Canadian Technical Report of Fisheries and Aquatic Sciences

Technical reports contain scientific and technical information that contributes to existing knowledge but which is not normally appropriate for primary literature. Technical reports are directed primarily toward a worldwide audience and have an international distribution. No restriction is placed on subject matter and the series reflects the broad interests and policies of the Department of Fisheries and Oceans, namely, fisheries and aquatic sciences.

Technical reports may be cited as full publications. The correct citation appears above the abstract of each report. Each report is abstracted in *Aquatic Sciences and Fisheries Abstracts* and indexed in the Department's annual index to scientific and technical publications.

Numbers 1-456 in this series were issued as Technical Reports of the Fisheries Research Board of Canada. Numbers 457-714 were issued as Department of the Environment, Fisheries and Marine Service, Research and Development Directorate Technical Reports. Numbers 715-924 were issued as Department of Fisheries and the Environment, Fisheries and Marine Service Technical Reports. The current series name was changed with report number 925.

Technical reports are produced regionally but are numbered nationally. Requests for individual reports will be filled by the issuing establishment listed on the front cover and title page. Out-of-stock reports will be supplied for a fee by commercial agents.

Rapport technique canadien des sciences halieutiques et aquatiques

Les rapports techniques contiennent des renseignements scientifiques et techniques qui constituent une contribution aux connaissances actuelles, mais qui ne sont pas normalement appropriés pour la publication dans un journal scientifique. Les rapports techniques sont destinés essentiellement à un public international et ils sont distribués à cet échelon. Il n'y a aucune restriction quant au sujet; de fait, la série reflète la vaste gamme des intérêts et des politiques du ministère des Pêches et des Océans, c'est-à-dire les sciences halieutiques et aquatiques.

Les rapports techniques peuvent être cités comme des publications complètes. Le titre exact paraît au-dessus du résumé de chaque rapport. Les rapports techniques sont résumés dans la revue *Résumés des sciences aquatiques et halieutiques*, et ils sont classés dans l'index annuel des publications scientifiques et techniques du Ministère.

Les numéros 1 à 456 de cette série ont été publiés à titre de rapports techniques de l'Office des recherches sur les pêcheries du Canada. Les numéros 457 à 714 sont parus à titre de rapports techniques de la Direction générale de la recherche et du développement, Service des pêches et de la mer, ministère de l'Environnement. Les numéros 715 à 924 ont été publiés à titre de rapports techniques du Service des pêches et de la mer, ministère des Pêches et de l'Environnement. Le nom actuel de la série a été établi lors de la parution du numéro 925.

Les rapports techniques sont produits à l'échelon régional, mais numérotés à l'échelon national. Les demandes de rapports seront satisfaites par l'établissement auteur dont le nom figure sur la couverture et la page du titre. Les rapports épuisés seront fournis contre rétribution par des agents commerciaux.

ABSTRACT

Bravender, B.A., C.D. Levings and T.J. Brown. 1993. A comparison of meiofauna available as fish food on Sturgeon and Roberts Banks, Fraser River estuary, British Columbia. Can. Tech. Rep. Fish. Aquat. Sci. 1904: 40 p.

During 1980-81 the communities of fish present at three different sites on the Fraser River estuary were sampled each month using a beach seine. In conjunction with this work, in order to assess the food available to the fish community in each area, the meiofauna and epifauna were also sampled with core samplers and an epibenthic sled.

Analysis of the core samples showed the mean densities of total meiofauna to be the greatest at Iona Island ($1,937 \pm 170 \text{ } 10 \text{ cm}^{-2}$) followed by Roberts Bank ($1,036 \pm 118 \text{ } 10 \text{ cm}^{-2}$) and Steveston ($335 \pm 41 \text{ } 10 \text{ cm}^{-2}$). Nematodes formed the highest percentage of the population at all three sites - Iona Island (19.5-78.0%), Steveston (5.4-73.3%) and Roberts Bank (11.4-94.6%).

The results of the sled sampling indicated the total mean epifaunal densities were highest at Roberts Bank ($51,656 \pm 10,310 \text{ m}^{-2}$) second greatest at Steveston ($16,622 \pm 6,325 \text{ m}^{-2}$) and lowest at Iona Island ($13,324 \pm 2,520 \text{ m}^{-2}$). Numerically, copepod nauplii comprised the most of the population at Iona Island (4.9-80.7%) and Steveston (3.0-94.6%) while the harpacticoid copepods were dominant at Roberts Bank (9.6-84.3%). Based on the potential food available, Roberts Bank was the most suitable area for the rearing of juvenile salmonids.

RÉSUMÉ

Bravender, B.A., C.D. Levings and T.J. Brown. 1993. A comparison of meiofauna available as fish food on Sturgeon and Roberts Banks, Fraser River estuary, British Columbia. Can. Tech. Rep. Fish. Aquat. Sci. 1904: 40 p.

Au cours de 1980 et 1981, les communautés de poissons présentes à trois endroits différents de l'estuaire du fleuve Fraser ont été échantillonnées chaque mois à l'aide d'une senne de rivage. Conjointement à ces travaux, afin d'évaluer le nourriture disponible pour les communautés de poissons de chaque

secteur, on a également échantillonné la meiofaune et l'épifaune à l'aide de carottiers et d'un traineau épibenthique.

L'analyse des carottes a indiqué que les densités meiofauniques moyennes totales étaient les plus fortes à Iona Island ($1,937 \pm 170$ 10 cm^{-2}), puis à Roberts Bank ($1,036 \pm 118$ 10 cm^{-2}) et à Steveston (335 ± 41 10 cm^{-2}). Les nématodes ont le pourcentage le plus élevé de population d'organismes aux trois emplacements: Iona Island (19.5-78.0%), Steveston (5.4-73.3%) et Roberts Bank (11.4-94.6%).

Les résultats de l'échantillonnage effectué à l'aide du traineau indiquaient que les densités epifauniques moyennes totales étaient les plus fortes à Roberts Bank ($51,656 \pm 10,310$ m^{-2}), puis à Steveston ($16,622 \pm 6,325$ m^{-2}), et les plus faibles à Iona Island ($1,324 \pm 2,520$ m^{-2}). Numériquement, ce sont les copépodes Nauplii qui étaient les plus importants à Iona Island (4.9-80.7%) et à Steveston (3.0-94.6%), alors que ce sont les copépodes harpacticoides qui dominaient à Roberts Bank (9.6-84.3%). En se basant sur la quantité de nourriture potentielle disponible, on peut conclure que Roberts Bank est l'endroit le plus adapté à l'élevage de saumon juvénile.

INTRODUCTION

For some time, the estuary of the Fraser River has been under pressure from industrial development along its shoreline and the increasing population in the region. In spite of this fact, studies conducted in the estuary in the late 1970's showed extensive use of both the sedge marshes (Carex lyngbyei) (Levy et al. 1982a,b) and mudflat areas (Goodman 1975; Greer et al. 1980) as a rearing site by juvenile salmonids and other species of fish.

In early 1980, three sites were chosen on Sturgeon and Roberts Banks for further study of the food available to the fish populations (Fig. 1). These sites were representative of some of the different habitats available on the banks and varied in sediment type, exposure, vegetative cover, salinity and temperature regimes. Table 1 provides a brief description of the stations. The station at Iona Island was located approximately five km from the sewage outfall. The site at Steveston was positioned in a highly exposed area, subjected to strong current action. The site on Roberts Bank was located on a manmade beach, namely the coal loading facility built in 1969 (Levings 1985), and beds of eelgrass (Zostera marina) were present on the surrounding mudflat. Sample sites were characterized by fine mud at Iona Island, sand at Steveston and a mud-sand mixture at Roberts Bank. At Iona Island, temperature and salinity ranged from 7-24°C and 2-22‰, at Steveston from 5-22°C and 2-20‰ and at Roberts Bank between 2-22°C and 14-28‰ (Gordon and Levings 1984). A more detailed discussion of the site locations and listing of physical data may be found in Conlin et al. (1982) and Gordon and Levings (1984).

Between April 15, 1980 and June 3, 1981, fourteen trips were made to the estuary. In conjunction with beach seine collections of the fish community (Gordon and Levings 1984) two sampling methods were used to sample the meiofauna in the sediment and the epifauna immediately above the bottom. The samples were all obtained at low tide and are from an elevation of approximately 0.5 m above chart datum.

MATERIALS AND METHODS

Two hundred and thirty-four samples of the meiofauna present in the top 1 cm of sediment were collected using small cores which sampled an area of 6.16 cm² (Sibert et al. 1982b). Fifty cm³ syringes, with the bottom end removed, were fitted with rubber stoppers, top and bottom, and inserted into the sediment at the water's edge on dry land. Six replicate cores were collected at each site and the top 1 cm was extruded from the core and preserved in 4% v/v formalin and rose bengal. In the laboratory, the meiofauna present in the core samples were separated from the sediment and debris by repeated decantation through a

44 μm sieve and were then counted using a dissecting microscope. If required, the samples were split with a Folsom splitter and 100 of the dominant organisms counted. The sample total was then calculated and recorded. The first 100 harpacticoids found were preserved and identified to species. Where there were a large number of harpacticoid copepods in the sample, the total number of each species was calculated as a proportion of the number identified.

One hundred and seventeen samples of near-bottom epifauna were collected at the same time as the cores using an epibenthic sled (Sibert et al. 1982a). The sled had a 10 cm x 10 cm mouth opening, adjustable to differing heights above the bottom, and was fitted with a 44 μm net (Sibert et al. 1977). Three replicate samples were taken at each site in water approximately 30 cm deep. The sled was towed for five metres, sampling an area of 0.5 m^2 each time. These samples were also preserved in 4% formalin and rose bengal and analyzed in the same manner as the core samples.

RESULTS AND DISCUSSION

A. CORE SAMPLES

A-1. Meiofauna densities

Analysis of the core samples showed the meiofauna at the three sites to be distinctly different, with twenty taxonomic categories found at Iona Island, seventeen at Steveston and twenty-six at Roberts Bank (Sibert et al. 1982b). The overall mean density of meiofauna was the highest at Iona Island ($1,937 \pm 170$ 10 cm^{-2}), followed by Roberts Bank ($1,036 \pm 118$ 10 cm^{-2}). In comparison, total mean densities were much lower at Steveston (335 ± 41 10 cm^{-2}) and each site showed its own unique seasonal pattern of abundance (Table 2, Fig. 2). At all three sites nematodes, copepod nauplii and harpacticoid copepods were the most numerous categories in the samples, with nematodes being abundant at all three sites and copepod nauplii and harpacticoids occurring in the highest numbers at Roberts Bank (Table 2, Figs. 3-5). Analysis of the cores by percent composition also indicated that the three sites are unique in their composition and seasonal cycles (Table 3, Fig 6). The variability in density and community structure at the three sites was most likely due to the differences in sediment and vegetation. At Iona Island there was reduced circulation, the site was very muddy and the discharge of domestic sewage into the area has had a profound influence in the form of a deep sludge layer close to the outfall (B.C. Research 1975; Otte and Levings 1975). At Steveston, there was good water circulation (Levings 1982) and the area was characterized by clean, well washed sand. At Roberts Bank, the sample site was on a man-made shoreline, namely the south shore of the coal port island. The sediment was a cobble-mud-sand mixture and eelgrass (*Zostera marina*) was

present.

A-2. Harpacticoid copepod species

Analysis of the harpacticoid copepods from the core samples showed only twenty-one species present at Iona Island, fourteen species at Steveston and forty-five at Roberts Bank (Sibert et al. 1982b). The unidentified copepodites (all the young stages of all harpacticoid species combined) were the dominant category at Iona Island and Roberts Bank and third in importance at Steveston (Table 4, Fig. 7). The Family Ectinosomatidae, which includes a number of genera which are difficult to separate, were also important at all three sites and were found throughout most of the year (Fig. 8). The remainder of the species occurred sporadically and suddenly, appearing only during certain months of the year. At Iona Island the abundance of Huntemannia jadensis varied throughout the sampling period and Microarthridion littorale was numerous in both the spring of 1980 and 1981. Two interstitial species, Leptastacus constrictus and Paraleptastacus spinicauda, showed peaks of abundance during the summer months at Steveston. At Roberts Bank several small epibenthic species, Amphiascoides sp., Dactylopodia sp. and Mesochra pygmaea were collected randomly throughout the sampling.

B. SLED SAMPLES

B-1. Epifauna densities

Analysis of the sled samples showed the richest epifaunal community to be at Roberts Bank where thirty categories of epifauna were found. There were twenty-nine categories at Iona Island and thirty-one at Steveston (Sibert et al. 1982a). The highest density of epifauna in any sample was found in May 1980 ($22,9291 \pm 27,947 \text{ m}^{-2}$) at Roberts Bank where the overall mean density was $51,656 \pm 10,310 \text{ m}^{-2}$. At Steveston, the epifauna reached a maximum of $96,047 \pm 53,641 \text{ m}^{-2}$ in September, 1980 with an overall mean density of $16,622 \pm 6,325 \text{ m}^{-2}$. The highest total density at Iona Island was $50,467 \pm 9,272 \text{ m}^{-2}$ in May, 1981 and the mean density for all samples was $13,324 \pm 2,520 \text{ m}^{-2}$ (Table 5, Fig. 9). At all three sites the copepod nauplii reached high densities at least once during the year, showing a strong seasonal cycle (Fig. 10). The harpacticoid copepods reached very high numbers m^{-2} in spring 1980 at Roberts Bank and showed several yearly peaks at the other two sites (Fig. 11). At all three sites calanoids, worms, eggs and rotifers made up a large proportion of the epibenthic community at some time, usually exhibiting one or two peaks in abundance during the year. At Roberts Bank, amphipods were also very numerous in the early spring.

The patterns of change in the total epifaunal community as well as the

dominant categories were different between the three sites. The percent composition of the sleds for harpacticoid copepods, copepod nauplii and nematodes changed from month to month at each station (Table 6, Fig. 12).

B-2. Harpacticoid copepod species

The highest number of harpacticoid copepod species found was fifty-six from Roberts Bank, followed by Iona Island and Steveston with thirty-six species each (Sibert et al. 1982a). The unidentified copepodites reached very high densities at Roberts Bank and showed an early spring peak at all three sites (Table 7, Fig. 13). Three typical mud dwelling species were the most numerous at Iona Island, Tachidius (Neotachidius) triangularis, Leimia vaga and Microarthridion littorale (Fig. 14). At Steveston, the Family Ectinosomatidae, Tachidius (Neotachidius) triangularis and Mesochra pygmaea occurred sporadically and in low numbers (Fig. 15). Samples from Roberts Bank showed very high densities of Tisbe sp. in the spring of 1980 while Harpacticus sp. and the Family Ectinosomatidae occurred year round (Fig. 16). At each of the stations, there were large seasonal variations in other species as well.

C. STATISTICAL ANALYSIS

To test whether the differences in meiofauna and epifauna at the three stations were significantly different, analysis of variance (ANOVA) was carried out after the sample data were transformed ($\log_{10}(X + 1)$). Where significant differences occurred, Bonferroni t-tests were used to separate or group the stations. The dominant categories and the most abundant species of harpacticoid copepod from both the core and sled samples were included in the analysis.

C-1. Core samples

The numerical abundance of the fifteen most common groups of meiofauna and the total counts at each site were tested between the three habitats. The ANOVAs indicated that thirteen groups and the total counts were highly significantly different ($P \leq 0.01$) between the three sites (Table 8). Using the Bonferroni t-test, the three stations were all grouped separately for nematodes, worms, amphipods, bivalves, ostracods and total abundance. Samples from Iona Island and Roberts Bank were grouped together for eggs, ectoprocts, cumaceans and hydroids. Samples from Steveston and Roberts Bank were grouped for harpacticoids and ciliates and those from Iona Island and Steveston were grouped for foraminiferans and rotifers. There was no significant difference between sites for copepod nauplii (all three sites were grouped together) and there was some overlap for turbellarians.

The same analysis carried out on the seven most common harpacticoid copepod species from the core samples showed the distribution of five of them to be significantly different between sites. The numbers of Huntemannia jadensis and Microarthridion littorale at Iona Island were significantly higher than at Steveston and Roberts Bank. Leptastacus constrictus was significantly higher and the unidentified copepodites were significantly lower at Steveston in comparison to the other two sites, while Amphiascoides sp. was significantly higher at Roberts Bank. All the stations were grouped together for Tachidius (Neotachidius) triangularis and there was some overlap between all three stations for the Family Ectinosomatidae (Table 9).

C-2. Sled samples

ANOVAs performed with data from the thirty most common epifaunal groups collected in the sled samples showed a significant difference between the three sites for eighteen of the categories (Table 10). The results of the t-tests showed that for twelve of these eighteen categories, samples from Iona Island were grouped with Steveston and those from Roberts Bank were separate. The harpacticoid copepods were the only group where all three stations were separated. Only the bivalves and ectoprocts showed some overlap between all three sites. The ANOVA on the total counts indicated a significant difference ($P \leq 0.01$), with the t-test showing samples from Iona Island and Steveston grouped separately from Roberts Bank. There was no significant difference between sites for worms, foraminiferans, barnacle cypris, hydroids, acarinans, rotifers, insects, cladocerans, decapods, ciliates, turbellarians and fish.

The harpacticoid species were identified from one hundred and sixteen sled samples and thirty-eight species were tested for similarity between the sites. Twenty-three showed a significant difference in distribution between the three stations ($P \leq 0.01$) (Table 11). Samples from Iona Island were grouped together with Steveston for seventeen of the species and Roberts Bank was separate. Iona Island and Roberts Bank were grouped together for only one species, Huntemannia jadensis. There was no significant difference between sites for Schizopera knabeni, Paralaophonte congenera congenera, Heterolaophonte variabilis, Ameira longipes, Parapseudoleptomesochra sp., Laophontid sp., Diosaccus spinatus, Apodopsyllus vermiculiformis, Amphiascopsis cinctus, Mesochra sp., Tegastidae sp. and Stenhelia peniculata. There was some overlap between the three sites for Tachidius (Neotachidius) triangularis, Amphiascus minutus and Paralaophonte pacifica.

D. COMPARISONS BETWEEN HABITATS AND OTHER ESTUARIES

The results of the statistical analysis indicate that the three sites are

representative of a variety of habitat types. The groupings from the core samples show that the meiofauna communities at all three sites are quite different, with Iona Island being somewhat more similar to Roberts Bank than Steveston. This was also evident from the percent composition of the cores, with each site seeming to follow a distinct pattern. The same is true for the occurrence of the harpacticoid copepod species in the cores at the three sites. Steveston was dominated by an interstitial species, Leptastacus constrictus, which could be expected because of the predominantly sandy sediment at this site. Two burrowing types, Huntemannia jadensis and Microarthridion littorale were most common at Iona Island, perhaps due to the prevalence of a surface sludge in the area. At Roberts Bank, the Family Ectinosomatidae was the most numerous in the cores, a group which is commonly found in association with vegetation.

The analysis of the epifauna from the sled samples showed a less clear separation of all three stations than for the cores with all the stations being grouped together for many of the categories. Where the stations were differentiated, Iona Island was most often grouped with Steveston and Roberts Bank was usually alone. Here the highest density of epifauna was observed, probably due to the presence of eelgrass. At this site, there were much higher numbers of truly epibenthic harpacticoids in the sleds which are normally found in association with eelgrass (e.g., Harpacticus sp., Zaus sp.). Comparisons between years showed the total harpacticoid abundances in 1981 to be much lower than in 1980 at both Roberts Bank and Steveston.

There have only been a few studies carried out previously on the meiofauna of the Iona Island - Sturgeon Banks area. Harrison (1981) sampled the meiofauna of the Iona Island area over a one year period in 1978 at two sites to the north of the jetty. She collected cores from a mud and a nearby sand site and found nematodes and harpacticoids to be dominant in the mud community, although in lower densities than were found in this study. An investigation of the nematodes at one site at Iona Island by Sharma and Webster (1983) found 24 species present in the sediments, but in much lower total numbers than reported here. A study carried out by Webb (1989, 1991a,b) on the harpacticoids in an eelgrass bed on Roberts Bank detected 55 species in the sediments and on the eelgrass. However this author sampled the blades of eelgrass and therefore sampled a different harpacticoid microhabitat than the present study.

A similar study has been carried out at the Campbell River estuary where, between 1982-1984, nine sites were sampled throughout the estuarine area with the same epibenthic sled (Kask and Brown 1984, 1985, 1986). In conjunction, samples of the juvenile salmon were also collected at the same sites. At the time of sampling, many of these sites were located in newly constructed marsh sites, and the overall mean total density was much lower (562-1148 m⁻²) over the three years of sampling than at any of the Fraser estuary sites (Kask et al.

1988a, 1988b).

It is accepted that harpacticoid copepods are an important food source for juvenile salmon rearing in the Fraser River estuary (Levings et al. 1991; Levy et al. 1982b; Webb 1991 a,b). During 1986, sampling of an eelgrass bed on Roberts Bank was carried out by D'Amours (1987). He sampled the entire harpacticoid copepod community and focused on Tisbe spp., Harpacticus uniremis and Zaus aurelii as the most available and preferred food sources for juvenile salmon. The results of the sampling of the epibenthic communities at the three sites showed these harpacticoids to reach their highest densities at Roberts Bank where they were dominant in the spring samples. Levings (1985) found extensive use of the low tide area at this site by juvenile pink, chum and chinook; harpacticoid copepods formed a substantial portion of their diet. Cordell and Simenstad (1988) have proposed that a complex consisting of Harpacticus sp., Zaus sp. and Tisbe sp. is indicative of a habitat suitable for the rearing of juvenile salmonids. In studies conducted by D'Amours (1987) and Webb (1989), these three taxa were heavily consumed by juvenile salmon on Roberts Bank. A comparison of this complex at all three sites showed that the highest numbers of Harpacticus sp., Zaus sp., and Tisbe sp. were found at Roberts Bank (Fig. 17). Of the three sites investigated, Roberts Bank was therefore the most suitable for the rearing of young fish.

ACKNOWLEDGMENTS

We would like to thank Dr. J.R. Sibert for proposing and supervising the sampling of meiofauna and for support during the sorting and identification of invertebrates from the surveys. Field support was provided by a number of staff in Fisheries Branch, DFO, in particular Messrs. Bruce Hillaby, Barry Lawley, and Kevin Conlin.

Table 1. Descriptions of the three stations sampled on the Fraser River estuary (see Conlin et al. 1982 for exact station locations).

Station No.	Station Name	Habitat type
1	Iona Island	On Sturgeon Bank, on the north side of the sewage channel near the end of the causeway, a man-made trench connected with the Iona Island sewage treatment plant; 90% sand-10% mud; moderate slope.
2	Steveston	On Sturgeon Bank, a relict river channel, on the southwest sand bar at 1 m tidal level; 100% sand; moderate slope.
3	Roberts Bank	On the Westshore Causeway man-made beach; cobble from mid-tide upshore, sand and eelgrass downshore; moderate slope.

Table 2. Mean numbers of meiofauna $10 \text{ cm}^{-2} \pm 1\text{SE}$ for core samples collected at Iona Island, Steveston and Roberts Bank. Only categories with average $\geq 0.1 \text{ } 10 \text{ cm}^{-2}$ included.
