A narrow range endemic species is described from NW Italy as *Chondrina feneriensis* spec. nov. The new species is classified with other centre-East Alpine taxa on the basis of a molecular phylogenetic analysis. It is closely related to *C. generosensis* Nordsieck, 1962. The two taxa differ morphologically in some characters of the shell and the genital tract, and in mitochondrial DNA sequence data. These differences, and the absence of intermediate forms, support its taxonomic status as a separate species, rather than a subspecies of *C. generosensis*.

Chondrina feneriensis spec. nov. is restricted to a small area in the Fenera massif in Piedmont, at the boundary between the Vercelli and the Novara districts, where it inhabits dry limestone cliffs.

Key words: Chondrinidae, taxonomy, ecology, distribution, Piedmont, Italy.

INTRODUCTION

The genus *Chondrina* Reichenbach, 1828, includes molluscs that are obligatorily associated with calcareous rocks. The genus is distributed in the Turanic-European-Mediterranean region. There are three areas with high species diversity in the genus, viz. the Iberian Peninsula with Morocco, the Alps, and the Balkans. The genus consists of more than 40 currently known species and several subspecies, but the number is slightly variable according to the different authors (Nordsieck, 1962, 1970; Gittenberger, 1973; Kerney et al., 1983; Gittenberger, 1984; Falkner, 1990; Schileyko, 1998; Gittenberger, 2002; Kokshoorn & Gittenberger, 2010; Schütt, 2010; Welter-Schultes, 2012; Bank, 2013).

The taxonomy of the genus has historically been based on morphological characteristics of the shell, because the genital tract is rather simple and generally devoid of important diagnostic characteristics. Only recently, revisions in the taxonomy of the genus have

been made based on DNA analyses (Kokshoorn et al., 2010).

Many of the Alpine species with a limited distribution are represented at the Italian side of the Alps. *Chondrina bergomensis* (Kuster, 1850) is an endemic species of the Bergamo province, in the central Prealps of Lombardy (Nordsieck, 1962; Graack, 1985; Manganelli et al., 1995; Eikenboom, 1996; Kokshoorn & Gittenberger, 2010; Welter-Schultes, 2012). *Chondrina generosensis* Nordsieck, 1962, is limited to the NW Lombardy and the neighbouring areas of Ticino (Switzerland) (Nordsieck, 1962; Gittenberger, 1973; Groh, 1990; Manganelli et al., 1995; Wüthrich, 1996; Proschwitz & Johannesson, 1996; Turner et al., 1998; Kokshoorn & Gittenberger, 2010; Boschi, 2011; Welter-Schultes, 2012; Rüetschi, 2013). *Chondrina megacheilos* (De Cristofori & Jan, 1832) is a polytypic species living in Italy (Alps and Prealps of Lombardy, Trentino-Alto Adige and western Venetia), in areas bordering Switzerland and in the southern Alps, between France and Liguria. Its subspecies are *C. m. megacheilos*, occurring in Lombardy and Ticino, *C. m. avenoides* (Westerlund, 1874) and *C. m. toscolana* (Schröder, 1913), present in more or less restricted areas along the central Alps, *C. m. frassineiana* Nardi, 2009, an endemic species of the Prealps of the Brescia province, *C. m. caziotana* Pilsbry, 1918, known from the western Alps, in a small area between the Alpes Maritimes in France and western Liguria (Nordsieck, 1962; Gittenberger, 1973; Kerney et al., 1983; Maassen, 1987; Manganelli et al., 1995; Eikenboom, 1996; Falkner & Stummer 1996; Nardi, 2009; Manganelli et al., 1995; Turner et al., 1998; Gerber, 2002; Kokshoorn & Gittenberger, 2010; Kokshoorn et al. 2010; Boschi, 2011; Gargominy et al., 2013; Welter-Schultes, 2012; Bank, 2013). *Chondrina multidentata* (Strobel, 1851), another polytypic species with three subspecies, i.e. *C. m. gredleriana* (Clessin, 1887), *C. m. multidentata* (Strobel, 1851) and *C. m. schista* (Westerlund, 1887), is distributed in the central-eastern Alps and Prealps, roughly between Lombardy and Friuli (Nordsieck, 1962; Gittenberger, 1973; Maassen, 1987; Boato et al., 1989; Manganelli et al., 1995; Eikenboom, 1996; Nardi, 2009; Kokshoorn et al. 2010; Kokshoorn & Gittenberger, 2010; Welter-Schultes, 2012; Bank, 2013). *Chondrina arcadica* (Reinhardt, 1881), another polytypic species with a large distribution in SE Europe, is represented in the NE Alps (Italy, Switzerland, Austria and Slovenia) with *C. a. clienta* (Westerlund, 1883) (Nordsieck, 1962; Gittenberger, 1973; Manganelli et al., 1995; Eikenboom, 1996; Boato et al., 1989; Nardi, 2009; Welter-Schultes, 2012). *Chondrina burtscheri* Falkner & Stummer, 1996, was described from the northern Alps of Austria, and has also doubtfully been reported from an isolated locality in Trentino-Alto Adige (Gerber, 2002; Nardi, 2009;

Kokshoorn & Gittenberger, 2010). Two other taxa are restricted to the French Alps, viz. *C. falkneri* Gittenberger, 2002, living in the departments Drôme and Isère, and *C. gerhardi* Gittenberger, 2002, known for a single locality in the department Hautes-Alpes (Gittenberger, 1973; Falkner et al., 2002; Gittenberger, 2002).

Chondrina avenacea (Bruguière, 1792), the polytypic type-species of the genus, is widespread in Italy in the Alps, in peninsular Italy, Sicily and Sardinia, as well as in many other European countries, from Spain to Croatia. Next to the nominotypical subspecies, which has a large range in southern Europe, there are many other subspecies, which are distributed in the eastern Prealps and the northern Balkans: *C. a. istriana* Ehrmann, 1931, *C. a. latilabris* (Stossich, 1895), *C. a. lepta* (Westerlund, 1887), *C. a. lessinica* (Adami, 1885) and *C. a. veneta* Nordsieck, 1962 (Nordsieck, 1962, 1970; Gittenberger, 1973; Boato et al., 1985; Wolf & Rähle, 1987; Boato et al., 1989; Manganelli et al., 1995; Falkner & Stummer, 1996; Turner et al., 1998; Gavetti et al., 2008; Liberto et al., 2010; Welter-Schultes, 2012; Bank, 2013; Pall-Gergely, 2013).

Rarity and fragmentation of limestone areas in the NW Italian Alps are responsible for the scarce occurrence of the genus *Chondrina* in northern Piedmont and Valle d'Aosta. The only records concern *C. a. avenacea*, historically collected in some localities of the Aosta province (Stabile, 1864; Lessona, 1880; Boettger, 1883; Pegorari, 1883; Pollonera, 1885). More recently the subspecies has also been found in NE Piedmont (province of Verbano-Cusio-Ossola) at two localities, viz. the Val Formazza (Nordsieck, 1962) and the NW slope of Agaro Lake (unpublished personal data). It has also been recorded in Val Divedro, on the southern slope of the Swiss Alps (Turner et al., 1998; Boschi, 2011). During searches carried out in the period 1986-2014 on the limestone massif of M. Fenera in NE Piedmont (at the boundary between the provinces of Vercelli and Novara) some populations of *Chondrina* have been sampled. These samples represent a single taxon, which is morphologically and genetically different from all other known taxa. It is considered a new species, which is described in this paper.

MATERIAL AND METHODS

Specimens were collected by hand from limestone cliffs. Dry shells were prepared to study shell morphology. A part of the samples was fixed in 80% ethanol to study the genitalia. Few specimens were fixed in 95% ethanol for DNA analysis.

Bodies were isolated by crushing the shells and were dissected using very fine, pointed watchmaker's forceps under a light stereo microscope. The genitalia

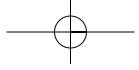

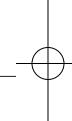

Fig. 1. Shells of *Chondrina feneriensis* spec. nov. (A-L) and *Chondrina generosensis* Nordsieck, 1962 (M-Q). **A**, holotype collected at Colma, M. Fenera (Valduggia, Vercelli), S. Cianfanelli, E. Talenti & M. Calcagno leg. 14/X/1990 (MZUFC GC/46039); **B-F**, paratypes (B-F) collected in the same locality, S. Cianfanelli, E. Talenti & M. Calcagno leg. 14/X/1990 (MZUFC GC/46040); **G-I**, paratypes collected near the Buco della Bondaccia, M. Fenera (Borgosesia, Vercelli), M. Bodon, F. Stoch & T. Pascutto leg. 13/VIII/1997 (MZUFC GC/46347); **J-L**, paratypes collected near the Grotte di Magiaiga, Ara, M. Fenera (Grignasco, Novara), M. Bodon leg. 20/V/1990 (MZUFC GC/46346); **M-Q**, shells collected at NE of the top of M. Generoso (San Fedele Intelvi, Como), G. Nardi, A. Braccia & R. Frassine leg. 13/VIII/2013 (MZUFC GC/45790).

were drawn using a camera lucida. All the parameters (shells height, shell diameter, aperture height and aperture diameter) were measured using a precision calliper, a millimetric lens, or a software installed on the light microscope. Radulae were obtained by dissecting out buccal bulbs. These were washed in distilled water, mounted on copper blocks, sputter-coated with gold and photographed using a

scanning electron microscope. Shells were photographed using a digital camera mounted on a light stereo microscope and processed with software for merging multiple focal planes.

For details on the acquisition of the molecular data, see Kokshoorn et al. (2010). Four individuals, representing each of the three sampling locations of *Chondrina* spec. nov., were used for DNA analysis.

Table 1. Shell parameters of five living populations and one shell deposit of *Chondrina feneriensis* spec. nov. from M. Fenera (Piedmont) and four living populations of *Chondrina generosensis* Nordsieck, 1962, from Lombardy. Acronyms: H = shell height, D = shell diameter, h = mouth height, d = mouth diameter (aperture minor diameter), N = number of shells. Mean ± standard deviation; min and max value in parenthesis.

Some presumably (based on morphological and biogeographical data) closely related taxa were included in the DNA analyses for comparison (see Table 3). *Chondrina avenacea* (Bruguière, 1792) was selected as an outgroup. A section of the mitochondrial Cytochrome Oxidase subunit I gene was sequenced (forward and reverse sequence) for each individual. The obtained DNA sequences were edited manually and aligned using ClustalW (Thompson et al., 1994). Neighbour-Joining analysis was performed using uncorrected pairwise distances. Branch support analyses

were performed using a bootstrap algorithm under both maximum likelihood (100 replicates) and parsimony (1,000 replicates) optimality criterion (Paup v4.0a146; Swofford, 2002). The maximum likelihood analysis was performed under the General Time Reversible model including a gamma distribution (shape 1.1818) and the proportion of invariable sites (0.5694). The resulting phenetic tree, including branch support, is shown in Figure 6.

The material examined is preserved in the following collections: Museo di Storia Naturale dell'Uni-

Table 3. List of the samples subjected to DNA analyses.

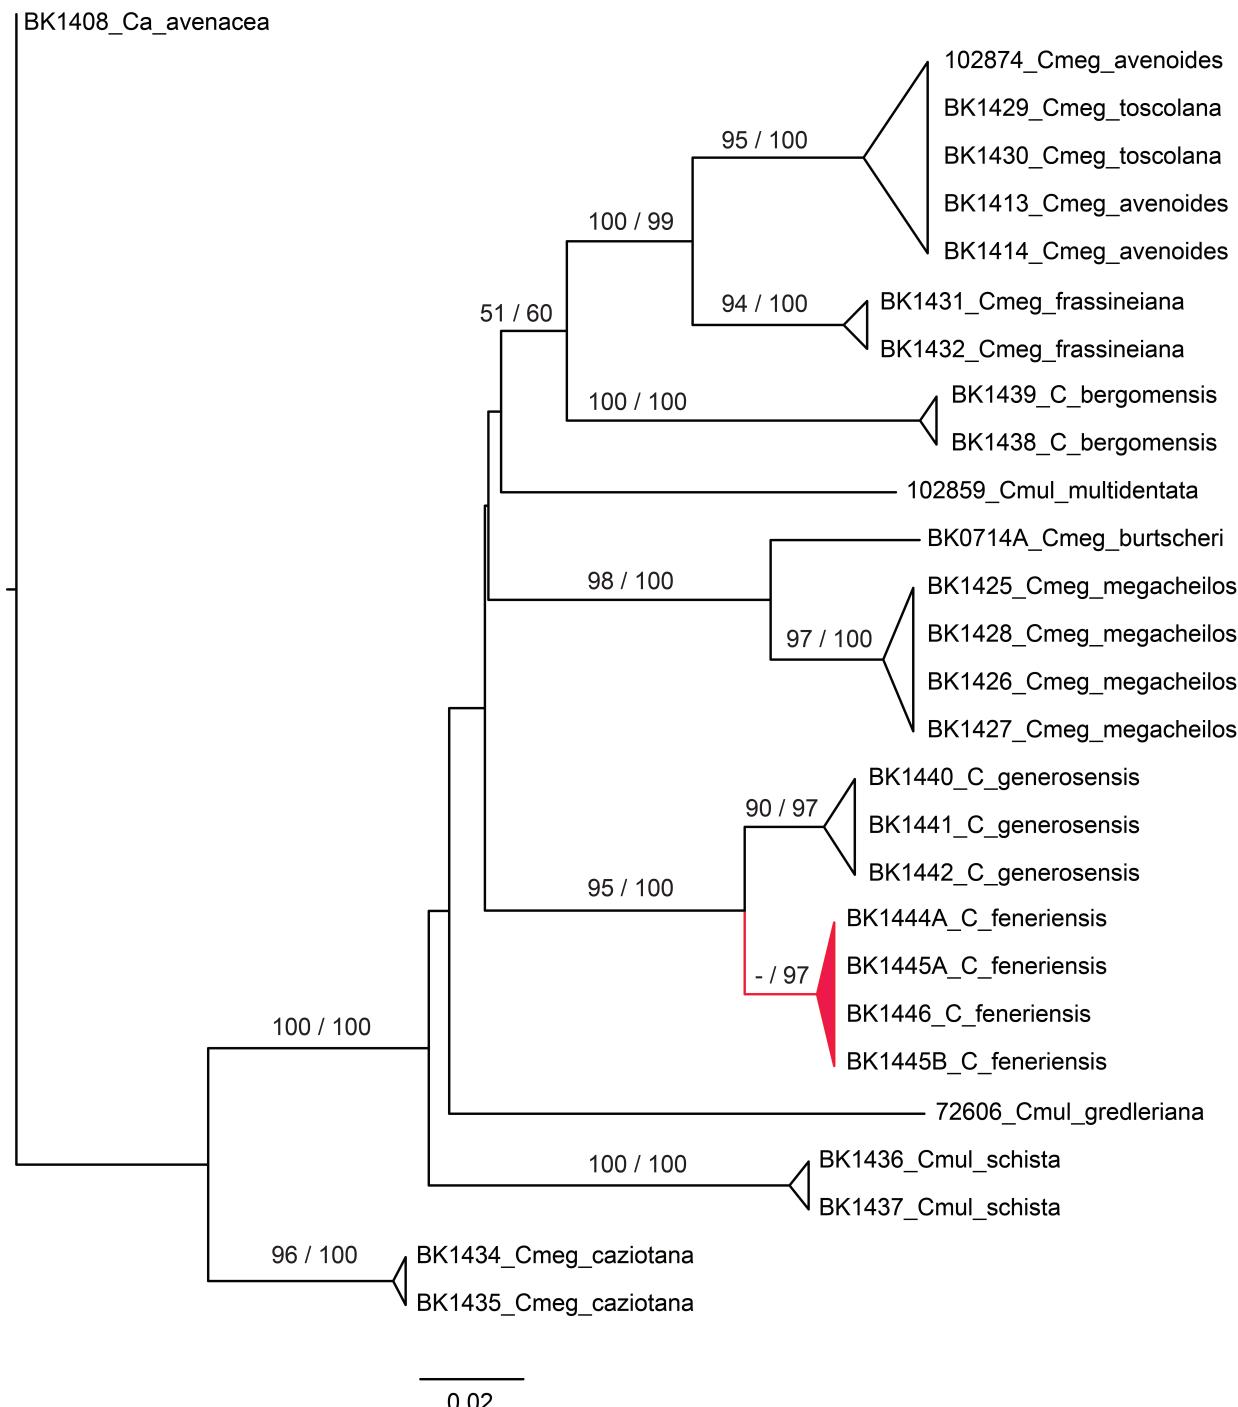

Fig. 6. Neighbour-Joining cladogram based on uncorrected pairwise distances between the DNA sequences. The clade containing the DNA sequences of *C. feneriensis* spec. nov. is highlighted in red. Branch lengths indicate uncorrected pairwise distances between taxa. Branch support > 50 % is provided for maximum likelihood and parsimony criterion respectively.

cal to conical with an acute apex, consisting of 6½ - 7½ slightly convex whorls, regularly increasing in size. Last whorl measuring about half the shell height; sutures deep. Protoconch inflated, granular. Surface finely covered by oblique, prominent, and regular longitudinal ribs. Aperture suboval, prosocline, basally rounded; peristome interrupted, thin, whitish, slightly thickened by a reflected white callus, mostly in the

columellar area. Aperture with 4-5 lamellae and 2-3 plicae. Lamellae: well developed angularis, sometimes a very small and deep spiralis, parietalis of the same size as the columellaris, small or very small infracolumellaris; two equally long, rather short palatal plicae, situated centrally, not reaching the peristome, sometimes an obsolete or tubercle-like infrapalatal plica. Umbilicus narrowly open, slit-like.

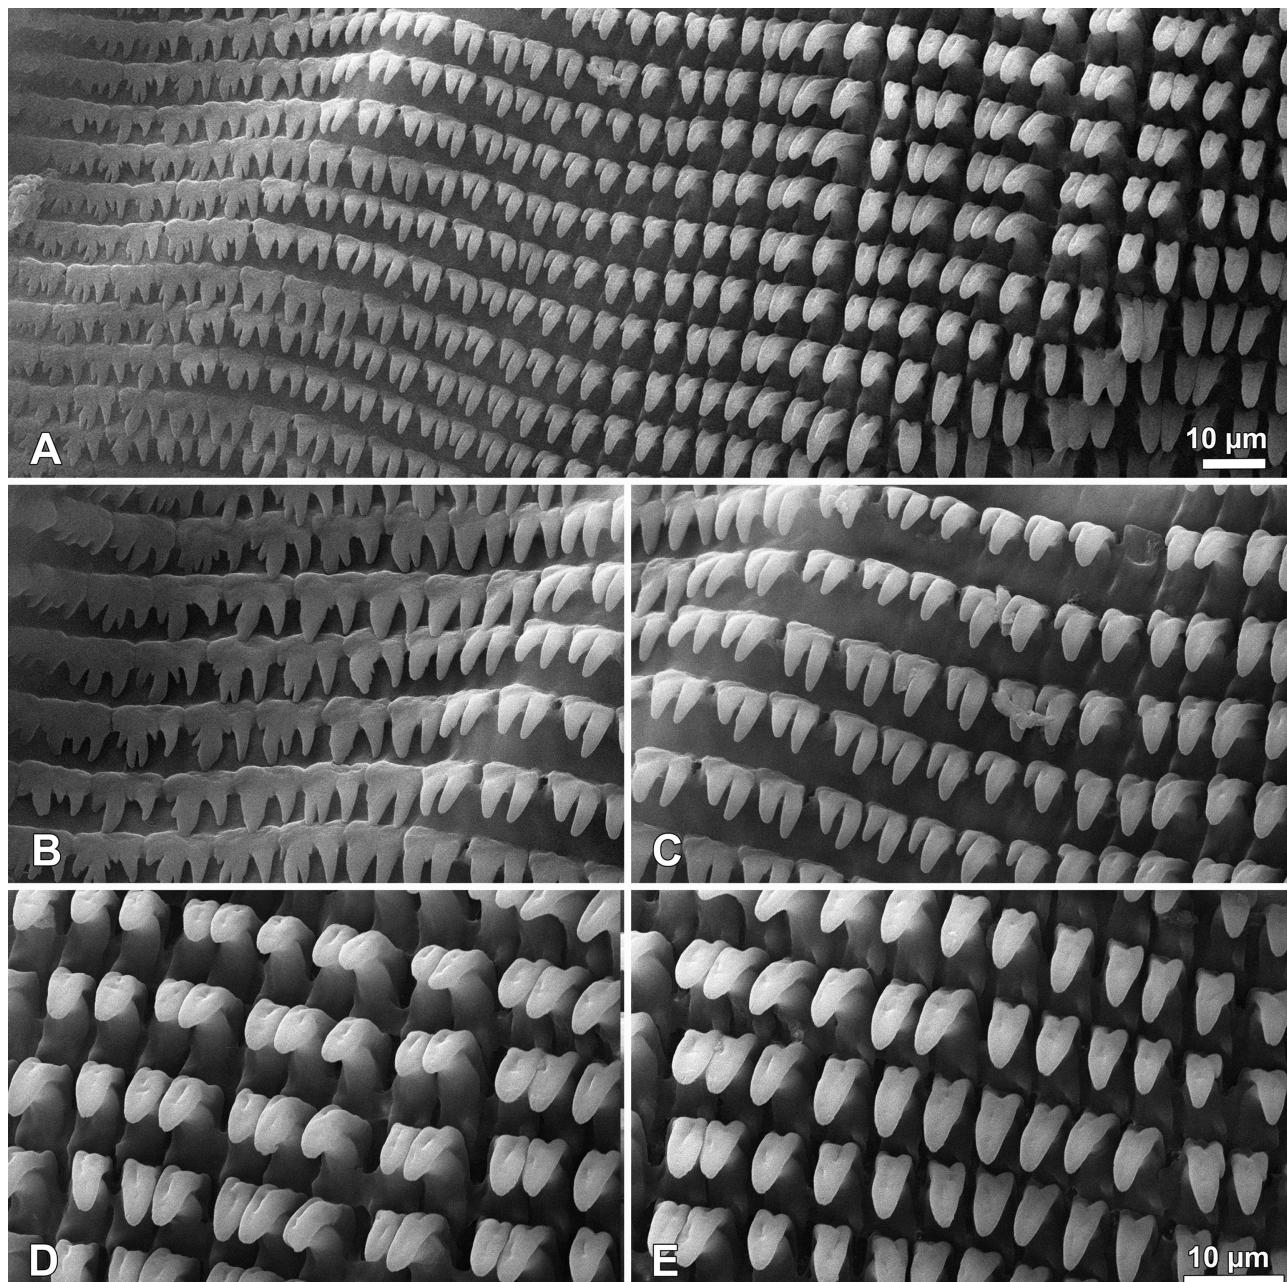

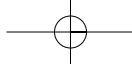

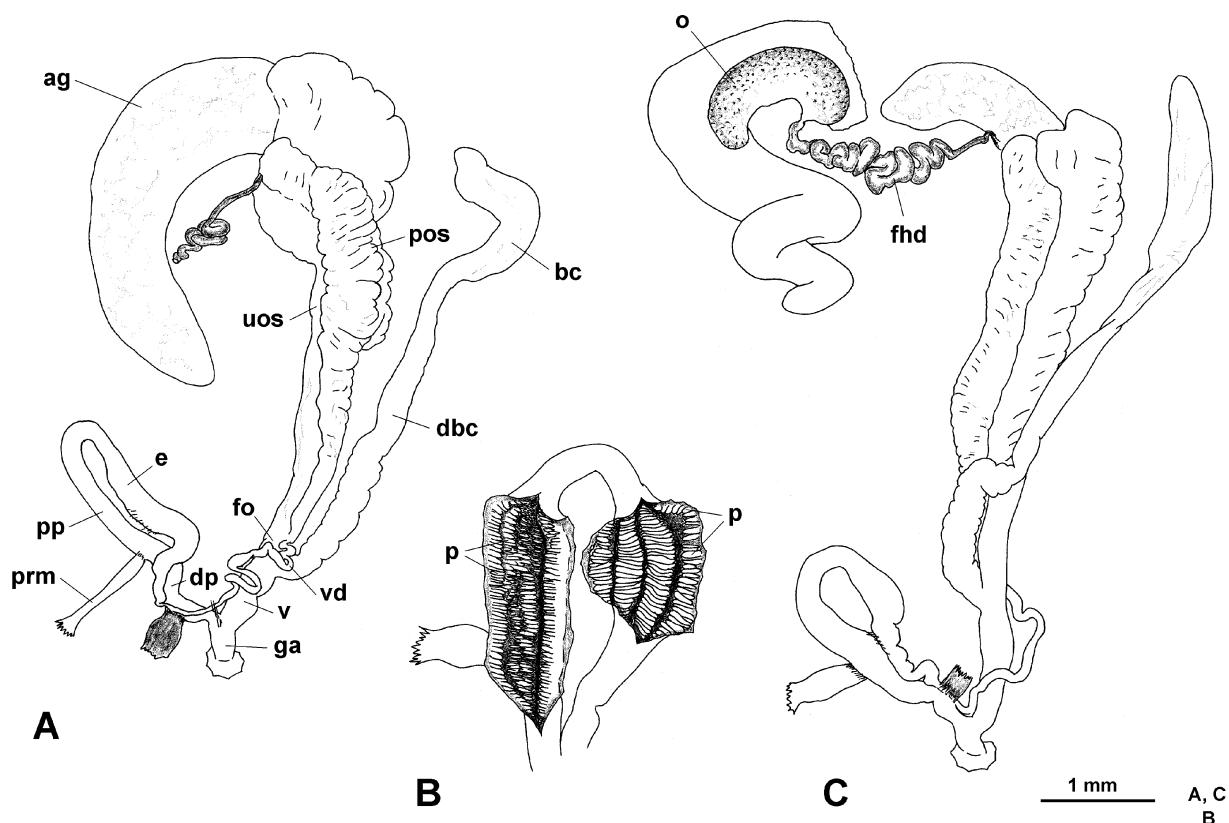

Fig. 7. Radula of *Chondrina generosensis* Nordsieck, 1962. Half portion of radula (A); magnification of marginal teeth (B); magnification of marginal and lateral teeth (C); magnification of lateral and central teeth (D); magnification of central and lateral teeth. Specimen collected at NE of the top of M. Generoso (San Fedele Intelvi, Como), G. Nardi, A. Braccia & R. Frassine leg. 13/VIII/2013 (MZUFC GC/45790 stub SEM MB/91).

Dimensions (Table 1). – Shell height 4.60 - 6.43 mm; diameter 1.98 - 2.53 mm; aperture height 1.44 - 2.28 mm; aperture diameter 1.19 - 1.83 mm.

Body. – Grey; tentacles and sole lightest.

Genitalia (6 specimens examined; Fig. 3). – Small ovotestis and convoluted hermaphrodite duct blackish; albumen gland variable in size; long ovispermiduct, continued in a short free oviduct and, beyond the duct of the bursa copulatrix, in a rather short and thin vagina, ending in a small genital atrium. Duct of the bursa copulatrix very long, without diverticulum;

bursa copulatrix long to very long, cylindrical or banana-like, rounded at the apex and reaching albumen gland. Thin and sinuous vas deferens, ending at the tip of the ephiphallus, where it is followed by a short, rounded, rudimentary but clear flagellum and by a cylindrical penis, which is longer than the ephiphallus. A short penial retractor muscle is inserted between the proximal and the distal part of the penis; proximal penis slightly shorter than distal one; small branch of right ommatophore retractor muscle inserting at the distal penis and vas deferens wall, near

76

Fig. 8. Genitalia of *Chondrina generosensis* Nordsieck, 1962. Whole genitalia (gonad excluded, A); inner structure of the proximal penis (B, left), and of the epiphallus (B, right); whole genitalia (C). Specimens collected at NE of the top of M. Generoso (San Fedele Intelvi, Como), G. Nardi, A. Braccia & R. Frassine leg. 13/VIII/2013 (MZUFC GC/45790). Acronyms in section Material and Methods.

genital atrium. Epiphallus and penis walls with internal longitudinal rows of papillae: 3 rows of papillae in the epiphallus, 2 elliptical and 1 subtriangular, and a series of secondary, very small papillae between the elliptical ones; 4-6 rows of elliptical or more irregular papillae in the proximal penis.

Radula (4 examined; Fig. 4). – With 90-100 parallel rows of teeth, each of which with c. 63-65 teeth. The central, unicuspид tooth has a prominent mesocone. It is flanked by 14-16 unicuspид lateral teeth at both sides. The following 3-4 bicuspid lateral teeth have a strong mesocone and a small ectocone. The 10-16 marginal teeth gradually change in the number and shapes of the cusps; the initial 4-6 marginal teeth have a mesocone and an equally large ectocone, whereas the following 6-10 marginal teeth change from tri- to irregularly multi-cuspid.

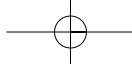

Etymology. – The name of the species refers to the Fenera mountain of the type locality, which encloses the entire currently known distributional range of the species.

Habitat. – Small populations inhabit the rocks, consisting of dolomite or dolomitic limestone, in rather

open environments.

Status and distribution. – The M. Fenera limestone massif (Piedmont, NW Italy) is located in the lower Valsesia, on the right slope of the Sesia valley, at the beginning of the alluvial soils of the Po River Basin. The distribution area of *C. feneriensis* spec. nov. is entirely within the protected SIC Monte Fenera (IT1120003) and Monte Fenera natural park. Because M. Fenera is situated in a preserved area, its protection should be guaranteed. However, excessive collection could represent a serious risk for this endemic species because of its very limited and disjunct distribution area (extended to a few square kilometres). It should be considered an endemic taxon with only five known stations, in one of which seems to be already extinct. Therefore it should urgently be included in the list of endangered species, the IUCN red list, and in the regional lists of protected species likely to be “vulnerable” according to the criteria of IUCN (IUCN, 2001).

Associated fauna. – No other chondrinids or molluscs typical of calcareous substrate in dry environments coexist in the same habitat. In most humid

environments at the base of cliffs, inside the rocky slits or the entrance of karst caves, other species are present, like *Charpentieria dyodon thomasiana* (Küster, 1850), *Helicodonta obvoluta* (Müller, 1774) and *Chilostoma padanum* (Stabile, 1864) (Pascutto, 1998; personal unpublished data). Other endemic species are already known from M. Fenera (Sindaco et al., 2008), but no other terrestrial snails or slugs. From a taxonomical point of view, *C. feneriensis* spec. nov. is closely related to *C. generosensis*, the distribution area of which is located further east, in the Prealps of Lugano (Fig. 5). No molluscs have their western distributional boundary in M. Fenera, but some species have their eastern boundary here (*Ariunculus speziae* Lessona, 1881), their south-eastern (*Retinella giustii* Riedel, 1998), or north-eastern limit (*Chilostoma padanum* (Stabile, 1864)) (Pascutto, 1998; Sindaco et al., 2008; personal unpublished data).

Differentiation. – Among the *Chondrina* species of the Southern Alps, *C. generosensis* is most similar to *C. feneriensis* spec. nov. in shell morphology. It is also geographically closest, known from a restricted area between Lombardy (Italy) and Ticino (Switzerland) (Fig. 5; Nordsieck, 1962; Groh, 1990; Turner et al., 1998; Boschi, 2011). Both species have a yellowish, small shell. *Chondrina feneriensis* spec. nov. is usually smaller (mean values in five populations 5.2- 6.0 mm in height and 2.2-2.4 mm in diameter, compared with 6.3 mm in height and 2.4-2.6 mm in diameter in two populations of *C. generosensis*, Tab. 1). It differs also from *C. generosensis* (Fig. 2E) by a more prominently striated shell surface, a more slender spire with a more clearly tapering apex, the spiral lamella missing or extremely reduced (small but always present in *C. generosensis*), and by the constant presence of two short palatal plicae, inside the aperture which do not reach the peristome edge. Sometimes, a third rudimentary plica (infrapalatal) is observed in *C. feneriensis* spec. nov. In *C. generosensis* the superior plica reaches the peristome edge and the inferior and the infrapalatal plicae are shorter but always well developed (Fig. 1 M-Q). These differences are also clear in the fossil shells of *C. feneriensis* spec. nov. The shells date from the Upper Pleistocene to Holocene (Fedele, 1966, 1971, 1972, 1973, 1976, 1988). They do not differ in shell morphology from the extant populations.

Chondrina feneriensis spec. nov. always has a little flagellum, between the ephiphallus and the proximal penis (Fig. 3). This flagellum has not been observed in *C. generosensis*. Specimens that are intermediate between *C. feneriensis* and *C. generosensis*, indicative of a subspecies status, are not known.

Chondrina feneriensis spec. nov. can easily be distinguished from all other closely related taxa living in the Alps, by the morphological characters. It differs

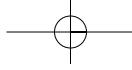

from the geographically also rather close *C. megacheilos* by its thinner, more prominently sculptured shell with a less conspicuously thickened and reflected lip and the plicae and lamellae in the aperture, that recall Bauplan I (Kokshoorn & Gittenberger, 2010), especially by a slimmer angular lamella, a very reduced or missing spiral lamella (spiral lamella elevated or evident in *C. megacheilos*, except in *C. m. avenoides*) and the lower number of palatal plicae (4-6 palatal plicae in *C. m. megacheilos*, only 3-4 in *C. m. avenoides*) (Manganelli et al., 1995; Falkner & Stummer, 1996; Nardi, 2009).

Compared to *C. burtscheri* Falkner & Stummer, 1996, a species that is closely related to *C. megacheilos*, the new species has a more prominent sculpture (dense, irregular, almost imperceptible in *C. burtscheri*), and another apertural armature (always 5 palatal plicae in *C. burtscheri*; Gerber, 2002; Kokshoorn & Gittenberger, 2010).

The differences between *C. feneriensis* spec. nov. and *C. multidentata* are clear: the former has a less slender shell, with more clearly striate surface, the aperture is not laterally compressed, the palatal plicae are not sinuous and not extending deep into the aperture and there are no tubercles on the peristomal margin. The conchological differences between *C. feneriensis* spec. nov. and *C. bergomensis* (Küster, 1850) are less obvious, because both species have a shell yellowish in colour and striated surfaces. However, in *C. feneriensis* spec. nov. the surface of the shell is finely rib-striate, whereas in *C. bergomensis* the ribs are slightly more prominent; a spiral lamella is lacking or obsolete versus always present in *C. bergomensis*, which can also be distinguished by the presence of three longer palatal plicae that are always present (Nordsieck, 1962; Eikenboom, 1996).

The last species belonging to the clade which includes the taxa mentioned above, i.e. *C. latilabris*, has a very different shell because of its reflected and thickened peristome and the plicae/lamellae inside the aperture that remind of *C. megacheilos* (see Nordsieck, 1962).

Among the other Alpine species, that are phylogenetically more distant according to molecular genetic investigations (Kokshoorn & Gittenberger, 2010), *C. avenacea* (Bruguière, 1792) is present, with the nominotypical subspecies, in a wide area of the Piedmont, but west of *C. feneriensis* spec. nov. (Fig. 5), and in many other areas of central and southern Europe (Gittenberger, 1973; Falkner, 1990; Kerney et al., 1983; Welter-Schultes, 2012; Bank, 2013), whereas the two subspecies *C. avenacea leptula* (Westerlund, 1887) and *C. avenacea istriana* Ehrmann, 1931, have an Alpine-eastern distribution (Nordsieck, 1962, 1970; Gittenberger, 1973; De Mattia & Prodan, 2010). By the presence of

two palatal plicae, a short superior palatal plica, not reaching the peristome, and the more prominent sculpture *C. feneriensis* spec. nov. can always be distinguished from these eastern taxa.

The Alpine populations of *Chondrina arcadica* (Reinhardt, 1881), belonging to the subspecies *Chondrina arcadica clienta* (Westerlund, 1883) (Nordsieck, 1962, 1970), differ from *C. feneriensis* spec. nov. by a more prominent sculpture and by the absence of the suprapalatalis. The poorly known species of the western French Alps, i.e. *C. falkneri* Gittenberger, 2002, and *C. gerhardi* Gittenberger, 2002, differ by the lack of clear palatal plicae. The same character allows to distinguish *C. feneriensis* spec. nov. from another Italian endemic taxon, i.e. *Chondrina oligodonta* (Del Prete, 1879), which is devoid of any palatal plicae too, and has a more southern distribution in Tuscany, in the Apuan Alps (Lanza, 1997; Manganelli et al., 2000; Welter-Schultes, 2012; Pall-Gergely, 2013).

The combination of characters of the shell, such as the presence of only two columellar lamellae and two short palatal plicae not reaching the peristome, allows to distinguish *C. feneriensis* spec. nov. from many other taxa from Europe and Morocco, with a few exceptions. These are however distinguishable by other characters (Nordsieck, 1970; Gittenberger, 1973; Kerney et al., 1983; Kokshoorn & Gittenberger, 2010; Welter-Schultes, 2012). Moreover, these other taxa are unrelated as shown by DNA analysis (Kokshoorn & Gittenberger, 2010; Kokshoorn et al., 2010).

DNA analyses. – The Neighbour-Joining analysis (Fig. 6) places *C. feneriensis* as a monophyletic sister group to *C. generosensis*. This placement is strongly supported by the parsimony and maximum likelihood phylogenetic analyses. Uncorrected pairwise distances within *C. feneriensis* range from 0.00146 to 0.00742 (average 0.00464). Between *C. feneriensis* and *C. generosensis* these values range from 0.02928 to 0.04100 (average 0.03648).

Given that the two closely related taxa form monophyletic clades, and that the genetic distance between *C. feneriensis* and *C. generosensis* is approximately an order of magnitude higher than the intraspecific genetic distance within *C. feneriensis*, we feel that the DNA analyses strongly support the differentiation between these taxa as valid species under the biological species concept.

DISCUSSION AND CONCLUSIONS

The taxa belonging to the genus *Chondrina* have always been distinguished on the basis of different combinations of the shell characteristics like dimensions, colouration, sculpture and, especially, apertural teeth (columellar and parietal lamellae, palatal plicae). De-

spite the fact that this last character is sometimes variable, also within the same taxon, it may provide a good basis to recognize interspecific diversity. Instead, the genital tract of *Chondrina* is rather simple and usually without diagnostic characters. The ratio between the length of penis and epiphallus is a rather variable character, therefore it cannot be used as a potentially diagnostic character.

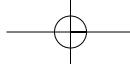

A correct reconstruction of the phylogenetic relationships within the genus *Chondrina*, cannot be based on single characters such as the shell and genitalia; the attempts, mainly based on the number of palatal plicae and on the presence/absence of the spiral lamella (Nordsieck, 1962; Gittenberger, 1973), were not realistic. Only thanks to genetic investigations (DNA analysis) it has been possible to have a reliable phylogenetic reconstruction, although a still preliminary one (Kokshoorn & Gittenberger, 2010).

ACKNOWLEDGEMENTS

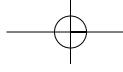

We wish to thank Stefano Birindelli (Turin, Italy), Emanuele Bodon (Genoa, Italy), Gabriella Vezzani (Genoa, Italy), Enrico Pezzoli (Bedulita, Bergamo, Italy), Fabio Stoch (Trevigliano Romano, Roma, Italy), Tiziano Pascutto (Biella, Italy), Micaela Calcagno (Florence, Italy) and Enrico Talenti (Florence, Italy), for their help during the researches; Francesco Fedele (Turin, Italy) for allowing the study of the fossil material collected during archaeological excavations in the caves of M. Fenera and for data on excavations, and Maurizio Ulivi (Centro Interdipartimentale di Servizi di Microscopia Elettronica e Microanalisi (MEMA) dell'Università di Firenze, Italy), for technical assistance. We are grateful also to Prof. Dr. Edmund Gittenberger and an anonymous reviewer for the critical revision of the manuscript.
