33 **ABSTRACT**

34 Tree ferns are common elements in subtropical Atlantic Forest, sometimes reaching
35 more than half of dominance at forest sites. Climate change could impact the
36 distribution and diversity of tree ferns, hence impacting the ecological processes
37 provided by them. We investigate the impacts of future climate changes in the potential
38 distribution of tree fern species, as well as in the α - and β -diversity. Our first hypothesis
39 (H_1) is that warmer climate in the future will increase the distribution of Cyatheaceae
40 species and decrease the distribution of Dicksoniaceae species. Due to a larger number
41 of Cyatheaceae than Dicksoniaceae, the richness will tend to increase. However, the
42 increase in richness might lead to homogenization, consequently decreasing β -diversity
43 (H_2). To test these hypotheses, we used distribution models to predict the potential
44 species distribution in the present and future. Then, we calculated the changes in
45 potential distribution areas, α -, and β -diversity components between scenarios. Finally,
46 we assessed the impact of these changes within Protected Areas. We found that
47 Dicksoniaceae distribution tends to shrink in the future, while half of Cyatheaceae tend
48 to lose distribution. Species richness tends to decrease in the future, as well as β -
49 diversity. At least 43% of the sites tend to have their species richness reduced, while
50 only 26% of sites tend to gain species. Our results suggest that species associated with
51 cold environments will lose suitable areas and are more threatened. Richness tends to
52 decrease mainly in sites with high precipitation seasonality. Furthermore, the tree ferns
53 assemblage tends to homogenize.

57

58 **1. INTRODUCTION**

59

60 Tree ferns are expressive elements in (sub)tropical forest formations (Tryon &
61 Tryon, 1982), sometimes establishing monodominant forests (Gasper et al., 2011). For
62 this reason, tree ferns act in the dynamics of the ecosystem and may affect the
63 regeneration of wood species and nutrient cycling (Brock, Perry, Lee & Burns, 2016).
64 In addition, they contribute to the process of ecological succession (Arens & Baracaldo,
65 1998), to biomass stock in tropical forests (Sarmiento, Pinillos, & Garay, 2005), and
66 provide microhabitat for several epiphytic plants, many of them occurring exclusively
67 on tree ferns caudices (Wagner, Mendieta-Leiva, & Zotz, 2015).

68 Tree ferns have suffered intense exploitation in the tropical forest due to
69 ornamental use of their caudices (Eleutério & Pérez-Salicrup, 2006; Hoshizaki, &
70 Moran, 2001), causing populational exhaustion of many species (Santiago, Mynssen,
71 Maurenza, Penedo, & Sfair, 2013). Combined with this, the actual high forest
72 fragmentation in the Atlantic Forest (Ribeiro, Metzger, Martensen, Ponzoni, & Hirota,
73 2009) plus climate change scenarios (IPCC, 2014; Lima, Ribeiro, Grelle, & Pinto, 2019)
74 are other potential sources of threat to tree ferns. These threats might change the density
75 and distribution of these species as well as the locations of the suitable area to grow and
76 reproduce.

77 Moreover, despite tree ferns being an important group in forest structure, these
78 plants are historically neglected in floristic and ecological studies in Brazil (Weigand &
79 Lehnert, 2016). There are two main families of tree ferns in subtropical Atlantic Forest:
80 Dicksoniaceae and Cyatheaceae. The former is represented by *Dicksonia sellowiana*, a
81 species that inhabits high and cold environments (Gasper et al., 2011), and *Lophosoria*

82 *quadripinnata*, that grows in ravines, doing best on moist, well-drained soil and in full
83 sun until 2000 m in eastern Brazil (Lehnert & Kessler, 2018). The later family (about 14
84 species) exhibits a preference for warm, humid and low seasonal climates (Bystriakova,
85 Schneider, & Coomes, 2011) and may benefit from warmer climate regimes.

86 The Intergovernmental Panel on Climate Change (IPCC) predicts shifts in
87 rainfall and temperature in the subtropical Atlantic Forest, and since water availability is
88 correlated to fern species richness (Kessler, Kluge, Hemp, & Ohlemüller, 2011), rainfall
89 regimes modifications could impact in ferns distribution. Therefore, a reduction of cold
90 environments and increasing of warm and humid environments may impact *D.*

91 *sellowiana*, an already endangered species, through the restriction of its occurrence area.

92 In this regard, our study sought to predict the impacts of future climate changes
93 in α - and β -diversity of tree ferns in the subtropical Atlantic Forest, as well as to predict
94 the impact in the potential distribution of each species. Our first hypothesis (H_1) is that
95 species from both families will change their potential distribution areas. We expect
96 Dicksoniaceae species will have their potential distribution area reduced (specially
97 *Dicksonia sellowiana*) because of their association with cold habitats — and
98 Cyatheaceae species will increase their potential distribution areas since they generally
99 occur along hot and humid regions. Our second hypothesis (H_2) is that the changes in
100 species distribution will affect α - and β -diversity. Since we expect the Cyatheaceae
101 species will increase their distribution range, hence increasing the overlap in species
102 areas, we expect an increase in α -diversity and a decrease in β -diversity, i.e., less
103 variation in species composition among sites, leading to a homogenization of our study
104 region.

105

106

107 **2. MATERIAL AND METHODS**

108

109 **2.1 Study area**

110 The study area is delimited by the subtropical Atlantic Forest, floristically distinct from
111 the tropical Atlantic Forest (Eisenlohr & Oliveira-Filho, 2014). The subtropical Atlantic
112 Forest occurs in southern Brazil as well as in parts of Argentina and Paraguay (C.
113 Galindo-Leal & Câmara, 2005). The predominant climate type is Cfa (temperate humid
114 with hot summer), with some areas fluctuating to Cfb (temperate humid with temperate
115 summer). The relief ranges from sea level to altitudes near 1200 m, including peaks that
116 reach almost 1900 m. Distinct forest types can be found, which includes Restinga, on
117 the coastal areas; Rainforests, in low altitudes at the coastal region (< 800–900 m);
118 Mixed Forests (*Araucaria* forest), generally in areas with altitudes over 800 m; and
119 Semideciduous Forests in low areas with high seasonality in precipitation (Figure 1).

120

121 **2.2 Data gathering**

122 Among the species that occur in subtropical Atlantic Forest (following Brazilian
123 Flora 2020 in construction 2019; Fernandes 1997; Lehnert & Weigand, 2016), we
124 identified 1167 records and 15 species from the literature (Fernandes, 1997; Vibrans,
125 Sevegnani, Lingner, Gasper, & Sabbagh, 2010) and herbaria (using SpeciesLink –
126 <http://splink.cria.org> and GBIF Global Biodiversity Information Facility –
127 <https://www.gbif.org>). Uncertain records were removed, as well as *Cyathea uleana* due
128 to its low number of registers.

129 The data available for the study area was under the effect of sampling biases.

130 This issue arose because, in the state of Santa Catarina, the Floristic and Forest

131 Inventory of Santa Catarina (IFFSC; Vibrans et al., 2010) had strongly sampled the
132 state's territory — an effort that did not take place in other locations of the study area.
133 To minimize sample biases, we performed spatial filtering on the occurrence data by
134 defining a buffer of $\cong 30$ km as a minimum distance between occurrence records in all
135 study areas (Fourcade, Engler, Rödder, & Secondi, 2014).

136 Climate data were obtained for the present and future climate change scenarios
137 from WorldClim v2.0 (Fick & Hijmans, 2017) and WorldClim v1.4 (Hijmans,
138 Cameron, Parra, Jones, & Jarvis, 2005), respectively. Data for the future scenario refers
139 to the year 2050 and was based on the climate projections made by IPCC. We used the
140 mean of four Earth System Models (ESM) for future modeling: NorESM1-M (Bentsen
141 et al., 2013), MIROC-ESM (Watanabe et al., 2011), HadGEM2-ES (Jones et al., 2011),
142 and CNRM-CM5 (Voltaire et al., 2013). For these models, two future scenarios were
143 selected: the most optimistic (RCP 2.6) and the most pessimistic (RCP 8.5), which were
144 elaborated and named accordingly to the concentration of carbon dioxide in the
145 atmosphere (W/m^2) between the pre-industrial period and the year 2100 (IPCC, 2014).
146 In all tested ESMs we chose 19 environmental variables (bioclim) with 2.5' resolution.
147 We used the Variance Inflation Factor (VIF) via the *vifstep* function on *usdm* R-package
148 (Naimi, Hamm, Groen, Skidmore, & Toxopeus, 2014; R Core Team 2015) to remove
149 collinearity. This function generates 5,000 random points across the climate layers and
150 calculates the VIF for each variable using a step-by-step procedure. At each step, the
151 layer with the highest VIF is removed from the set. The process is repeated until only
152 variables with a VIF value below a defined threshold remain. We used a restrictive VIF
153 value ($VIF = 5$) that reduced the 19 climate variables to six: Annual Mean Temperature
154 (BIO01), Isothermality (BIO03), Temperature Annual Range (BIO07), Mean
155 Temperature of Driest Quarter (BIO09), Precipitation of Wettest Month (BIO13) and
156 Precipitation of Coldest Quarter (BIO19).
157

158 **2.3 Species Distribution Models (SDMs)**

159
160 We used SDMs to predict current and future distributions of each species. Our
161 SDMs were formulated using the *sdm* R-package (Naimi & Araújo, 2016) through five
162 different algorithms: MaxEnt (Phillips, Dudík, & Schapire, 2004), Boosted Regression
163 Trees (BRT; Friedman, 2001), Generalized Linear Models (GLM; McCullagh &
164 Nelder, 1989), Multivariate Adaptive Regression Spline (MARS; Friedman, 1991), and
165 Support Vector Machine (SVM; Vapnik, 2013), all with default settings. Moreover, as
166 proposed by Barbet-Massin, Jiguet, Albert, & Thuiller (2012), we applied 10 000
167 pseudo-absences for each species randomly created across the study area.

168 We evaluated the performance of the models generated by each algorithm
169 through a cross-validation procedure with 10 repetitions, where data were randomly
170 divided into training, amounting to 70% of the data, and testing, comprising the
171 remaining 30%. Two statistical methods were responsible for evaluating the robustness
172 of the models: Area Under the Curve (AUC) of the receiver operating characteristic
173 curve (ROC; Fielding & Bell, 1997) — a threshold-independent metric — and True
174 Skill Statistic (TSS; Allouche, Tsoar, & Kadmon, 2006) — a threshold-dependent
175 metric. All generated models were above the previously established cutoff values (AUC
176 > 0.70 and TSS > 0.40).

177 To avoid biases created by choosing a single statistical algorithm, as pointed out
178 by several studies (e.g., Araújo & New, 2007; Grenouillet, Buisson, Casajus, & Lek,

179 2011), we built a single final model through an ensemble approach. In this sense, the
180 models generated by statistical algorithms were projected using current and future
181 climate, and the ensemble model for each scenario was considered as the mean
182 weighted by the AUC value of the projections of each algorithm. Binary maps
183 (presence-absence) were made based on the threshold that maximizes the sensitivity
184 plus specificity of the models (maxSSS; Liu, Newell, & White, 2016), calculated with
185 the R-package *SDMtools* (VanDerWal, Falconi, Januchowski, Shoo, & Storlie, 2014).
186 The threshold was calculated for each species based on the final ensemble map of the
187 current scenario. Likewise, the resulting threshold value for the current scenario was
188 also used to build binary maps for future scenarios.

189

190 **2.4 Species distribution and diversity patterns**

191

192 To understand how climate change will affect species distribution and diversity
193 patterns, the study area was divided into hexagonal cells of $\cong 200$ km². Based on SDM
194 predictions for tree ferns, we measured for each scenario the changes of suitable cells
195 for all species and the α - and β -diversity indexes. We also evaluate the same metrics
196 exclusively in grid cells that overlap Protected Areas (PAs) in the study region. We
197 obtained the boundaries of PAs from the World Database on Protected Areas (UNEP-
198 WCMC, 2019). Therefore, we can compare species distribution and diversity indexes
199 between protected and non-protected areas for any specific scenario.

200 We measured α -diversity as the number of species present in each cell, i.e., the
201 predicted species richness. We calculated the β -diversity as the total variance of the
202 community (Total β -diversity, or BD_{TOTAL} ; *sensu* Legendre & De Cáceres, 2013) and it
203 was subsequently decomposed in Local Contributions to β -Diversity (LCBD). LCBD
204 represents the ecological uniqueness of each hexagonal cell regarding species
205 composition. We calculated BD_{TOTAL} based on the Jaccard dissimilarity coefficient (1–
206 similarity). Then, the LCBD was determined based on the partition of BD_{TOTAL} between
207 the cells (Legendre & De Cáceres, 2013). The significance of the LCBD values for each
208 cell was obtained through 999 permutations, where the species are distributed randomly
209 and independently along the grid and the LCBD values are calculated for each random
210 distribution. Significant LCBD values were those with p-value < 0.05.

211 Finally, we followed Legendre (2014) by partitioning the BD_{TOTAL} in species
212 replacement and richness difference components, using the replacement (*Repl_j*) and
213 richness difference (*RichDiff_j*) indexes of the Podani family (*sensu* Podani & Schmera,
214 2011; Legendre, 2014). All β -diversity metrics were calculated with the *adespatial* R-
215 package (Dray et al., 2019) using the functions *beta.div* and *beta.div.comp*. We used
216 QGIS 3.8 (QGIS Development Team 2019) to generate the maps. Lastly, to test
217 differences in α -diversity between current and future scenarios, we conducted the
218 Wilcoxon Rank-Sum Test, a non-parametric unpaired test, for the current scenario \times
219 RCP 2.6 scenario and current scenario \times RCP 8.5 scenario.

220

221 **3. Results**

222

223 All models had a good predictive power (AUC: mean = 0.825, sd = 0.05; TSS:
224 mean = 0.623, sd = 0.14 — for individual distribution maps and statistical performance

225 of each SDM see the supporting information S1, and the interactive maps in
226 <https://avrodrigues.shinyapps.io/tferns/>). Overall, the predicted impacts of climate
227 change on species were similar in both RCP 2.6 and RCP 8.5 (Table 1), where
228 Dicksoniaceae species tend to lose area of distribution and half of Cyatheaceae species
229 tend to increase its area of occurrence — while the other half tends to decrease. Also,
230 currently suitable areas inside PAs also suffer a significant reduction for many tree
231 ferns.

232

233 **3.1 α -diversity**

234

235 The highest α -diversity values (current and future scenarios, Figure 2) were
236 found in the Rainforest areas. In the west, where α -diversity is low in the current
237 scenario, many sites tend to become unsuitable for all the species in the future.
238 Furthermore, PAs harbor a higher average of α -diversity when compared to the
239 subtropical Atlantic Forest. At the same time, PAs will lose fewer species than non-PAs
240 and gain more species than non-PAs regions (Table 2).

241

242 **3.2 β -diversity**

243

244 The BD_{TOTAL} is predicted to decrease with climate change (Table 3), indicating
245 community homogenization along the study area. The LCBD values (Figure 3) ranged
246 from 3.2×10^{-4} to 5.5×10^{-4} in the current scenario, 2.7×10^{-4} to 5.8×10^{-4} in the RCP
247 2.6 scenario and 2.5×10^{-4} to 6.0×10^{-4} in the RCP 8.5 scenario, indicating an increase
248 in LCBD at some locations in the future and a decrease in others. Considering only PAs,
249 community homogenization is like the rest of the study area (Table 3).

250

251

252 **4. DISCUSSION**

253

254 **4.1 Changes in species distribution**

255

256 Our first hypothesis was that the species potential distribution would change in
257 future climate scenarios — where Dicksoniaceae species would have its distribution
258 reduced and Cyatheaceae species would have its distribution increased. We partially
259 confirmed our expectation since Dicksoniaceae species indeed had their potential
260 distribution reduced in both future scenarios, but only half of Cyatheaceae species had
261 their potential distribution increased. *Cyathea phalerata*, a common species in southern
262 Brazil, had its potential area reduced in both scenarios, and *Alsophila setosa* — one of
263 the most common tree ferns in forest communities in subtropical Atlantic Forest
264 (Lingner et al., 2015) — increased its area of occurrence in scenario RCP 2.6 but
265 decreased in RCP 8.5. *Cyathea feeana*, recently segregated from *C. corcovadensis*
266 (Lehnert & Weigand, 2013), had the most reduced potential occurrence area. All
267 Cyatheaceae species that were predicted to lose potential area in the future by our model
268 showed climatic suitability for the coldest regions of the study area at the current
269 scenario (Figures S1-S14 and interactive maps in
270 <https://avrodrigues.shinyapps.io/tferns/>).

271

272 A global analysis of Cyatheaceae distribution patterns showed a clear preference
273 of the group for hotter and wetter locations with low seasonality, although some species
show a capacity to occupy relatively cold regions, rarely where minimum temperatures

274 drop below freezing (Bystriakova et al., 2011). Half of the Cyatheaceae species
275 analyzed here were able to occupy the coldest areas of the current Mixed Forest.
276 However, few Cyatheaceae species were able to occupy areas of Semideciduous Forest,
277 where there is higher seasonality in precipitation than areas of Rainforest and eastern
278 Mixed Forest (Oliveira-Filho, Budke, Jarenkow, Eisenlohr, & Neves, 2015; Oliveira-
279 Filho & Fontes, 2000). The effects of high temperatures, reducing the cold intensity
280 (Wilson, Walters, Mayle, Lingner, & Vibrans, 2019), set up favorable conditions for
281 some of Cyatheaceae, since they expanded to it.

282 *Dicksonia sellowiana*, a species able to withstand colder environments (Gasper et
283 al., 2011), was restricted to higher and colder locations, wherein the Mixed Forest
284 predominates. In the same way, *L. quadripinnata* seems able to inhabit the colder
285 regions of the Mixed Forest. In addition, the warmer areas of the Rainforest also
286 showed high climatic suitability for this species. In fact, *L. quadripinnata* has been
287 recorded in both temperate (Ricci, 1996) and tropical (Bernabe et al., 1999) Rainforests.
288 In this sense, precipitation rather than temperature appears to be the main determinant of
289 *L. quadripinnata* occurrence.

290

291 **4.2 Changes in diversity patterns**

292

293 The second hypothesis was that the different responses of Dicksoniaceae and
294 Cyatheaceae species should cause significant changes in diversity patterns. Our
295 expectation was that species richness (α -diversity) would increase, following the
296 increase in overlapping distributions of Cyateaceae species, which in turn would lead to
297 a decrease of β -diversity. Our expectation about α -diversity was not confirmed since we
298 found evidence for less species richness per cell in the future scenarios. Nevertheless,
299 we found evidence for future homogenization of cells in the subtropical Atlantic Forest,
300 since both BD_{TOTAL} and LCBD values tend to decrease in future scenarios.

301 Our estimates indicate that at least 40% of the sites (cells) will lose richness in
302 the subtropical Atlantic Forest. This is due to a reduction in the area of distributions for
303 Cyatheaceae species, against our expectations. This loss can affect the conservation of
304 other biological groups that depend on tree ferns caudices, such as epiphytes — some of
305 these growths exclusively in tree ferns (Mehltreter, 2008). These changes may be
306 associated with variations in precipitation since water availability seems to be an
307 important species richness predictor for ferns, as pointed out by several authors
308 (Aldasoro, Cabezas, & Aedo, 2004; Gasper, Eisenlohr, & Salino, 2015; Kessler et al.,
309 2011). The current low α -diversity of tree ferns observed in the midwest and far west, as
310 well as the reduction of α -diversity in the future scenarios, may be caused by the rainfall
311 regime and high climatic seasonality (Bystriakova et al., 2011; Cabré, Solman, &
312 Núñez, 2016).

313 In the study region, the BD_{TOTAL} is more influenced by *RichDiff_j* among the
314 sites than by *Repl_j* (Figure 3 and Table 3). Together, these results indicate that local
315 extinctions are important drivers of homogenization in species composition of tree
316 ferns. The high influence of *RichDiff_j* in β -diversity could be explained by the
317 environmental filtering process (Atmar & Patterson, 1993). This process is evidenced
318 by the loss of species in the west region, with high precipitation seasonality, and by the
319 loss of more suitable areas by species from a colder climate. Working with ferns
320 communities in the northern Atlantic Forest, da Costa, Aman, de Paiva Farias, & Barros
321 (2019) found a higher contribution of species replacement than of species differences in
322 ferns on a regional and local scale in tropical Atlantic Forest. The authors listed high

323 dispersal ability, niche preferences, and the heterogeneous structure of the Atlantic
324 forest as the three main factors that contribute to species replacement. Two differences
325 between the studies could explain the different results: i) our study used local
326 assemblage in coarse scale, provided by the stack of SDMs, which is not able to capture
327 differences in microhabitats as in da Costa et al. (2019), and ii) we focused on the tree
328 ferns niches rather than all ferns species in the subtropical Atlantic Forest.

329

330 **4.3 Implications for biodiversity conservation agenda**

331

332 Our results provide relevant insights to the conservation of tree ferns by predicting
333 which species will lose larger proportions of adequate habitat in the future (Table 1).
334 We note that this phenomenon will mainly affect species that occupy higher areas such
335 as *A. capensis*, *C. feeana*, *C. villosa*, *S. gardneri*, *L. quadripinnata*, and *D. sellowiana*.
336 Although extinctions did not occur in our study area, historically endangered species
337 such as *D. sellowiana* had their potential distribution area greatly diminished (−42%).
338 Also, the climate changes can alter the threatened status from endangered (Santiago et
339 al. 2013) to critically endangered (considering IUCN 2012 criteria of population size
340 reduction: A1cB1b). *C. feeana* and *S. gardneri* (currently present in 424 and 386 cells,
341 respectively), both endemic to eastern Brazil, seem to be the most threatened species in
342 the future considering the reduction in cell numbers (to 208 in RCP 2.6 and 95 in RCP
343 8.5 for *C. feeana*; and to 217 in RCP 2.6 and 134 cells in RCP 8.5 for *S. gardneri*).
344 *Cyathea feeana* occurs from 500 to 1750 m and was recently segregated from *C.*
345 *corcovadensis* (Lehnert & Weigand, 2013), which may bias our results since not all
346 herbaria (despite our best efforts) review these records. *Sphaeropteris gardneri* occurs
347 between 450–600 m and few individuals were found by the IFFSC project (Gasper et
348 al., 2018).

349 More than half of the studied species are predicted to lose suitable areas, even
350 inside PAs (Table 2). So, in order to safeguard these species, new PAs will be needed as
351 they play an essential role in protecting species *in situ* (Chape, Harrison, Spalding, &
352 Lysenko, 2005). However, these new PAs may too have reduced long-term
353 effectiveness in species conservation since they are also going to be impacted by
354 climate change. Then, to optimize cost-benefit analysis of implementing new PAs,
355 lawmakers and specialists should always consider species conservation now and in the
356 future (Araújo, Alagador, Cabeza, Nogués-Bravo, & Thuiller, 2011). Also, LCBD
357 values should be interpreted with caution when looking at alternative indexes for
358 conservation use since they are not always positively correlated to species richness
359 (Legendre & De Cáceres, 2013; Silva & Hernández, 2014).

360 Unfortunately, some PAs in higher altitudes, such as Parque Nacional de São
361 Joaquim — where *D. sellowiana*, as well as other threatened species (such as *Araucaria*
362 *angustifolia*; Wilson et al., 2019) may find suitable areas in the future — are threatened
363 to be downsized (see the workgroup created to study the protected area boundaries;
364 ICMBio 2019).

365 At last, we expected that some tree fern species could expand their distributions
366 as a result of climate change. However, we must not extrapolate, without deep analysis,
367 this expansion to other groups. It is well known that animals (Radchuk et al., 2019) and
368 plants (Corlett & Westcott, 2013) will not be able to keep up, in general, with the
369 changes affecting the planet.

616 **Table 1.** Comparisons between potential areas occupied by the tree ferns in all
 617 scenarios (current, RCP 2.6, and RCP 8.5). The percentages are based on the subtropical
 618 area of the Atlantic Forest ($\cong 731.788 \text{ km}^2$) and Protected Areas inserted into the study
 619 region. Negative values (**bold**) indicate a reduction of the potential area, while positive
 620 values indicate an increase in the potential area. The “Current” column indicates the
 621 predicted number of suitable cells at the present.

Protected Areas			Species (record number)	Subtropical Atlantic Forest		
Current	RCP 2.6	RCP 8.5		Current	RCP 2.6	RCP 8.5
CYATHEACEAE						
340	-27.06	-43.82	<i>Alsophila capensis</i> (20)	815	-40.61	-55.71

635 **Table 2.** Mean species per cell and changes in α -diversity in the future scenarios (RCP
636 2.6, and RCP 8.5) for the whole study area and PAs only. “Gain”, “equal” and “loss”
637 indicates the proportion of cells that will respectively gain, keep the same number, or
638 lose species in each future scenario.

Protected Areas			α -diversity	Subtropical Atlantic Forest		
Current	RCP 2.6	RCP 8.5		Current	RCP 2.6	RCP 8.5
3.6	3.4	3.1	Mean per cell ²	5.53	5.15	4.68
-	26.56	21.83	Gain (%)	-	23.52	18.06
-	30.32	25.97	Equal (%)	-	28.00	20.36
-	43.12	52.20	Loss (%)	-	48.48	61.58

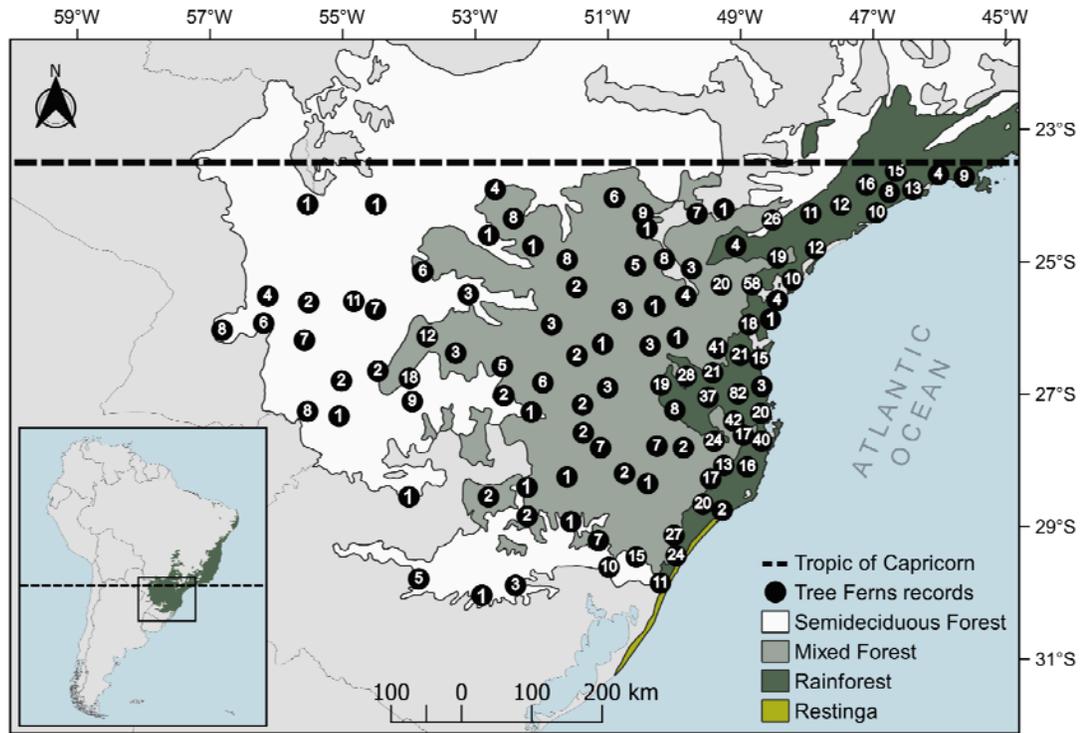

639 ²Mean differences between current and future scenarios were supported by the
640 Wilcoxon Rank-Sum Test (p-value < 0.001).
