation to Makkovikian-age Berthe and Molson Lake terranes (green), the Labradoria Terrane (blue), Archean crust (pink) and the Manicouagan Impact Crater (M). BC=Baie Comeau. (Published data from Dickin and Higgins, 1992; Thomson et al., 2011.)

Dickin and Higgins (1992), while providing evidence for a major 1.5 Ga crustal event that would later be named the Quebecia Terrane, also identified a few samples distinct from the main sample suite yielded depleted mantle model ages of 1.7-2.0 Ga. They speculated that this may represent a separate, earlier crust forming event or a supracrustal sequence with a lithology resembling arc-derived sediments.

Hynes (2010) made a study of these enigmatic older crustal ages in the Saguenay and Baie Comeau areas of the Quebecia Terrane within Central Quebec. Hynes' study involved identifying and mapping crustal formation ages of old Paleoproterozoic

(>1.65Ga) crustal blocks that lie within the young 1.5 Ga Quebecia arc terrane. Through reconnaissance Sm-Nd isotope mapping of samples from the Saguenay and Baie Comeau areas, this study constrained the boundaries of the old crustal blocks in limited areas with Sm-Nd isotopic evidence, and proposed that the two fragments may connect to form an old crust panel running through the younger Quebecia arc. Figure 1.10 shows this model for the extended old crust panel.

*Figure 1.10: Proposed extent of old crust (purple) within the Quebecia terrane (grey) (Hynes, 2010)*

Ultimately, Hynes proposed that the Quebecia Terrane may represent a tectonic setting where fragments of old lithosphere were rifted from the Laurentian margin and later incorporated into the younger arc terrane formed by subduction related magmatism;

However, more research was still needed to provide a working model of how the old fragments got to their current position within the younger Quebecia terrane, and where these fragments came from.

Samples directly north of the Quebecia Terrane may help answer the question of the origin of these old fragments. The Grenville Province contains one of the largest and best preserved terrestrial impact structures, the Manicouagan Impact Structure, which is found just north of the Quebecia terrane. The Manicouagan region contains large areas of Proterozoic and Archean orthogneiss, and is subdivided into several Grenvillian lithotectonic terranes: the Gagnon terrane, Hart Jaune terrane, the Berthe Terrane, and the Manicouagan Imbricate Zone (MIZ) (Spray et al., 2010).

The Berthe Terrane is comprised of several smaller fragments that have been termed the Southern Domains. It is located southeast of the Manicouagan reservoir within the allochthonous belt (Hynes et al., 2000). Through Nd isotope analysis, the southern domains show a restricted range of Paleoproterozoic model ages from 1.7 to 2.0 Ga. A Sm-Nd isochron for samples in the Manicouagan area compared with suites from Eastern and Southern Labrador showed that Berthe Terrane model ages fell between the distributions from eastern and southern Labrador - suggesting that the Berthe Terrane represents Makkovikian age crust that was reworked during the Labradorian orogeny (Figure 1.11).

*Figure 1.11: Sm-Nd isochron diagram for analyzed orthogneiss samples from the Berthe Terrane in relation to suites from Southern Labrador, Gagnon and Makkovikia (Modified from Thomson et al., 2011)*

The present study utilizes Sm-Nd isotopic evidence and crustal age mapping to further investigate the northern and eastern extension of the older crustal fragments near Baie Comeau in an effort to constrain their boundaries. Ultimately, the study aims to deduce an origin for these fragments and a tectonic model of their inclusion within the Quebecia Terrane. The study focused on a series of approximately N-S transects and one

NE-SW transect within Central Quebec and the Baie Comeau area to map the boundaries of the old fragments (Figure 1.12).

*Figure 1.12: A sample transect map for the study area. BC=Baie Comeau. Red line: Baie Comeau transect for which major element geochemical data were obtained*

## **Chapter 2 – Neodymium Model Ages**

### ***2.1 Introduction***

When continental crust is extracted from the mantle, it remains buoyant relative to the mantle and creates terrestrial microcontinents that collide and form larger macrocontinents. The boundaries between these microcontinents prior to collision and accretion can be obscured by metamorphism, such as seen in the Grenville Province due to the Grenville Orogeny. Model ages can be used to identify the time at which the continental crust was extracted from the mantle, allowing the ability to date the formation of the crustal terranes and to map the boundaries between them.

The metamorphic events that affected the Grenville Province are responsible for resetting some isotope systems that could be used as dating techniques. The Samarium-Neodymium (Sm-Nd) isotope system is an ideal method for dating metamorphic rocks such as in this case because it is resistant to this resetting. The elements themselves have very similar chemical properties to each other and are relatively immobile during high grade metamorphism, erosion and igneous intrusions (Green et al., 1969; McCulloch and Wasserberg, 1978), therefore the system remains closed. Hence, the Sm-Nd dating technique can yield model crustal formation ages of the terranes as they would have been prior to metamorphism.

## 2.2 The Samarium-Neodymium Dating Method

Samarium has several radioactive isotopes ( $^{147}\text{Sm}$ ,  $^{148}\text{Sm}$  and  $^{149}\text{Sm}$ ) however  $^{147}\text{Sm}$  is the most useful as it has a half-life of 106 Ga – allowing it to produce small, but measurable differences in the daughter product  $^{143}\text{Nd}$  over millions of years (Dickin, 2005). This provides the basis of the Sm-Nd dating system. The radioactive decay law using the Sm-Nd method is expressed by the following formula:

$$\frac{^{143}\text{Nd}}{^{144}\text{Nd}} = \left( \frac{^{143}\text{Nd}}{^{144}\text{Nd}} \right)_i + \frac{^{147}\text{Sm}}{^{144}\text{Nd}} (e^{\lambda t} - 1)$$

Where  $\lambda$  = radiometric decay constant,  $t$  = age of the sample

The three ratios required to solve the age equation are the present day isotopic ratios of  $^{143}\text{Nd}/^{144}\text{Nd}$  and  $^{147}\text{Sm}/^{144}\text{Nd}$ , which are measured by mass spectrometry, and the initial isotopic ratio of  $^{143}\text{Nd}/^{144}\text{Nd}$ , which must be determined before age calculation. The initial isotopic ratio can be obtained from a mantle model, which assumes that the initial  $^{143}\text{Nd}/^{144}\text{Nd}$  ratio of the rock is equal to the  $^{143}\text{Nd}/^{144}\text{Nd}$  ratio of the mantle at the time it is extracted (Nelson and DePaolo, 1984).

Originally, the  $T_{\text{CHUR}}$  model by DePaolo and Wasserburg (1976a, 1976b) was used to obtain the initial isotopic ratio of the mantle for the dating method. This model, shown in Figure 2.1, represents the Nd isotope ratio through earth's history. The Chondritic Uniform Reservoir (CHUR) is an established benchmark for the isotopic composition of chondrite meteorites as a representation of the evolution of solar-system bodies such as Earth (Dickin, 2005). Studies have shown that samarium and neodymium isotope ratios present in terrestrial samples are roughly similar in

abundances to chondritic meteorites (DePaolo and Wasserburg, 1976a, 1976b), leading to the currently accepted theory that mantle composition was derived from the same source as chondrite samples; thus, Earth accreted from material with chondritic signatures.

Figure 2.1: Nd isotope evolution diagram;  $T_{\text{met}}$  = age of metamorphic event;  $T_{\text{sed}}$  = age of erosion event;  $f$  = fractionation of sample Sm/Nd (Dickin, 2005)

In DePaolo and Wasserburg's 1976a study, a new notion was also developed by normalizing all initial  $^{143}\text{Nd}/^{144}\text{Nd}$  isotopic ratios to CHUR to remove any effects of the slight fractionation that occurs between Sm and Nd, and for easier comparison between of different aged samples:

$$\epsilon Nd(t) = \left[ \frac{\left( \frac{^{143}\text{Nd}}{^{144}\text{Nd}} \right)_{\text{sample}}(t)}{\left( \frac{^{143}\text{Nd}}{^{144}\text{Nd}} \right)_{\text{CHUR}}(t)} - 1 \right] \times 10^4$$

DePaolo and Wasserburg (1976b) proposed that if this model is correct, and the CHUR evolution line accurately identifies the initial Nd isotope ratio of the mantle through time, then any measurement of Sm-Nd ratios in a crustal rock can be compared to the model and yield a model age for the formation of that rock, as long as there is sufficient isotope fractionation during crustal extraction from the mantle.

This model is represented by the following formula:

$$T_{\text{CHUR}} = \frac{1}{\lambda} \ln \left[ 1 + \frac{\left( \frac{^{143}\text{Nd}}{^{144}\text{Nd}} \right)_{\text{sample}} - \left( \frac{^{143}\text{Nd}}{^{144}\text{Nd}} \right)_{\text{CHUR}}}{\left( \frac{^{147}\text{Sm}}{^{144}\text{Nd}} \right)_{\text{sample}} - \left( \frac{^{147}\text{Sm}}{^{144}\text{Nd}} \right)_{\text{CHUR}}} \right]$$

Although Archean plutons fit the CHUR line, Mid-ocean ridge basalts (MORB) samples lay +7 to +12  $\epsilon$  units above the CHUR line (Figure 2.2) – leaving a gap between Archean CHUR data and the depleted MORB source (indicated by elevated Sm/Nd ratios) due to a lack of Proterozoic data.

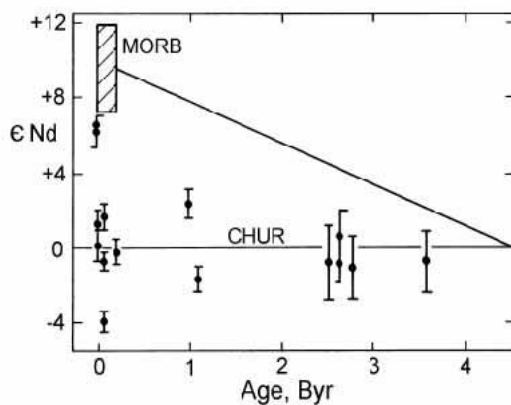

Figure 2.2: Diagram of Nd isotope evolution against time, showing terrestrial sample deviations from the CHUR line in  $\epsilon$  units. (DePaolo and Wasserburg, 1976b)

DePaolo (1981) recognized that Archean samples that fell within error of the CHUR line could actually lie on a curved corresponding to the progressive depletion of the mantle in light rare earth elements (LREE), representing a depleted-mantle evolution

line. To test this, DePaolo (1981) studied the Proterozoic basement from the Colorado Front Range and presented the initial  $^{143}\text{Nd}/^{144}\text{Nd}$  ratios of the samples in Figure 2.3.

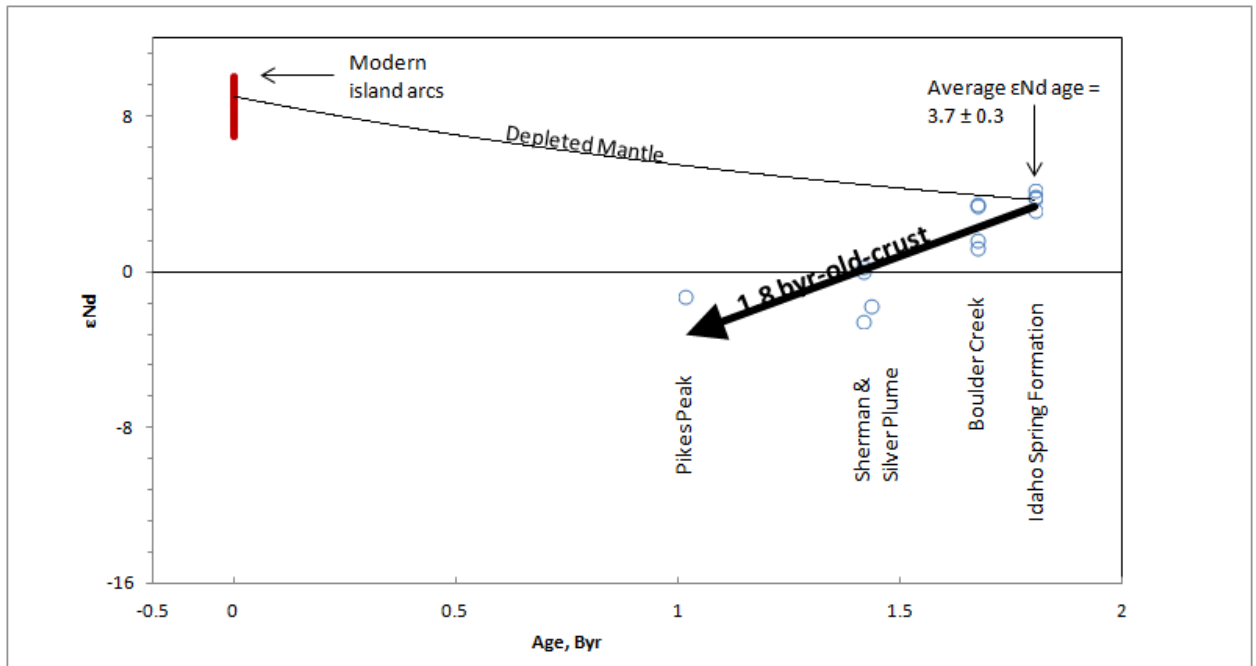

Figure 2.3: Plot of  $\epsilon\text{Nd}$  against time, showing the Colorado Front Range data relative to a depleted-mantle evolution. (After DePaolo, 1981)

DePaolo (1981) fitted a quadratic curve to the data, representing the Nd isotope evolution of a depleted reservoir that was a source for subduction-related magmatism. The curve begins on the CHUR evolution line in the early Archean, but evolves steadily to the present day. The composition of the depleted reservoir, relative to CHUR, is given as:

$$\epsilon\text{Nd}(T) = 0.25T^2 - 3T + 8.5$$

Sm-Nd model ages calculated using the depleted mantle curve are denoted  $T_{\text{DM}}$ , and have been shown empirically to yield more accurate indications of crustal formation ages than  $T_{\text{CHUR}}$  ages for studies of continental evolution (DePaolo, 1981).

Mass spectrometry was utilized at McMaster University in Hamilton to analyze the samples for their Sm-Nd isotope signatures in order to establish model ages. Please refer to Appendix A for detailed laboratory techniques.

## **Chapter 3 – Results**

### ***3.1 Nd Isotope Data***

The current study aimed to investigate the extent of the old Paleoproterozoic crustal block within the younger Mesoproterozoic Quebecia terrane, as well as provide evidence for its origin and tectonic history. The results of the present study, along with previously published data, have been compiled into three tables (See Appendix B). Table B-1 shows model age results that fall within the age range corresponding to the Quebecia Terrane (1.46-1.64 Ga) as defined by Dickin (2000), Table B-2 gives the results for model ages that are Labradorian to Makkovikian (1.7-2.0 Ga), while Table B-3 contains intermediate model age results that area attributed to Nd mixing at the boundaries between old and young blocks (1.65-1.69 Ga).

Samples which returned model ages which seemed anomalous were duplicated and reanalysed to check the results, either by complete redissolution or a duplicate analysis for  $^{143}\text{Nd}/^{144}\text{Nd}$  ratio. Samples indicated by a ‘\*’ were taken from Hynes (2010), ‘\*\*’ from Dickin and Higgins (1992) and ‘\*\*\*’ from Dickin (2000). After the crustal formation ages were calculated, they were plotted in ArcGIS (Figure 3.1). The Paleoproterozoic ages appear to form a sinusoidal pattern in the Baie Comeau (BC) area in Central Quebec – suggesting they could have originated as a single elongated block extending through the Mesoproterozoic Quebecia Terrane.

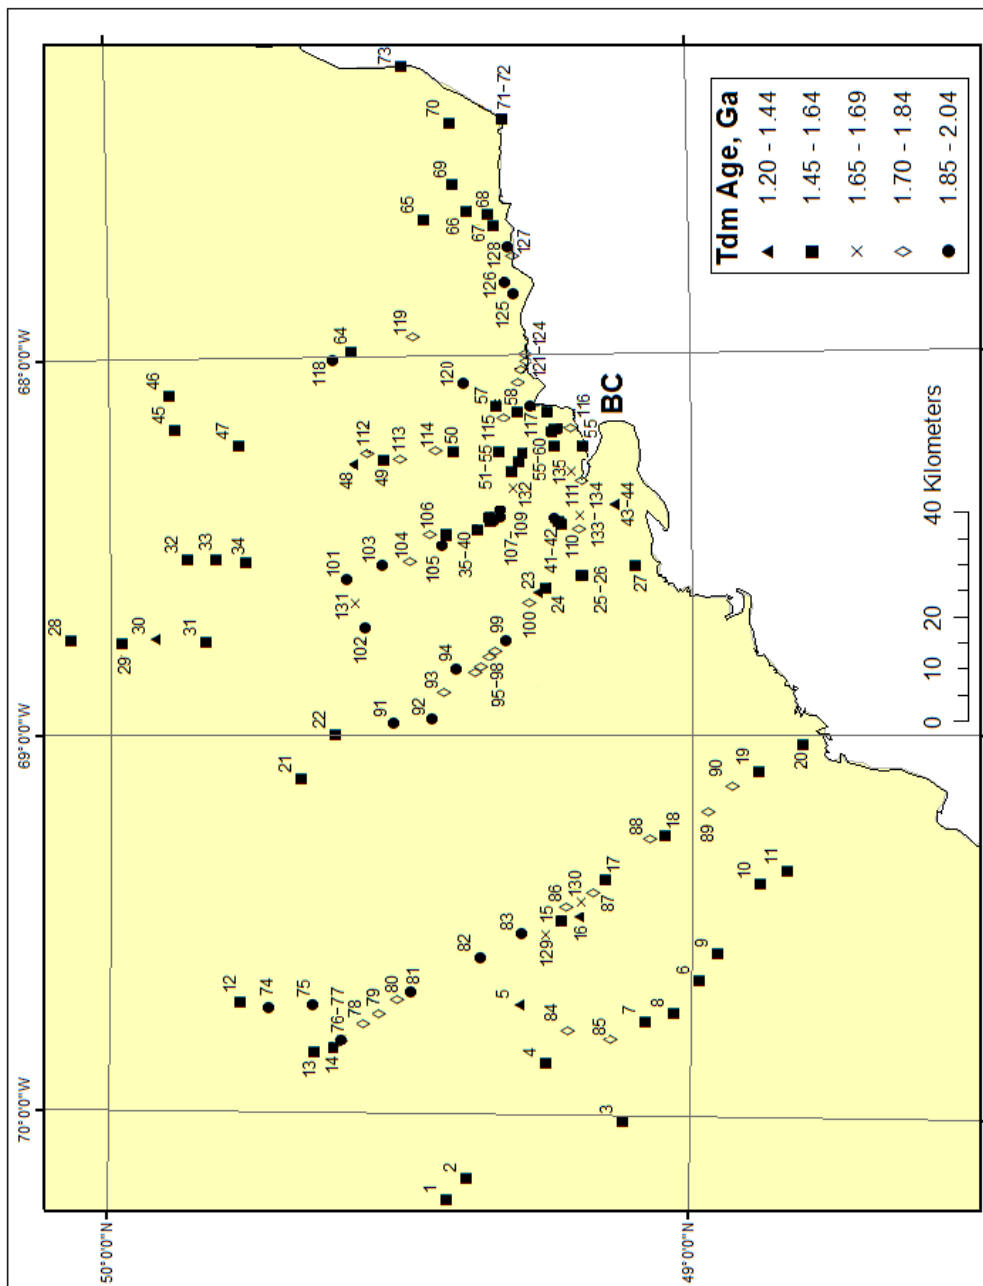

Figure 3.1: A numbered map of all the sample data found in tables B-1, B-2 and B-3.

A Sm-Nd isochron diagram was generated using the age categories in the above tables, along with several published reference suites (Figure 3.2).

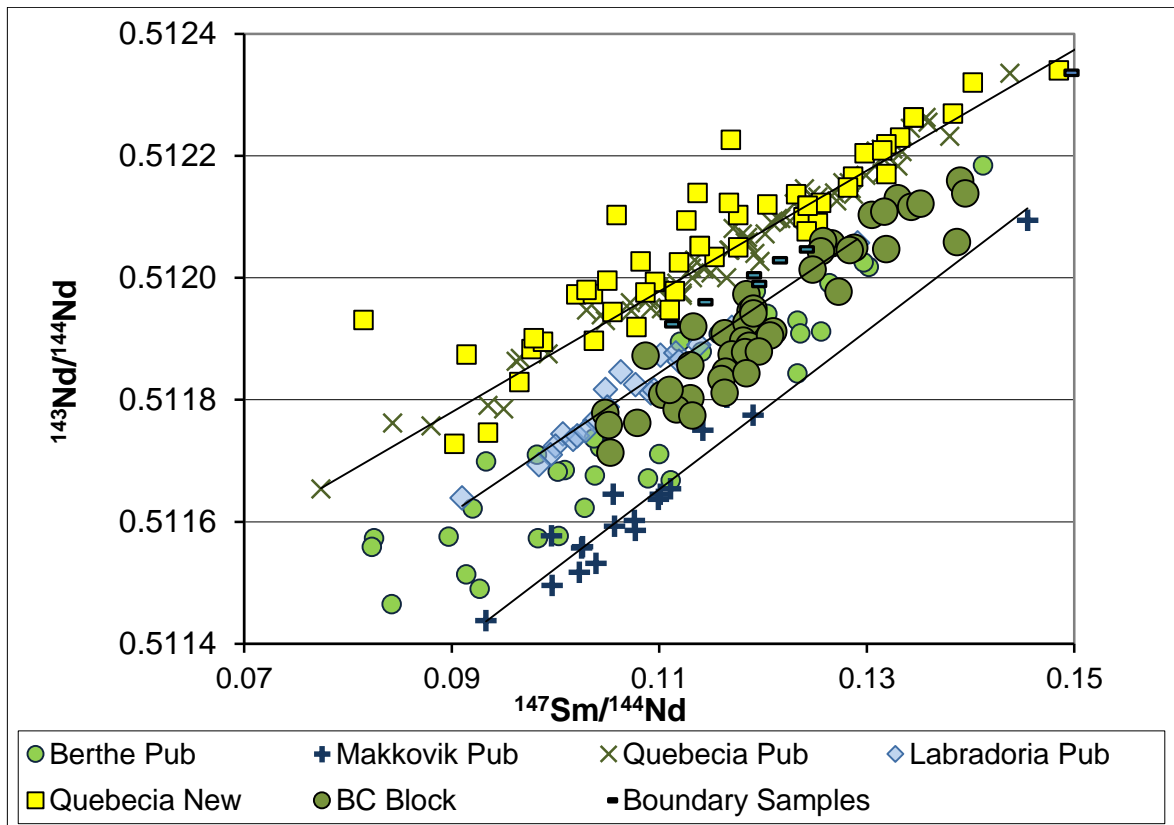

Figure 3.2: An isochron diagram comparing published data for the Quebecia Terrane, Makkovik province, Labradoria, and the Berthe Terrane with the current study. (Published data from Dickin, 2000; Hynes, 2010; Kerr and Fryer, 1994; Ketchum et al., 2002; Thomson et al., 2011).

New Quebecia-aged samples plot close to the published suite for Quebecia. In contrast, rocks from the Paleoproterozoic Baie Comeau block fall between the reference lines for the juvenile Labradoria Terrane and the Makkovik Province. This suggests the BC Block may contain a mixture of Nd with Makkovikian and Labradorian ages.

The Berthe Terrane exhibits a similar mixing pattern between Labradorian and Makkovikian aged crustal material, suggesting that a Laurentian source similar to the Berthe Terrane may have been detached to form the old block within Quebecia. As shown in Figure 1 by the red circles, the Berthe Terrane directly north of Quebecia has already

been attributed to the intrusion of Labradorian magmas into an older Makkovikian terrane.

To further examine the possible origins of the Baie Comeau block, it is compared with  $T_{dm}$  ages of the surrounding terranes in Figure 3.3, which presents a series of histograms illustrating the frequency of model ages for previous studies in Labradoria, Makkovikia, Quebecia and the Berthe Terrane, along with the current study.

The data distribution for the new Quebecia samples shows a peak at 1.55 Ga, which accurately reflects the published Quebecia peak value. In contrast, the BC Block shows a distribution ranging from 1.7-2 Ga, with peaks at 1.75 Ga and 1.85 Ga, illustrating a similar distribution to the Berthe Terrane but slightly shifted downward in age. This suggests that the Berthe Terrane and the BC block contain slightly different mixtures of Makkovik and Labradoria components. This may reflect reworking of Makkovikian crust in a Labradorian-age continental margin arc, as proposed for SE Labrador (Moumlow, 2014). The fact that the BC Block contains a slightly larger fraction of Labradorian Nd suggests that it may represent a slightly more out-board segment of this continental margin than the crust presently preserved in the Berthe Terrane.

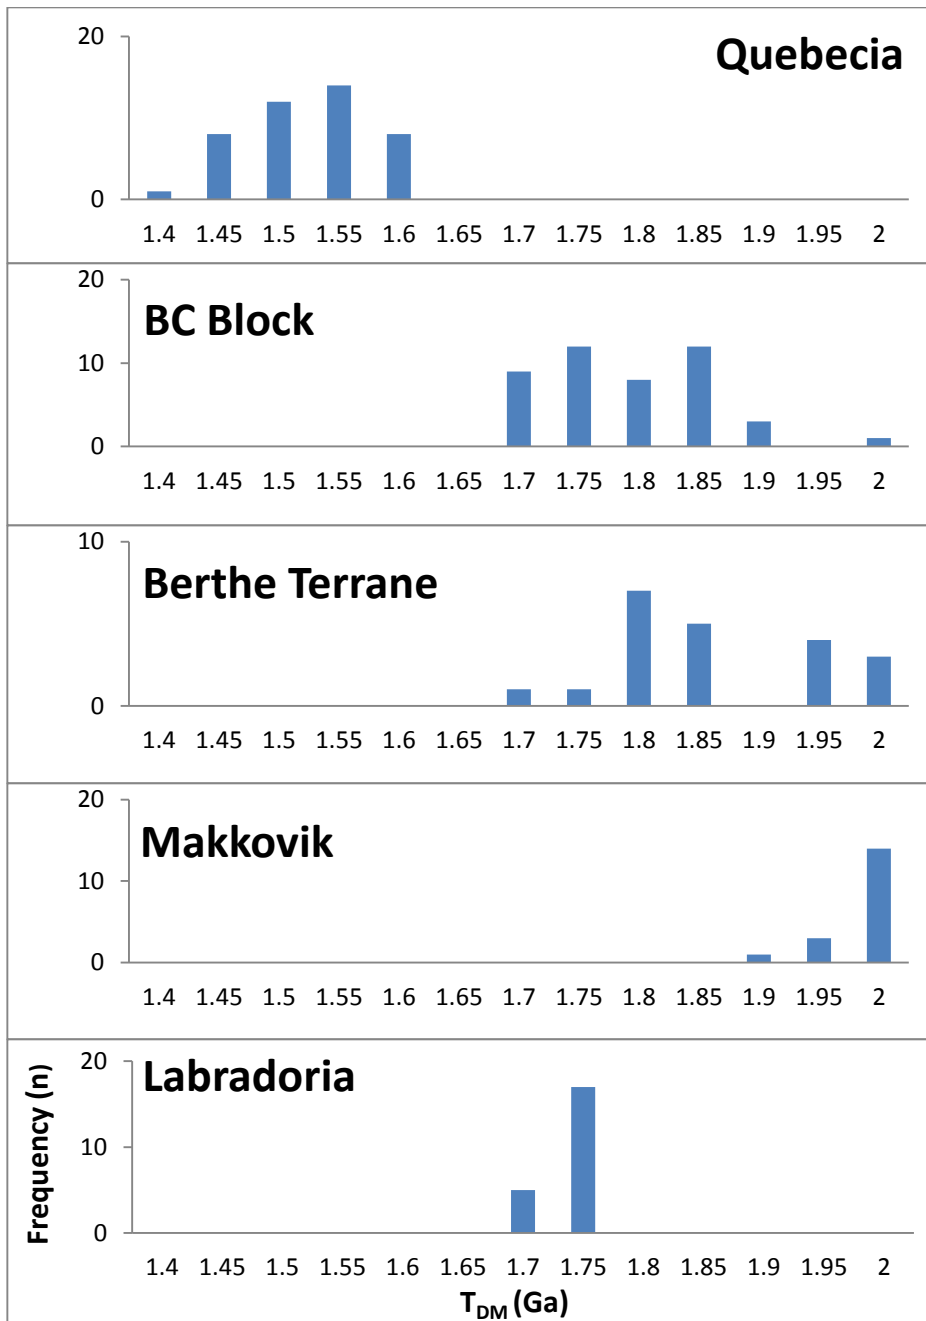

Figure 3.3: Distribution of  $T_{DM}$  age for the BC block compared with the surrounding terranes of Quebecia, Berthe, Labradoria, Makkovik. (Published data from Hynes, 2010; Kerr and Fryer, 1994; Ketchum et al., 2002; Thomson et al., 2011.)

### 3.2 Geochemical Analysis

In order to compare the petrology of the BC block with the Quebecia Terrane, samples from the principal transect west of BC were analyzed geochemically. These results are shown in Table 3.4 (See Appendix B). The results were compared with published data to produce a series of geochemical plots shown in Figure 3.4, 3.5, 3.6, 3.7 and 3.8. Published data from the Kohistan Arc (Jagoutz et al., 2009) was included to represent an oceanic arc for comparison.

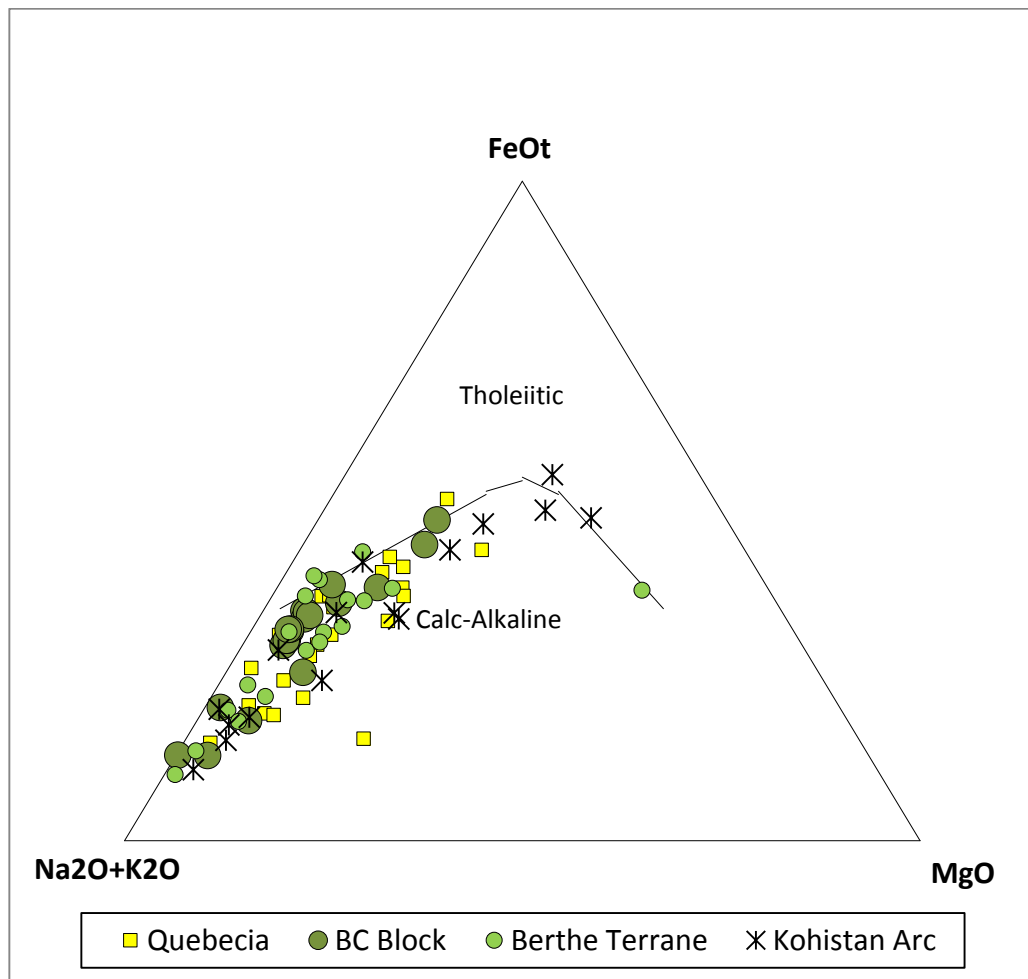

Figure 3.4: AFM Ternary diagram comparing published Quebecia, Berthe Terrane and Kohistan Arc data with the BC Block (Published data from Dickin and Higgins, 1992; Thomson et al., 2011; Jagoutz et al., 2009; Kimmerle, 2014; and Slaman, 2013).

Figure 3.4 shows an AFM Ternary Diagram that was generated using the relative proportions of oxides  $\text{Na}_2\text{O} + \text{K}_2\text{O}$  (A),  $\text{FeO}$  total (F), and  $\text{MgO}$  (M). The majority of the samples lie within the calc-alkaline section of the AFM Ternary diagram, confirming that all of the samples are arc related. The data were then plotted on a Q (quartz) and P (plagioclase) petrochemical diagram to further classify granitoid rocks using their whole rock chemical composition (Figure 3.5).

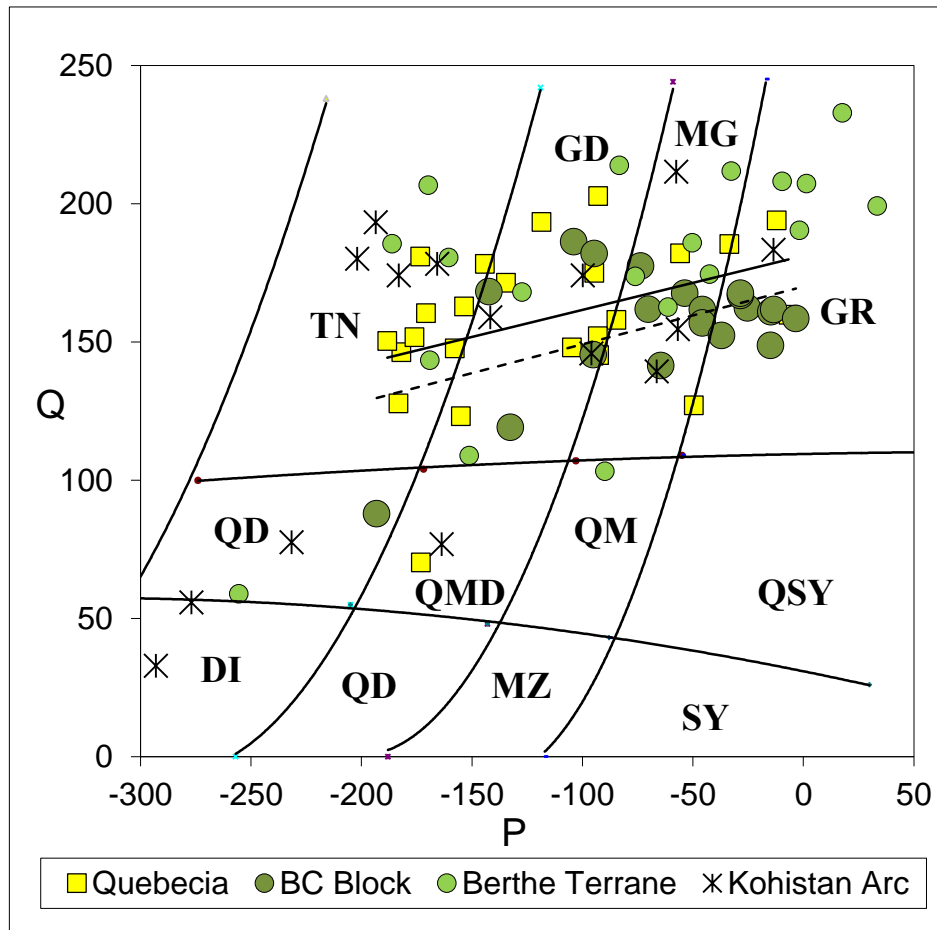

Figure 3.5: *Q-P Petrochemical diagram after Debon and LeFort (1983) comparing published Quebecia, Berthe Terrane and Kohistan Arc data with the BC Block. Solid line: Quebecia trend line, dashed line: BC Block trend line (Published data from Dickin and Higgins, 1992; Thomson et al., 2011; Jagoutz et al., 2009; Kimmerle, 2014; and Slaman, 2013).*

The Kohistan Arc, representing a mature oceanic arc, trends along the left side of the diagram, spanning from diorite to granodiorite. The Mesoproterozoic Quebecia samples plot predominantly in the upper region of the plot with a concentration in the tonalite and granodiorite fields (solid trend line). In contrast, samples from the BC Block plot lower and to the right (dashed trend line) indicating a lower silica, more alkaline suite.

A TAS diagram (Le Bas et al., 1986) was generated to compare silica saturation between the different sample suites (Figure 3.6). In this diagram, the Kohistan Arc suite spans mostly the entire silica oversaturated bottom region, whereas the BC Block has a tighter cluster around the boundary between oversaturated and saturated, with concentrations in the dacite (O3) and rhyolite fields. The Berthe Terrane and Quebecia Terrane suites show a similar distribution within dacite and rhyolite fields but are more scattered within the oversaturated region. This diagram is again showing that the BC block (dashed trend line) is more alkaline and less oversaturated with silica than the Kohistan arc and the Quebecia terrane (solid trend line).

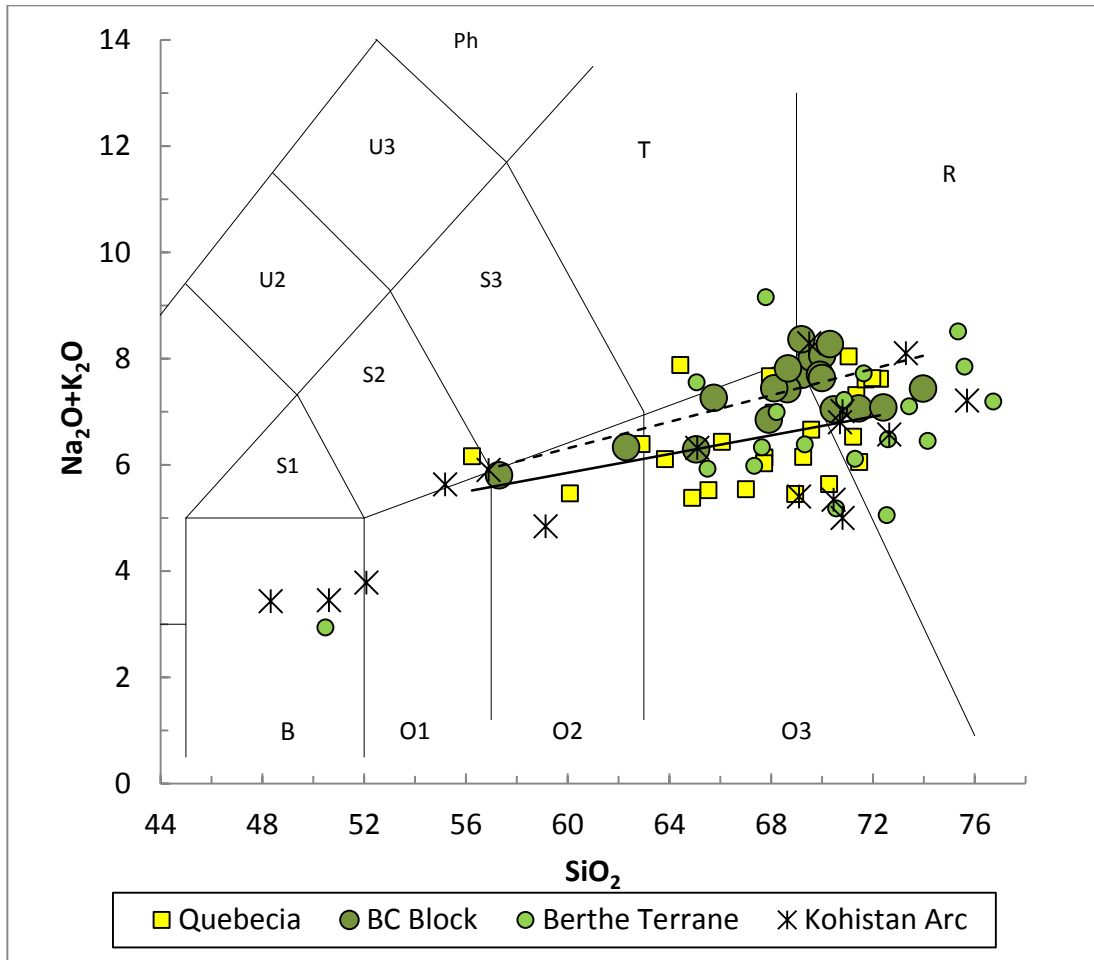

Figure 3.6: A TAS diagram comparing total alkalis and  $\text{SiO}_2$  (Le Bas et al., 1986). U2, U3: Generally Silica Under saturated; Ph: Phonolite; S1, S2, S3: Generally Silica-Saturated; T: Trachyte or Trachydacite; B: Basalt; O1 (Basaltic andesite), O2 (Andesite), O3 (dacite): Generally Silica Oversaturated. Solid line: Quebecia trend line, dashed line: BC Block trend line (Published data from Dickin and Higgins, 1992; Thomson et al., 2011; Jagoutz et al., 2009; Kimmerle, 2014; and Slaman, 2013).

In order to further differentiate between tectono-magmatic environments, a  $R_1$ - $R_2$  diagram was generated to compare the calculated chemical limits of the sample suites (Figure 3.7).

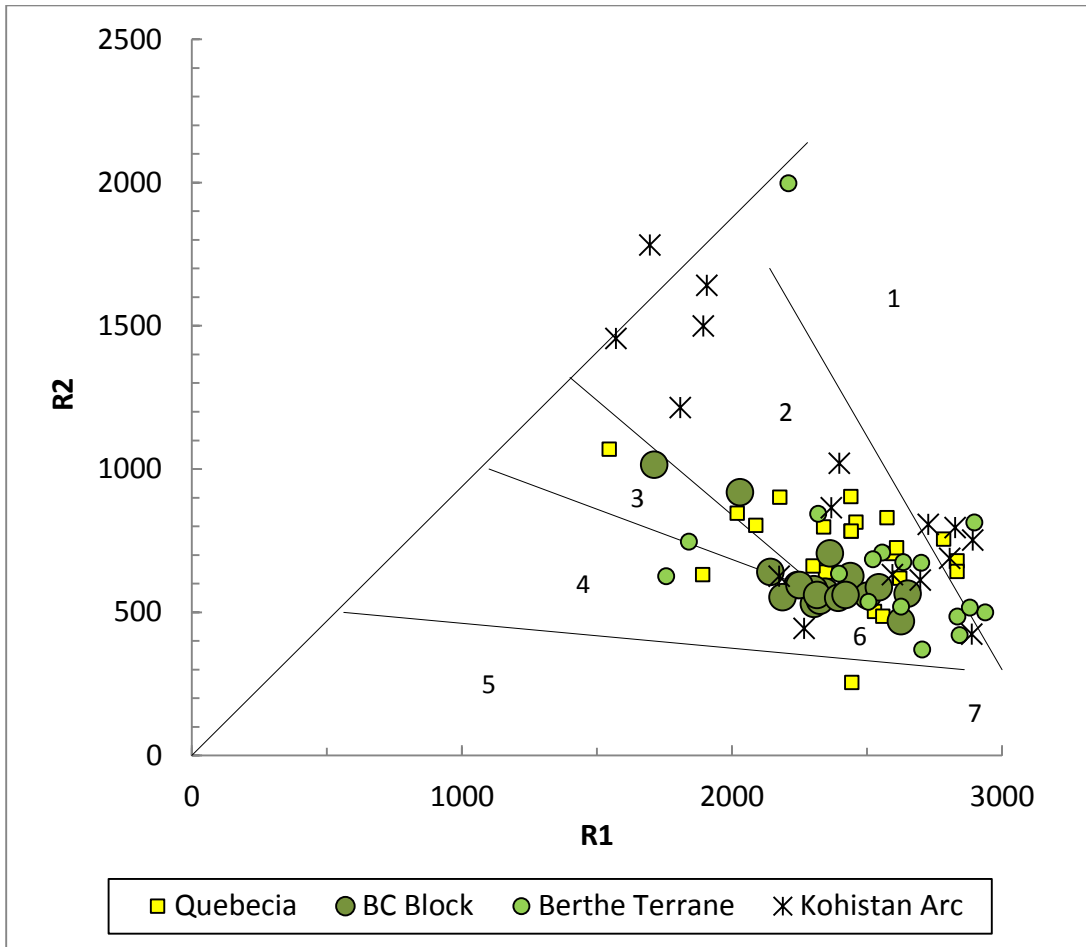

Figure 3.7:  $R_1$ - $R_2$  diagram: A geochemical classification of granitic rocks by Batchelor and Bowden (1985).  $R_1$ :  $4Si - 11(Na+K) - 2(Fe + Ti)$ ,  $R_2$ :  $6Ca + 2Mg + Al$ . Region 1: Mantle fractionates, Region 2: Pre-plate collision, Region 3: post-collision uplift, Region 4: late orogenic, Region 5: Anorogenic, Region 6: Syn-collisional, Region 7: Post orogenic. (Published data from Dickin and Higgins, 1992; Thomson et al., 2011; Jagoutz et al., 2009; Kimmerle, 2014; and Slaman, 2013).

In the  $R_1$ - $R_2$  diagram, majority of the Kohistan Arc samples plot within Region 1 and 2, corresponding to mantle fractionate and pre-plate collision. The Quebecia samples plot similarly within Region 2. In contrast, the BC Block and Berthe Terrane mainly lay within Region 4 and 6, corresponding to late orogenic and syn-collisional activity. This suggests the BC block and Berthe Terrane are more mature, continental arcs in

comparison to the more primitive, oceanic arc setting Kohistan Arc and Quebecia Terrane.

Lastly, potassium oxide was plotted against zirconium concentration to further show the distribution of alkalinity (Figure 3.8). Trend lines for the BC Block (dashed line) and Quebecia (solid line) were also plotted.

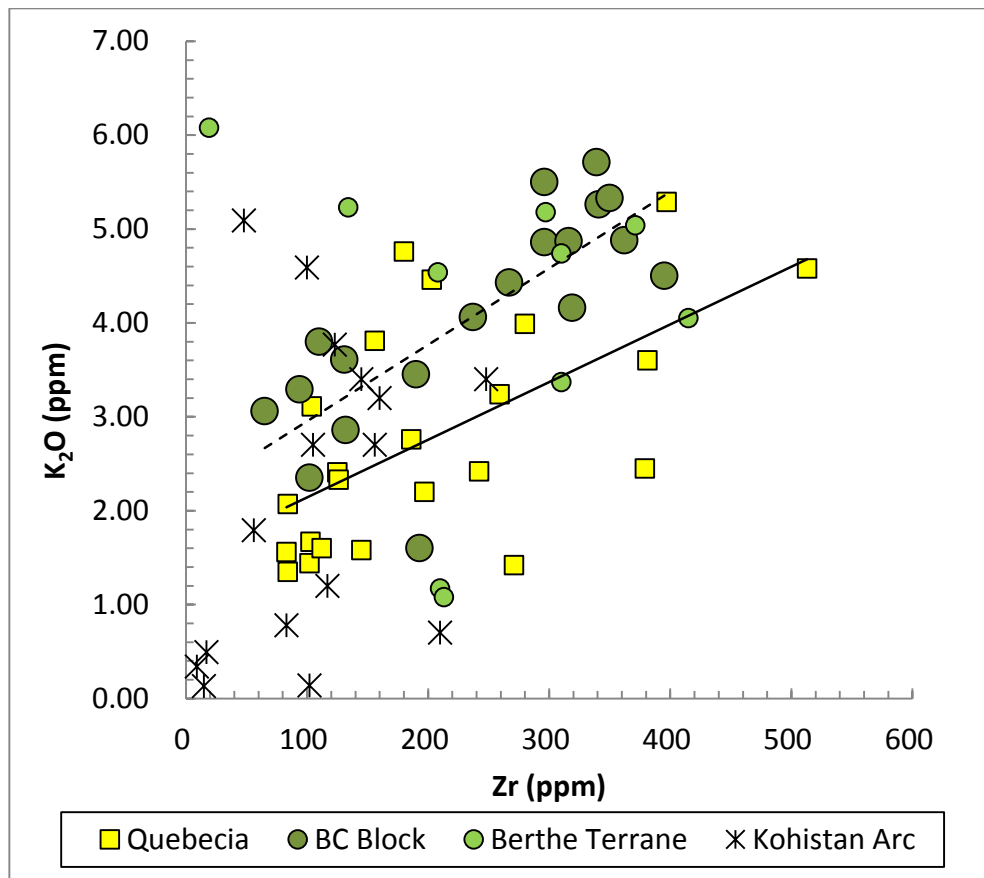

Figure 3.8: Petrochemical chart comparing potassium oxide ( $K_2O$ ) and zirconium (Zr). (Published data from Dickin and Higgins, 1992; Thomson et al., 2011; Jagoutz et al., 2009; Kimmerle, 2014; and Slaman, 2013).

As shown by the trend lines, the BC Block plots higher in  $K_2O$ , indicating it is a more alkaline suite. In contrast, the Quebecia samples plot lower in  $K_2O$ , suggesting they are less alkaline, representing a juvenile arc similar to Kohistan.

### 3.3: Distance vs. $T_{dm}$ Transects

The BC Transect shown in Figure 1.12 (red line) was further graphically analyzed by plotting the sample ages with the N-S distance relative to the farthest northern point above the BC Block boundary (Figure 3.9). For comparison, a transect from the Berthe Terrane and Quebecia near Manicouagan were also plotted.

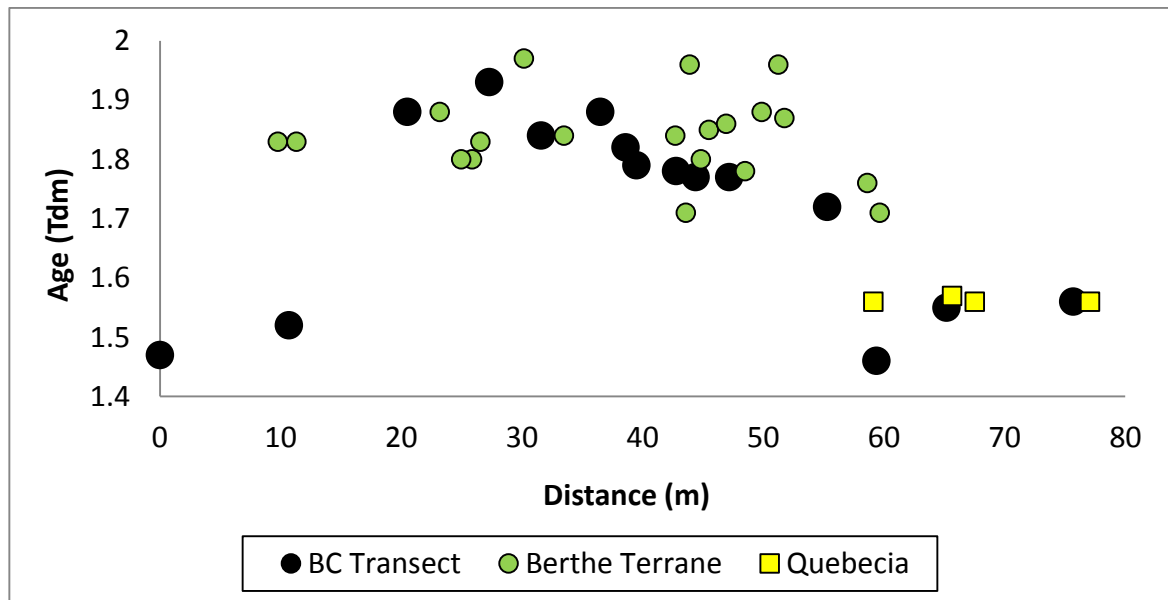

Figure 3.9: Model age/distance transect graph for the BC Transect (Published data from Thomson et al., 2011; Dickin and Higgins, 1992).

The BC Transect in Figure 3.9 begins north of the proposed old block boundary (m=0) where the samples are Mesoproterozoic in age (1.5-1.55 Ga) which represent Quebecia. As the transect moves into the old block boundary, the plotted samples yield

much older ages (1.7-1.9 Ga) and have been correlated with a Berthe Terrane transect (green circles) to show the similarity in age on the graph. As the BC transect moves out of the proposed old block boundary, the samples are again younger and correlate well with a small Quebecia transect (yellow squares).

## **Chapter 4: Discussion**

### ***4.1 Discussion of Results***

The present study has mapped crustal formation ages of the Quebecia Terrane ( $1.52 \pm 0.09$  Ga) in contrast to the Paleoproterozoic block identified ( $1.81 \pm 0.07$  Ga). An interpolation map was created to highlight the Paleoproterozoic ages and ultimately, determine a shape for this old Baie Comeau panel extending through the Quebecia Terrane (Figure 4.1).

*Figure 4.1: An inverse distance weighted interpolation of the Baie Comeau (BC) area in Central Quebec; Highlighting a possible shape for the Paleoproterozoic panel extending through the Quebecia Terrane.*

As shown in Figure 4.1, the interpolation succeeded in highlighting the older Paleoproterozoic ages within the Baie Comeau area (blue) as two or three broken panels, as opposed to Hynes' (2010) one large panel (Figure 1.10). There was no solid evidence to link the Baie Comeau segments to the Saguenay, however as this model shows two or three separate blocks, it is not inconceivable that they are still from the same tectonic event and were broken due to Grenville metamorphism.

To further validate the highlighted panel from Figure 4.1, the regional geology was incorporated into ArcGIS along with the interpolation. Figure 4.2 shows the regional geology (obtained from *Energie et Ressources naturelles, Québec*) overlain by possible BC block fragments drawn in an effort to agree with the both the interpolation and the mapped geology. By comparing the two figures, it can be seen that there are strong NS geologic features that cut across the interpolation in Figure 4.1 (shown by the yellow star in Figure 4.2), suggesting that there is a break in the BC panel and it is instead divided into several separate segments that take the form of a mega-boudins. Since there are no roads within this area for sample collection, we rely on the geologic mapping for the shape of the BC fragment in that area.

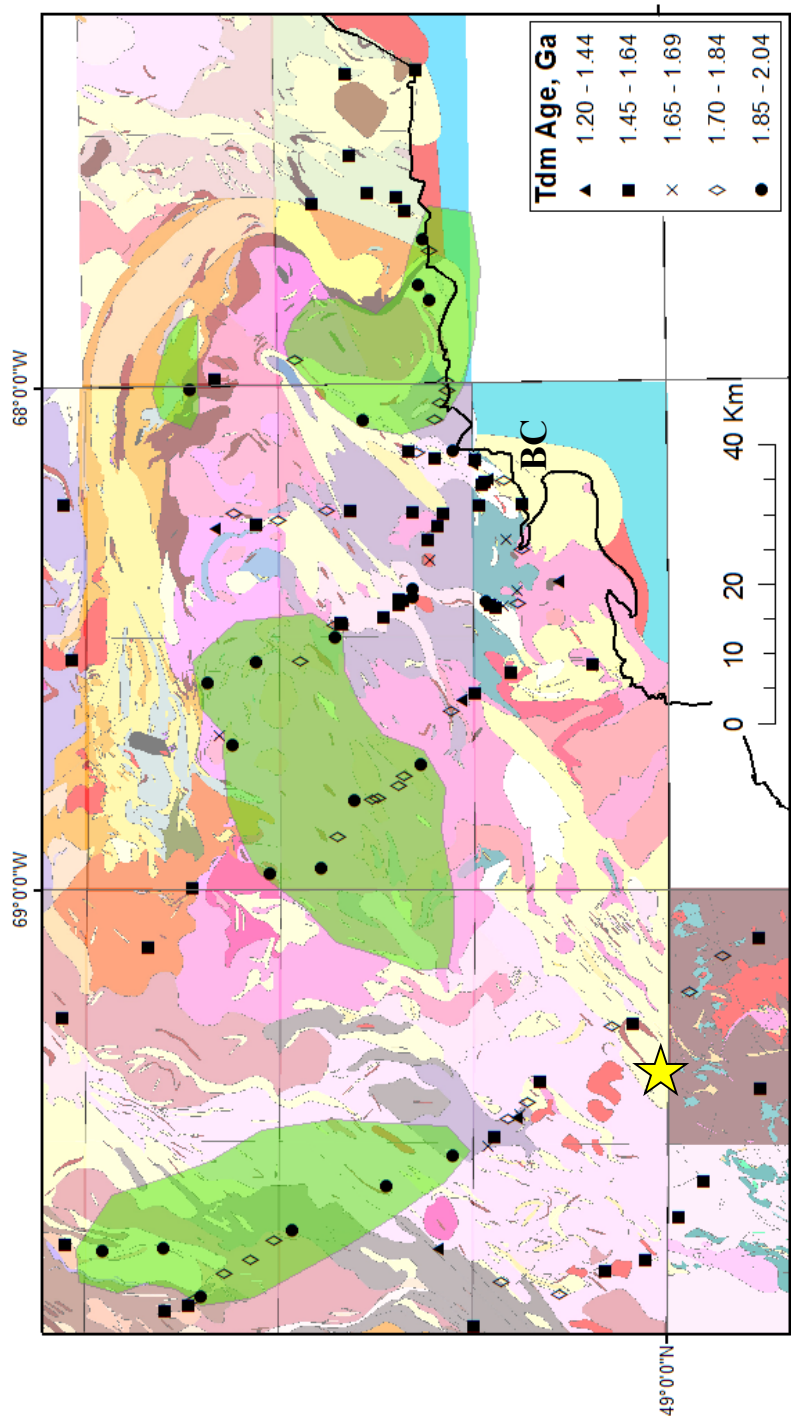

Figure 4.2: Possible configuration of the BC block fragments overlaying the regional geology. Pinks and greys: granitoid orthogneiss, oranges: anorthosite, yellow: mainly paragneiss. Yellow star indicates areas of NS linear features (Geologic maps from *Energie et Ressources naturelles, Québec*) BC: Baie Comeau.

By comparing the Sm-Nd signatures from this study with previous published work in Chapter 3, it is shown that this old block exhibits a similar mixed source signature to the Berthe Terrane. The old block may have been detached from the Paleoproterozoic margin of Laurentia and reaccruted between two blocks of the Quebecia Terrane. This leads to a model involving a division of Quebecia into separate north and south accreting terranes. The exact mechanics of this event are still unclear, however, comparison with a modern analogue may shed some light on the process.

The tectonic evolution of the Grenville Province has many similarities to that of the Sumatra region in Southeast Asia. Southeast Asia, like Laurentia, is a complex assembly of crustal terranes and volcanic arcs with tectonic boundaries between them. It is possible that the tectonic history of the old crustal block identified within the Quebecia arc may be analogous to that of West Sumatra.

#### ***4.2 Southeast Asia: A Modern Analogue***

Similar to the older BC block presented in the current study, the question of how West Sumatra was transported to its current position between two younger terranes was a problem when trying to reconstruct the plate tectonics of the Sumatra region. However, being of Phanerozoic age, the tectonic history of SE Asia has been reconstructed based on floral and faunal data, as well as its deformational history. Despite the absence of these data in the Grenville Province due to its older age, the mechanism behind the

transportation of West Sumatra can be used as an analogue to explain the origin of the older crustal fragments contained within Quebecia.

As shown in Figure 4.3, West Sumatra is an elongated terrane wedged between the Woyla terrane to the southwest and the Sibumasu terrane to the northeast. This region of Southeast Asia is also often referred to as Sundaland. A more detailed tectonic map of these terranes is shown in Figure 4.4.

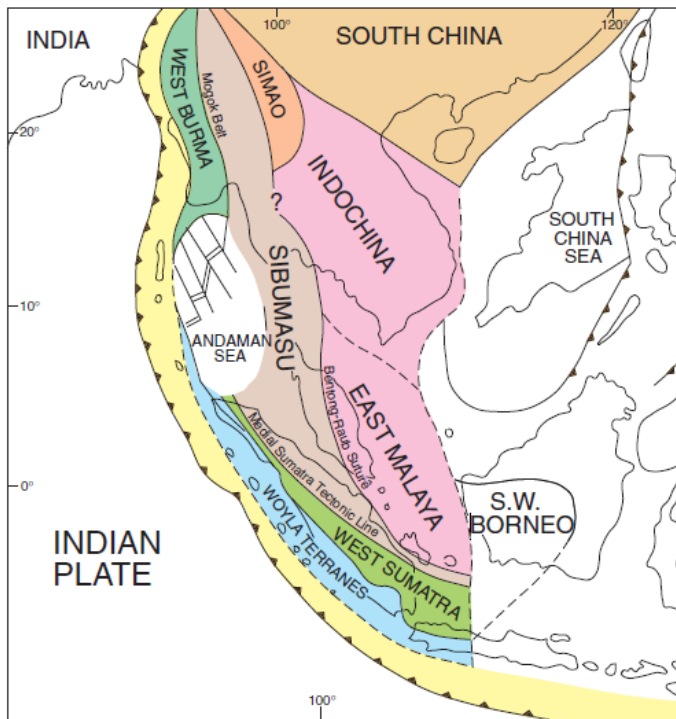

Figure 4.3: Continental tectonic blocks in Southeast Asia (Barber and Crow, 2009)

West Sumatra is composed mostly of Carboniferous aged units with a few Permian units, bounded to the northeast by Permo-Carboniferous units of Sibumasu (East Sumatra) and to the southwest by the younger Jurassic-Cretaceous units of the Woyla terrane (Figure 4.4). The contact between West Sumatra and the Sibumasu (East Sumatra) terrane is marked by the Medial Sumatra Tectonic Zone (MSTZ); this zone is marked by

highly deformed rocks including schists and gneisses, and is suggested to be the main locus of translation of West Sumatra outboard Sibumasu. Ultimately, understanding the tectonic events that placed West Sumatra outboard of Sibumasu may allow the Sumatra region to be used as an analogue to the Quebecia Arc.

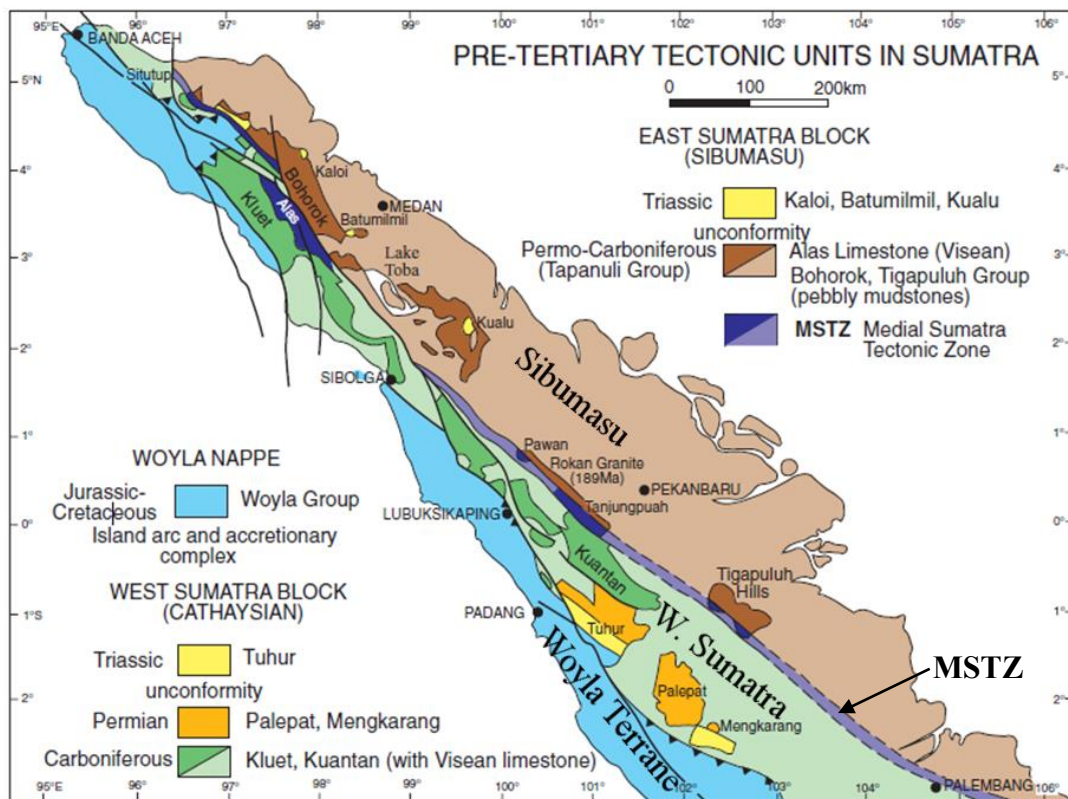

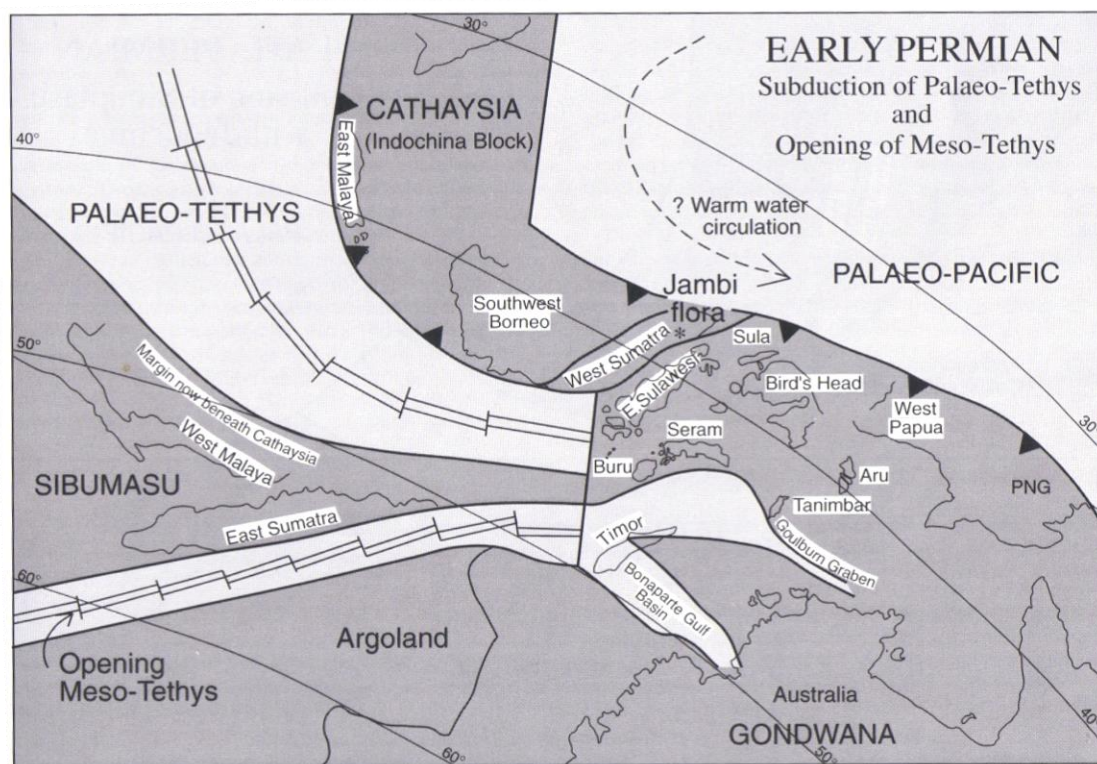

Figure 4.4: Distribution of the stratigraphic and tectonic units in Sumatra; darker shade indicate outcrop, lighter tons indicate areas where pre-Tertiary is overlain by Tertiary and Quaternary sediments (Barber and Crow, 2009)

In the Late Paleozoic, Asia as a whole was amalgamated from terranes derived from the northern margin of East Gondwana. Although Sibumasu and West Sumatra are of similar age, mapped floral and faunal data strongly suggests that these terranes had different origins (Barber and Crow, 2009); Sibumasu from western Gondwana, and West Sumatra from Cathaysia, a northern peripheral region of Gondwana (Figure 4.5). During

the Early Permian, Cathaysia was a peripheral region of Gondwana that would eventually make up the landmasses of China and South Asian countries, including the Sumatra region. In Figure 4.5, Cathaysia is shown as the collection of South China, East Malaya, Borneo and West Sumatra. Based on floral and faunal evidence, West Sumatra originated as a piece of Cathaysia, while Sibumasu came from western Gondwana.

*Figure 4.5: Paleogeography of NE Gondwana and SE Asian terranes in the Early Permian, showing the subduction of the Palaeo-Tethys between Sibumasu and Cathaysia, and the opening of the Meso-Tethys between Sibumasu and Gondwana (Barber et al., 2005).*

The tectonic history of the Sumatra region can be loosely summarized in 3 major steps:

(1) While the Paleotethys was still spreading in the Early Permian, its northern margin began to subduct beneath Cathaysia. Meanwhile, Sibumasu began to rift from Western Gondwana (toward Cathaysia, Figure 4.5).

(2) In the late Permian to early Triassic, Sibumasu collided with Cathaysia (Figure 4.6).

(3) Strike-slip movement along the MSTZ placed West Sumatra outboard of Sibumasu (shown in Figure 4.7).

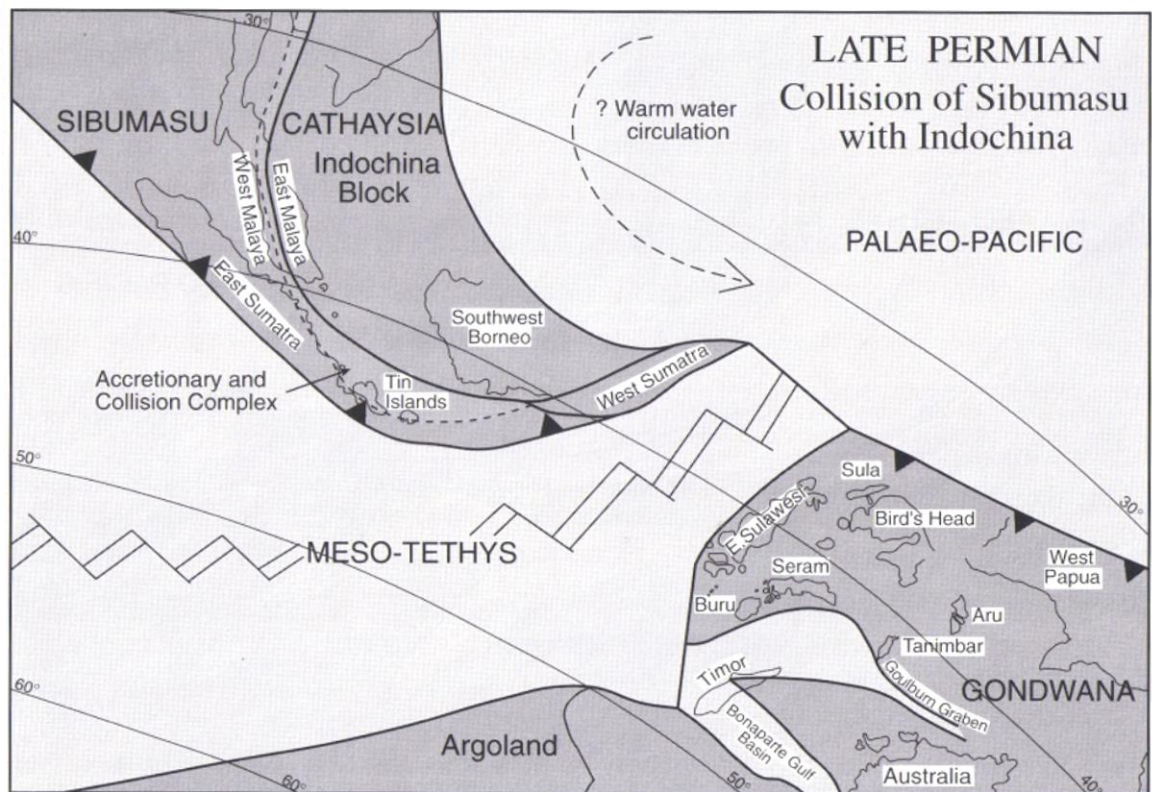

Figure 4.6: Paleogeography of NE Gondwana and SE Asian Terranes in the Late Permian (Barber et al., 2005)

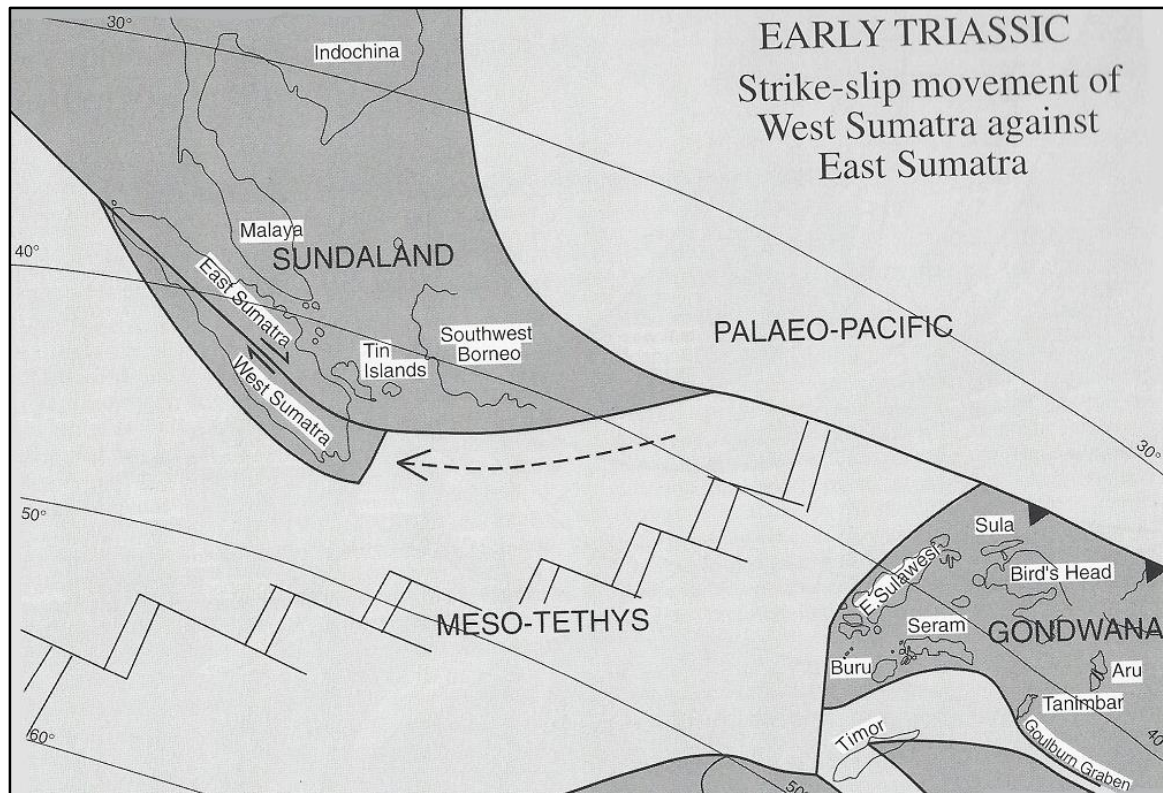

Figure 4.7: Paleogeographic map of the SE Asian terrane in the Early Triassic (Barber et al., 2005)

It is suggested that West Sumatra moved westwards from the southeastern extremity of Cathaysia (Figure 4.5) via strike-slip faulting along the MSTZ to its current position outboard of Sibumasu (shown in Figure 4.6 and 4.7 as East Sumatra).

Hutchinson (1994) suggested that this translation occurred during the Cenozoic; However a comparison of Carboniferous, Permian and Triassic sequences of the eastern Sumatra Sibumasu Terrane shows continuity of Middle to Upper Triassic sediments across West Sumatra, the MSTZ, Sibumasu and Malaya (Figure 4.8) – suggesting that these blocks had their present relationships before Mid-Triassic times (Barber et al., 2005).

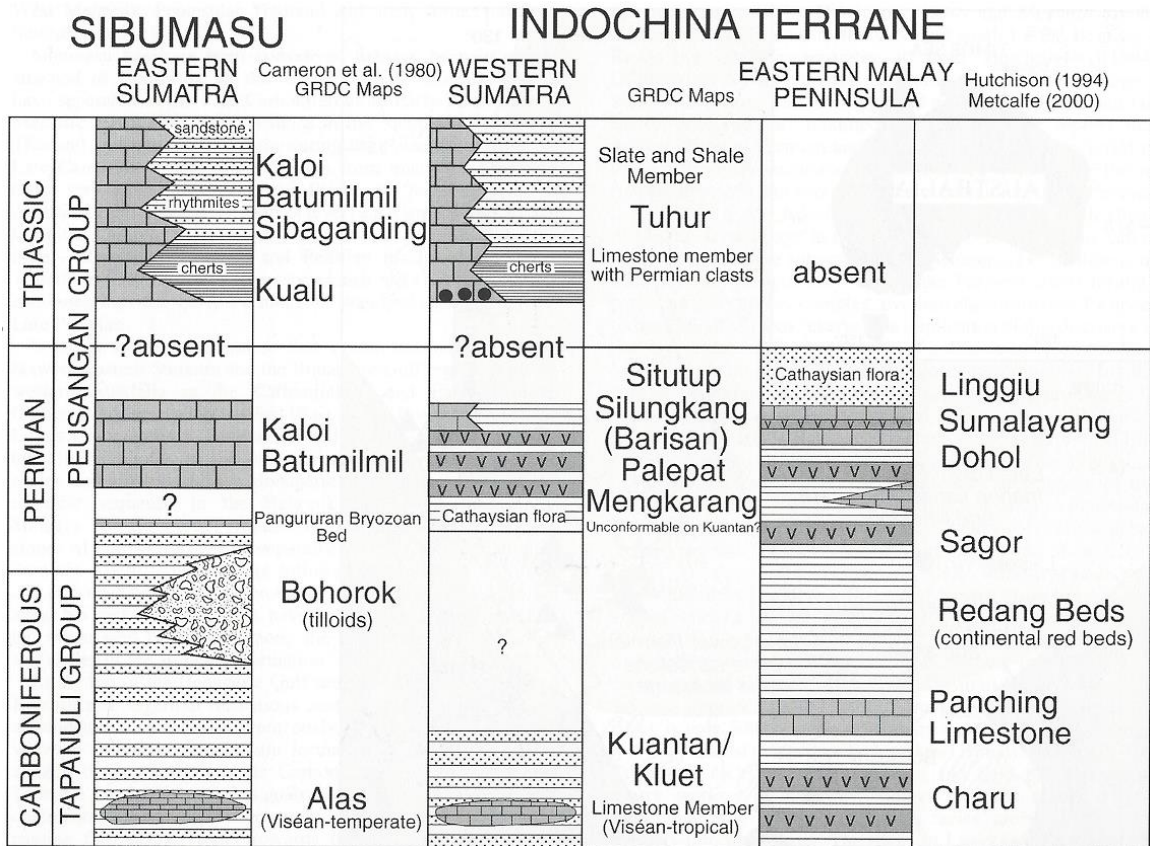

Figure 4.8: Comparisons of the sediment sequences in Sibumasu (Eastern Sumatra) and Western Sumatra (Barber and Crow, 2005)

These sedimentary sequences also show no record of sediments for the late Permian/early Triassic, therefore it is suggested that the translation of West Sumatra to its position outboard of Sibumasu occurred during this time (Barber et. al, 2005).

Therefore, using the detailed tectonic history of West Sumatra as an analogue, it is plausible that a Paleoproterozoic crustal panel was translated southwest from the Berthe Terrane during the accretion of Quebecia in multiple stages, causing it to become inserted between a north and south portion of the younger Mesoproterozoic Quebecia terranes.

### 4.3 Orogenic Model

Utilizing Barber and Crow's 2003 cross-section for the evolution of Sumatra as a basis, a similar model can be proposed for the tectonic history of the old crustal fragment within Quebecia (Figure 4.9). In this model, blocks are transported out of and into the line of cross section by transcurrent movement along the margin.

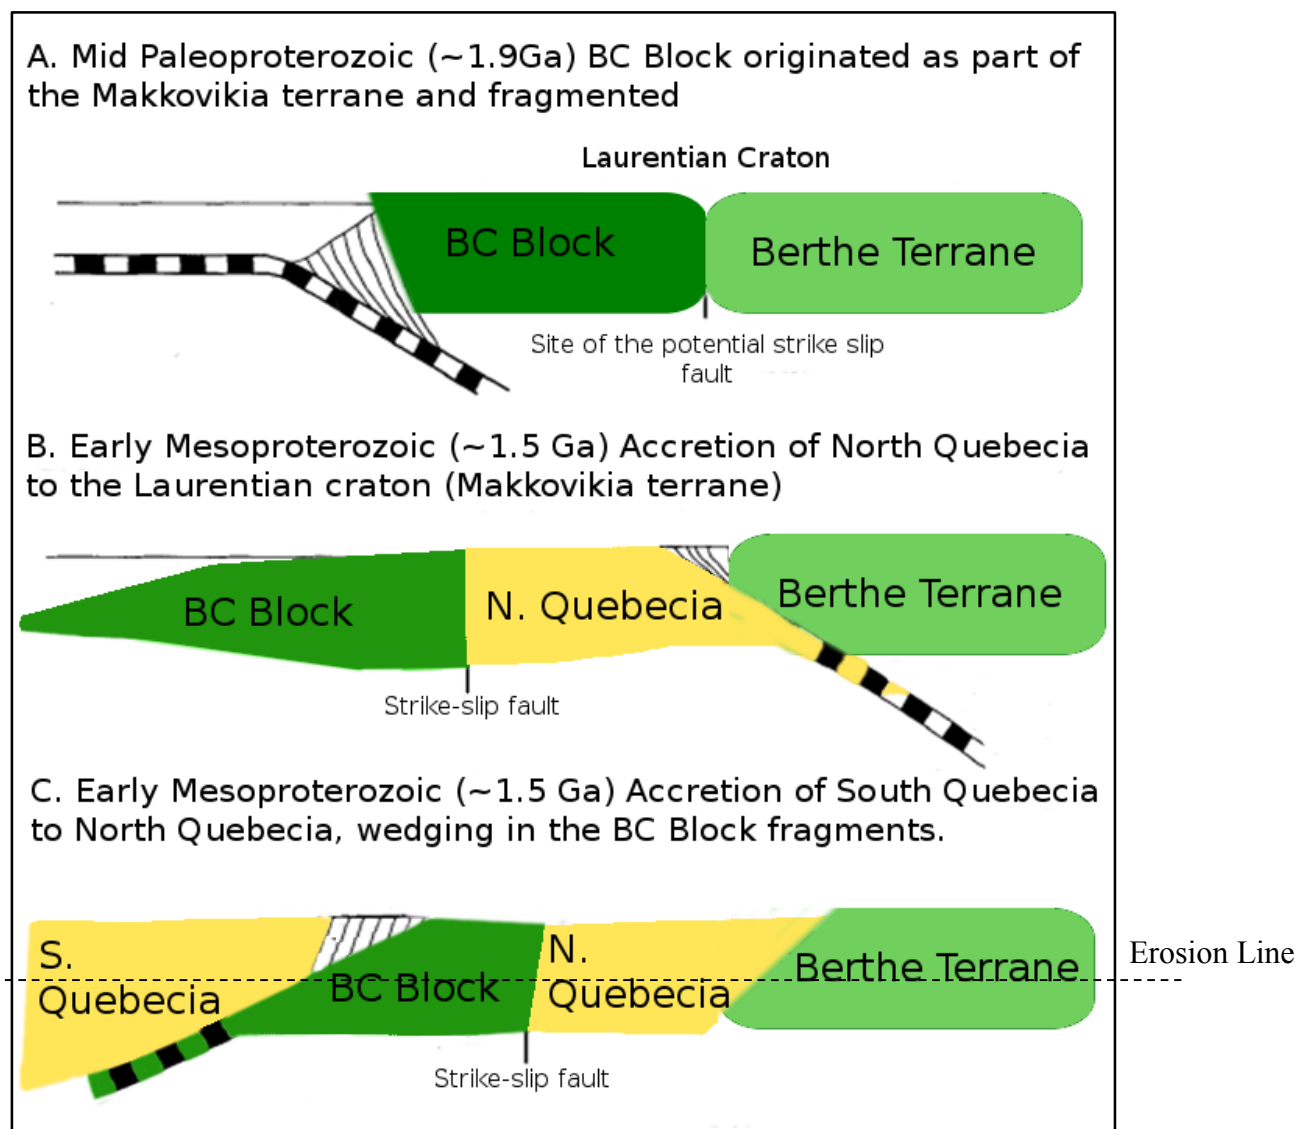

Figure 4.9: Proposed tectonic model for placement of the old block within the Quebecia Terrane (After Barber and Crow, 2003).

During the mid-Paleoproterozoic, the BC block was originally a piece of the Berthe Terrane to the north (Figure 4.9, A). Subduction under Laurentia began in the early Mesoproterozoic, bringing the Quebecia arc to accrete at the margin (Figure 4.9, B). Between these two periods, strike slip tectonics would have transported the BC block south from its origin similar to how the WSB was transported along the MSTZ to its current position outboard of Sibumasu. The BC block would have then reaccreted between a south and north portion of the Quebecia Terrane (Figure 4.9, C).

## Chapter 5: Conclusions

The current study aimed to further outline the boundary of the Paleoproterozoic block defined by Dickin and Higgins (1992) and later Hynes (2010) in the Baie Comeau region of Central Quebec, Canada. Figure 5.1 shows a summary of the final mapped BC block fragments (dark green) and their spatial relation to their proposed origins in the Berthe Terrane (light green). The complete dataset allows a re-examination of the questions raised by Condie (2013) regarding gaps in the ages of crustal material on the Laurentian margin.

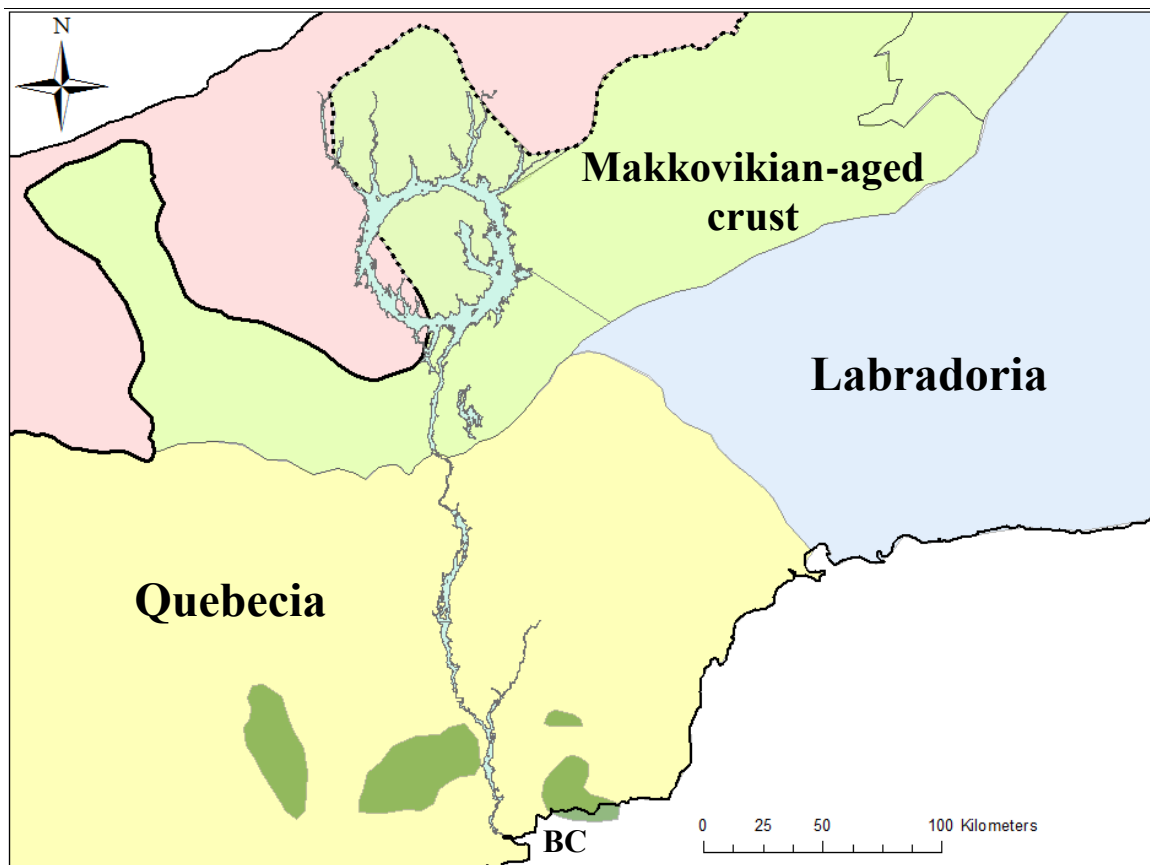

Figure 5.1: a map of the north eastern portion of the Grenville Province showing the old blocks (dark green), Quebecia (yellow), Makkovikian-age Berthe and Molson Lake Terranes (green), Labradoria (blue) and Archean (pink). BC: Baie Comeau.

Similar to Condie's zircon age histogram (Figure 1.5), Figure 5.2 presents a compilation of the data from the current study. The red bar (1.65-1.69 Ga) represents samples which are geographically located between areas of old and young crust, and therefore their intermediate ages are attributed to local mixing phenomena.

*Figure 5.2: A histogram summary of the model ages for this study. Red bar indicates the border samples as outlined in Table B-3.*

These locations are shown in Figure 5.3, which is an enlargement of the area around Baie Comeau to show the locations of the 1.65-1.69 Ga age samples relative to the older and younger crustal blocks. Based on their locations, these samples do not represent an actual crustal formation event and therefore indicate there is a real gap in crustal formation ages in the study area.

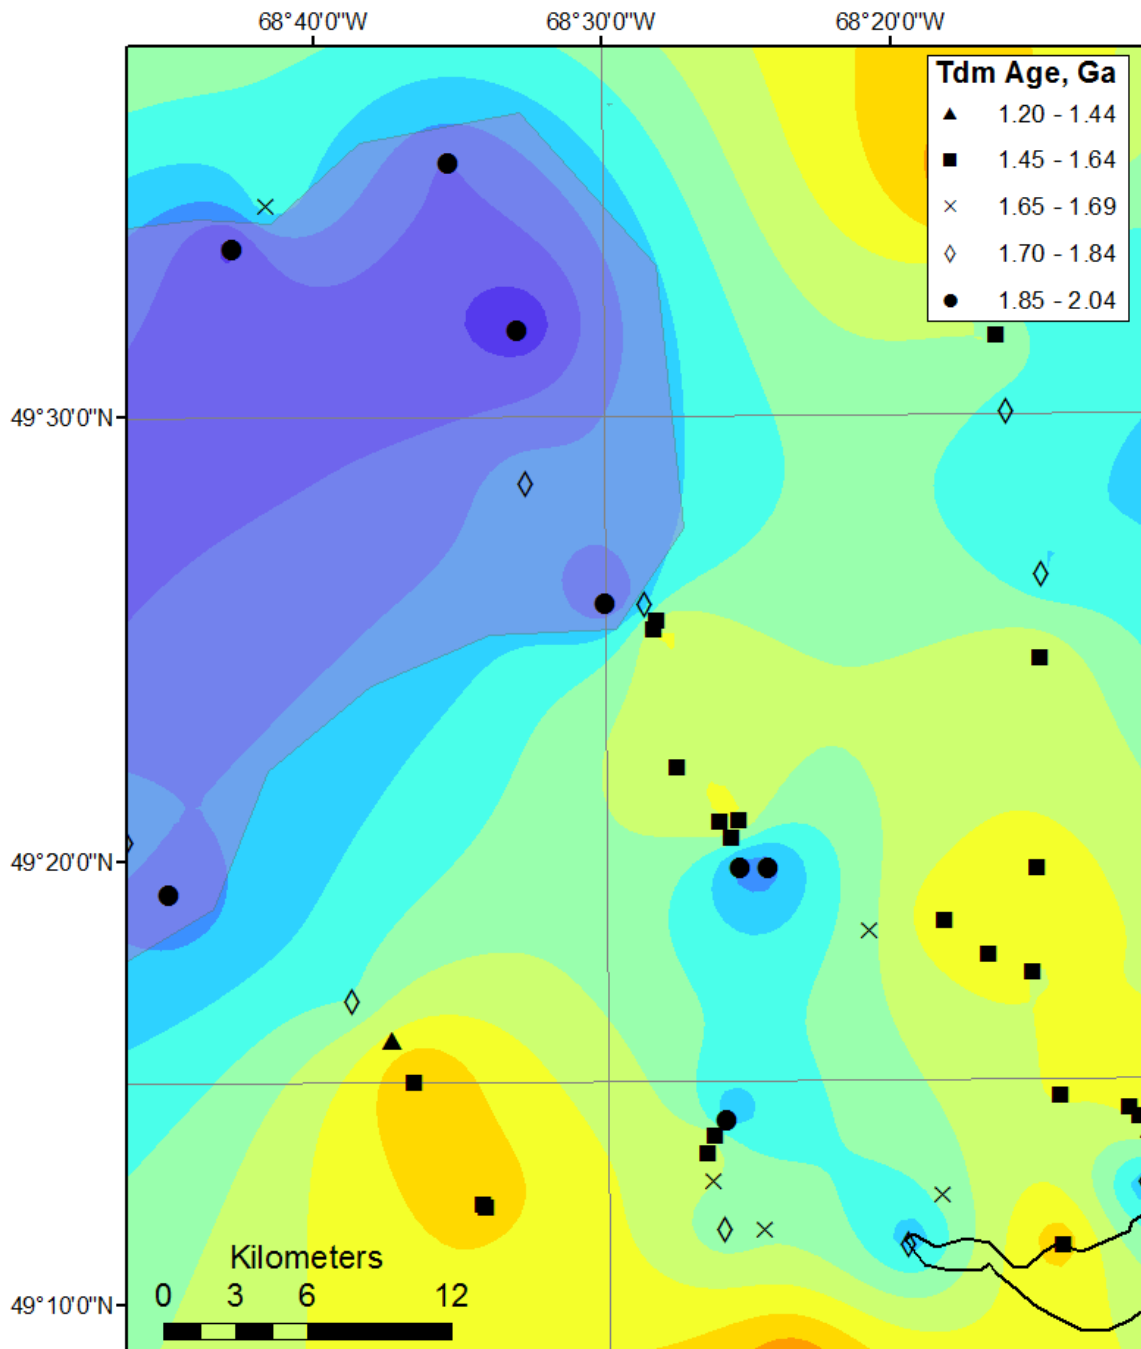

Figure 5.3: Enlargement of area around Baie Comeau, showing the boundary samples (X's) in relation to the surrounding blocks of old and young crust

The crustal formation age gap demonstrated in Figure 5.2 corresponds to Condie's gap in U-Pb zircon ages (Figure 1.5). This substantiates the case that there is a genuine gap in crustal formation between the Labradorian and Pinwarian events (the latter representing Quebecia).

Based on the modern analogue that was presented in Chapter 4, it is suggested that crustal evolution on the Laurentian margin during the Mesoproterozoic involved transport of crustal terranes along the continental margin during arc accretion processes. This suggests that the evolution of the margin did not involve major removal of crustal material, but simply rearrangement of existing terranes. Hence it is concluded that there is a genuine gap of crustal formation on the Laurentian margin between the Labradorian and Pinwarian events.

One of the issues raised by this argument is the question of the termination of the Labradorian terrane east of Manicouagan (Figure 5.1). It could be suggested that Labradorian-aged crust was removed by subduction, but Dickin (2000) argued that the original extent of Labradorian crust is marked by the extent of the Trans-Labrador Batholith (Figure 1.8). This late Labradorian igneous suite is associated with the accretion of the Labradorian terrane to Laurentia. The fact that it terminates just to the east of Manicouagan suggests that this was the original limit of the Labradorian terrane (Dickin, 2000).

In order to better understand the possible point of origin of the old crustal panels in the Baie Comeau area, it would be necessary to conduct more detailed mapping of the western continuation of the Berthe Terrane (Figure 5.1). This is an area with poor access

that has not been mapped in detail, but additional study of the boundary between Makkovikian/Labradorian and Pinwarian aged crust could clarify whether this is a suitable site for the detachment of the Baie Comeau old crustal fragments.

Since Quebecia is now divided into north and south terranes to accommodate an old panel, it should now be regarded as a Composite Arc Belt. A similar idea was proposed in Ontario for a Composite Arc Belt within the Central Metasedimentary Belt (Carr et al., 2000), but Dickin and McNutt (2007) argued that the proposed Composite Arc Belt of Ontario is actually a failed back arc rift zone. This conclusion was based on the geometry of the model age distribution, the presence of alkaline rocks and marbles, and the rift-like geochemistry of mafic volcanics and intrusions (Smith and Holm, 1990). In the present study none of the above criteria are met, and the Quebecia Composite Arc Belt consists of much larger accreted terranes with distinct ages and calc-alkaline signatures, making it a much more convincing candidate for a Composite Arc Belt.

## **Appendix A: Field and Laboratory Techniques**

### ***A1 – Introduction***

The analysis for the Sm-Nd method involves three broad steps of field collection and sample powdering, chemical processes on the samples, and mass spectrometry. Each step has an associated well-defined methodology as described below, and must be followed precisely in order to ensure repeatability and valid, comparable results.

### ***A2 Field Sample Collection***

Orthogneiss samples were collected at road cut outcrops within Central Quebec. Sample distribution was primarily controlled by presence and access of logging roads and availability of outcrop within the study areas. Sample selection was based on the availability of fresh, unweathered and relatively homogenous rocks, so that the crustal formation of that rock sample would be accurate representation of the unit as a whole. A 12 lb. sledge hammer and crow bar was used to extract the samples, as well as utilization of proper personal safety equipment. At each location a GPS reading was taken and sample location was recorded on the site map.

### ***A3 Pulverization***

To prepare samples for chemical dissolution, they first have to be crushed into a fine powder within the rock crush room on McMaster University campus. First, samples were scrubbed with a wire brush in order to remove any contamination such as moss and dirt, and then using a hydraulic splitter, the samples were split into smaller ~5cm<sup>3</sup> pieces.

These pieces were then processed through a jaw crusher, which first would be contaminated with some of the current sample in order to avoid dust contamination from previous samples. The jaw crusher would grind the sample into gravel sized  $\sim 1\text{cm}^3$  pieces. The gravel would then be divided in half using a table top random sorter, leaving behind enough to fill and run a disc mill, yielding a powdered sample.

#### ***A4 Chemical Dissolution***

Teflon coated plastic bombs were labelled with the sample name and treated to remove static to avoid mass inaccuracies. Each bomb, with lid, was then placed on an analytical scale and their weight recorded. 150mg of sample powder was added to each corresponding bomb with a clean spatula, reweighed and recorded.

In order to separate the Neodymium and Samarium from the sample, silicate and carbonate components must first be dissolved. This dissolution of the sample powder took place in the Spectrochemistry Clean Lab at McMaster University. The bombs were lined up in a fume hood where 10ml of Hydrofluoric Acid (HF) was added to each and the lids secured tightly. The bombs were then placed in protective plastic jackets and placed in a  $140^\circ\text{C}$  oven for 4 days. The bombs were then removed when cooled, and then placed on hot plates for evaporation. After the HF was evaporated, 5ml of concentrated nitric acid ( $\text{HNO}_3$ ) was loaded in each and the bombs were returned to the hotplates. After evaporation, 5ml of 6 molar Hydrochloric Acid (HCl) was added to each bomb and again placed in the oven overnight. WHIMIS protocol for handling hazardous chemicals was followed at all times.

The samples were then split so that both isotope ratio (IR) and isotope dilution (ID) analysis can be performed. Samples are first diluted with 10ml of de-ionized water and then bomb, sample, and lid, were placed on the analytical scale to be weighed and recorded. Each sample was then split into two beakers, one for IR and one for ID, where samples marked ID were then spiked with a  $^{150}\text{Nd}$ - $^{149}\text{Sm}$  enriched solution. This process was done by weighing the spike bottle, tarring the mass and adding approximately 150mg of spike to each sample. The spike bottle would then be reweighed and the amount of spike recorded. After completion, beakers were then placed on hotplates for evaporation.

### ***A5 Chromatography***

In order to concentrate the Neodymium and Samarium in each sample, column chemistry was conducted in two stages. The first stage uses the method of cation exchange chromatography, which separates major elements and isolates the rare earth elements (REE) based on their binding affinities to the resin within the columns. The second stage is Rare Earth Element Chromatography, which separates out Nd and Sm.

In preparation for the first stage cation columns, 0.4 M HCl was used to dissolve the samples to a total of 2ml within test tubes and then centrifuged. 1ml of each sample was loaded with a pipette into the cation columns, and then washed through with 20ml of 3 M  $\text{HNO}_3$ , which removes Na, Ca and other major elements. 10ml of 3 M  $\text{HNO}_3$  is then washed through to collect the REEs. After collection, the

samples were placed under heat lamps for evaporation and 1mL of 0.4 M HCl was added in order to load the samples into the next stage of columns.

Next 1ml of each sample was loaded using a pipette into the REE chromatography columns. The samples were washed through with 10ml of 0.4 M HCl, then 10ml of 0.4 M HCl to collect the Nd in all samples. Next, for just the ID samples, 2ml of 1 M HCl was washed through, and then 12ml of 1 M HCl was used to collect the Sm. The resulting samples were evaporated under heat lamps. One drop of 0.0003 M H<sub>3</sub>PO<sub>4</sub> was added to the residue once dry, and then evaporated again until near dryness.

### ***A6 Isotopic Analysis via Mass Spectrometry***

The samples were then prepared to be loaded into the VG isomass 345 mass spectrometer in the Isotope Geochronology lab at McMaster University. 0.4µL of 0.2 molar H<sub>3</sub>PO<sub>4</sub> was added to the dried samples and the solution was then loaded on the center of a double rhenium tantalum filament bead. A 2 amps current was then passed through the bead to dry the sample, and then the beads were loaded into the mass spectrometer for analysis.

A La Jolla standard was run with every barrel and produced a mean value of 0.511855. The resulting analyses for the duration of this study are shown in Table A-1. All spiked samples analyses with a run precision >0.02% were rejected or repeated, along with unspiked samples with a run precision of >0.01%.
