Comparing the genome sequences of free-living organisms in the first 1 billion years of eukaryotic evolution enables predictions to be made about the genome of the last common ancestor. The genome sequence of the amoeboid flagellate *Naegleria gruberi* reported in 2010 reveals the surprising complexity of this unicellular organism as a common eukaryotic ancestor.

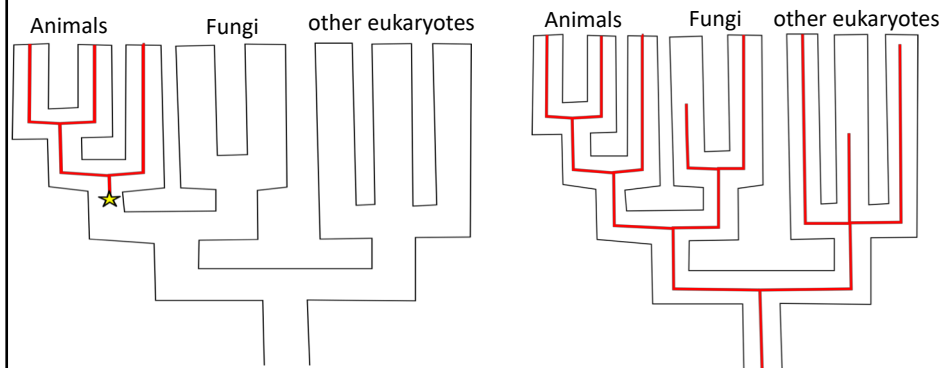

How we revealed the trend of a complex ancestor and independent loss

A combination of:

- New genomes at crucial positions
- Improved sensitivity of sequence similarity searches (and homologs that are orthologs)
- Studying gene families with a lot of pre-LECA duplications

Improved sensitivity of sequence similarity searches reveals lineage specific genes to be ancient with orthologs across eukaryotes

Improved sensitivity of sequence similarity searches. Profile-based searches reveal ancient origins of CKK

The CKK Domain (DUF1781) Binds Microtubules and Defines the CAMSAP/*ssp4* Family of Animal Proteins

We describe a structural domain common to proteins related to human calmodulin-regulated spectrin-associated protein1 (CAMSAP1). Analysis of the sequence of CAMSAP1 identified a domain near the C-terminus common to CAMSAP1 and two other mammalian proteins KIAA1078 and KIAA1543, which we term a CKK domain. This domain was also present in invertebrate CAMSAP1 homologues and was found in all available eumetazoan genomes (including cnidaria), but not in the placozoan *Trichoplax adhaerens*, nor in any nonmetazoan organism. Analysis of codon alignments by the site-wise likelihood ratio method gave evidence for strong purifying selection on all codons of mammalian CKK domains, potentially indicating conserved function. Interestingly, the *Drosophila* homologue of the CAMSAP family is encoded by the *ssp4* gene, which is required for normal formation of mitotic spindles. To investigate function of the CKK domain, human CAMSAP1-enhanced green fluorescent protein (EGFP) and fragments including the CKK domain were ex-

We conclude that the CKK domain binds microtubules and represents a domain that evolved with the metazoa.

Evolution by gene loss

Ricard Albalat and Cristian Cañestro

Abstract | The recent increase in genomic data is revealing an unexpected perspective of gene loss as a pervasive source of genetic variation that can cause adaptive phenotypic diversity. This novel perspective of gene loss is raising new fundamental questions. How relevant has gene loss been in the divergence of phyla? How do genes change from being essential to dispensable and finally to being lost? Is gene loss mostly neutral, or can it be an effective way of adaptation? These questions are addressed, and insights are discussed from genomic studies of gene loss in populations and their relevance in evolutionary biology and biomedicine.

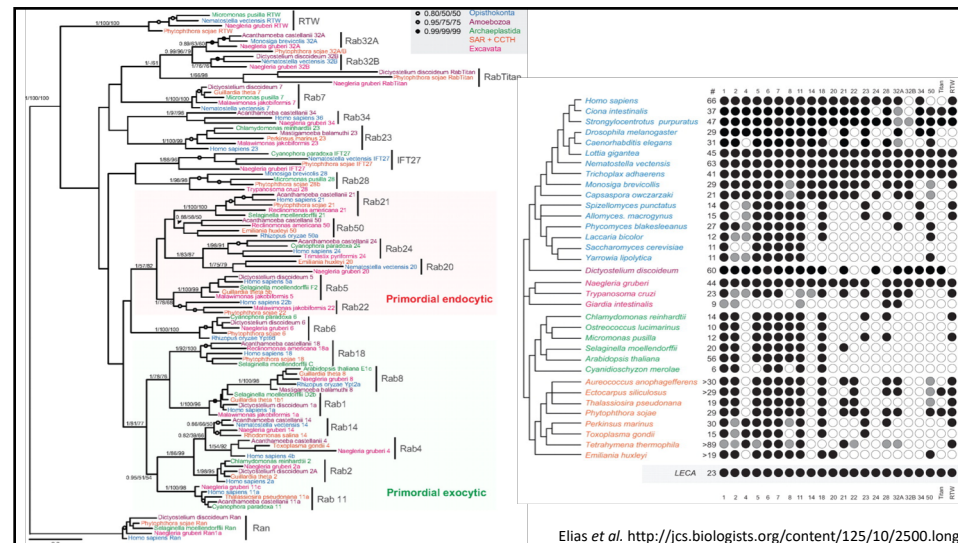

Pseudogenization
An evolutionary phenomenon whereby a gene loses its function, accumulates mutations and becomes a pseudogene.

Eumetazoan
Clade that classically includes all animals (metazoan) except sponges and Placozoa.

Loss is nothing else but change, and change is Nature's delight — Marcus Aurelius, AD 121–180

Great attention has in the past been paid to the mechanisms of evolution by gene duplication (that is, neofunctionalization and subfunctionalization)^{1,2}. By contrast, gene loss has often been associated with the loss of redundant gene duplicates without apparent functional consequences, and therefore this process has not been neglected as an evolutionary force. However,

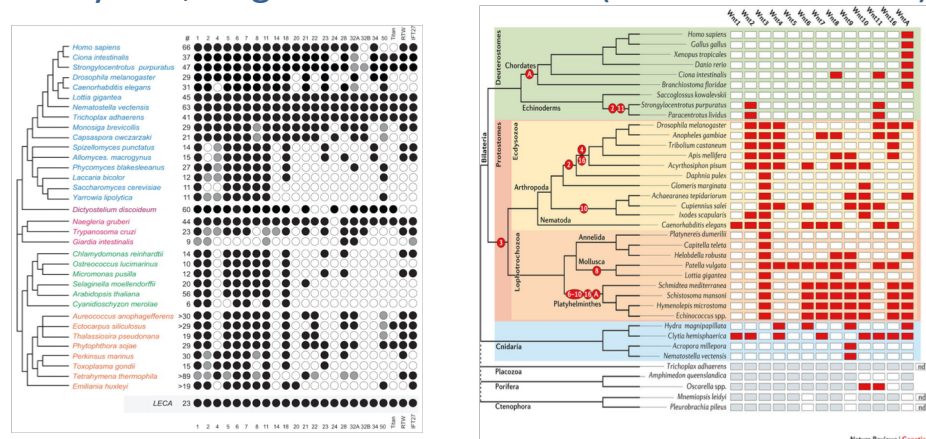

Here, we address some of the fundamental questions in evolutionary biology that have emerged from this novel perspective of evolution by gene loss. Examples from all life kingdoms are covered, from bacteria to fungi and from plants to animals, including key examples of gene loss in humans. We review how gene loss has affected the evolution of different phyla and address key questions, including how genes can become dispensable, how many of our current genes are actually dispensable, how patterns of gene loss are biased, and whether the effects of

wingless (Wnt) : a paradigmatic example of the pervasiveness of gene loss during metazoan evolution. (after gene duplication)

Duplication/Loss at different levels. e.g. origin of eukaryotes, origin of animals WNT (“scale invariant”?)

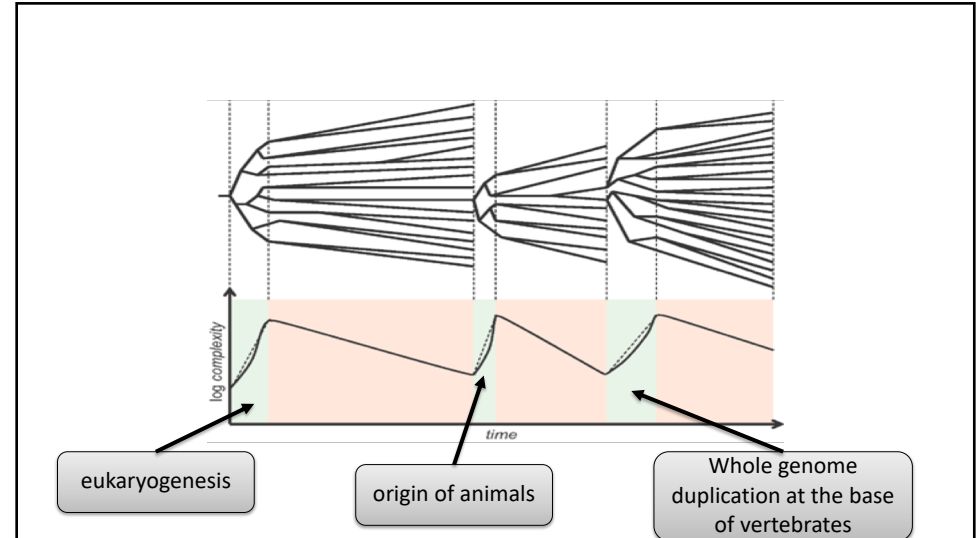

Genome reduction as the dominant mode of evolution

Yuri I. Wolf* and Eugene V. Koonin

A common belief is that evolution generally proceeds towards greater complexity at both the organismal and the genomic level, numerous examples of reductive evolution of parasites and symbionts notwithstanding. However, recent evolutionary reconstructions challenge this notion. Two notable examples are the reconstruction of the complex archaeal ancestor and the intron-rich ancestor of eukaryotes. In both cases, evolution in most

Introduction: Complexity can either increase or decrease during the evolution of various life forms

The textbook depiction of the evolution of life on earth is that of an ascent toward a steadily increasing organismal complexity: from primitive protocells to prokaryotic cells to the eukaryotic cell to multicellular organisms to animals
