Donor/recipient pairs were genotyped for cytokine polymorphisms including IL-1α -889, IL-1β -511, IL-1β +3962, IL-1R pst1 1970, IL-1RA mspa1 11100, IL-4Rα +1902, IL-12 -1188, IFN-γ +874(A/T), TGF-β codons 10 and 25, TNF-α -308, TNF-α -238, IL-2+166, IL-2 -330, IL-4 -1098, IL-4 -590, -33, IL-6 -174, IL-6 nt565, and IL-10 -1082, -819, and -592. Cytokine typing was performed by PCR-SSP assay.

Negative association was found between aGVHD and donor IL-10 GCC haplotype or donor IL-4Ra A allele in the whole population studied. When we compared within the leukemia subgroup, we observed positive association between recipient IL-1α -889/C allele and negative association between recipient IL-10 CAA haplotype and donor IL-4Ra A allele and development of aGVHD. We also observed possible positive and negative association for different genotypes and aGVHD; however, on multivariate analysis only donor IL-4Ra and donor IL-12 showed significant association. We conclude that several cytokine polymorphisms are positively and negatively associated with aGVHD in Iranian HLA matched siblings, of which IL-4Ra and IL-12 may play important roles.

[1]University of Geneva, Geneva, Switzerland, [2]University of Lausanne, Lausanne, Switzerland, [3]Universitat Pompeu Fabra, Barcelona, Spain, [4]Department of Neuroscience, Children's Hospital Bambino Gesù,, Rome, Italy, [5]Centre for Genomic Regulation, Biomedical Research Park (PRBB), Barcelona, Spain, [6]Institut Jerome Lejeune, Paris, France, [7]Cliniques universitaires Saint-Luc, UCL, Bruxelles, Belgium, [8]Université Saint-Joseph, Beirut, Lebanon, [9]CHU de Saint-Etienne, hôpital Nord, Saint-Etienne, Cedex, France, [10]Department of Medical Genetics, University of Athens, Athens, Greece, [11]Medical Genetics Unit, Hospital, IRCCS, Giovanni Rotondo, Italy, [12]de Biologie Fonctionnelle et Adaptative (BFA), CNRS EAC 4413, Université Paris Diderot, Paris, France.

Congenital heart defect (CHD) is a common developmental defect of Down syndrome (DS) occurring in 40% of cases. While carrying three copies of genes or other functional genomic elements on chromosome 21 increases the risk for CHD, trisomy 21 itself is not sufficient to cause CHD. Thus additional genetic variation and/or environmental factors could contribute to CHD risk. Here we use association studies to identify genomic variations that in concert with trisomy 21, determine the risk for CHD in DS. This case-control GWAS includes 187 DS with CHD (AVSD=69, ASD=53, VSD=65) as cases, and 151 DS without CHD as controls. Chromosome 21 specific association study revealed rs2832616 and rs1943950 (both cis-eQTLs for KRTAP7-1 gene) as CHD risk alleles (adjusted p-values < 0.05). Furthermore rs2183593 and rs7282991 (both cis-eQTLs for ADARB1 gene) were identified as risk factors for ASD. Since DS is likely to be a disorder of gene expression, 2-locus interaction was applied for whole genome eQTLs. A pair of interacting eQTL on chr2 and chr11 was identified. Furthermore, a search for chr21 risk CNVs for CHD was performed using a customized chr21 array of 135K probes across 55 DS-CHD and 53 DS controls. It revealed two CNV regions (FDR=0.04) located in the region previously associated with CHD risk in DS and another CNV region (FDR=0.03) upstream of POFUT2 gene. We propose that the CHD risk of DS is determined by specific SNPs and CNVs variations on chr21 and interaction of non-chr 21 genomic variants.

P08.12

Recommendations for genome-wide search for epistatic loci

T. Vaitsiakhovich[1], *C. Herold*[2], *D. Drichel*[2], *A. Lacour*[2], *V. Schüller*[1], *T. Becker*[2,1];
[1]Institute for Medical Biometry, Informatics and Epidemiology, University of Bonn, Bonn, Germany, [2]German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany.

Various strategies to identify interacting SNPs in GWAS studies were evaluated. Series of „realistic“ disease models were defined on a 2-SNP-genotype table by specification of allele frequencies, penetrances, minimal distance between available and causal SNPs. We compared single-marker analysis with multi-marker analysis, investigated performance of tests for interaction and tests including both marginal and interaction effects, so-called „tests allowing for interaction“. We compared case-only with case-control tests for interaction and contrasted the performance of allelic and genotypic models.

A subtle problem is that tests including marginal effects may become significant because of the marginal effect of just one SNP from a pair. Since our goal was to detect both SNPs, we embedded tests allowing for interaction in a two-step strategy: analysis of all pairs with a test with marginal effects, followed up by an interaction test on significant pairs remained after multiple testing adjustment.

For about 5% of settings the most efficient strategy is single-marker analysis, typically when allele frequencies are high or causal variant tagging is poor. For another 5% of models the most powerful strategy is testing for interaction without inclusion of marginal effects provided that a case-only test is used. Genotypic case-only test is typically more powerful than allelic case-only test. In the remaining majority of scenarios, a hybrid strategy is most suitable: genome-wide interaction analysis with a combined case-only-interaction/marginal-effects test; follow-up analysis of the significant pairs with a test for interaction excluding the strongest marginal effect but allowing for marginal effect of the second potential SNP.

The power of meta-analysis of RNA-seq datasets for eQTL identification

D. V. Zhernakova[1], *H. Westra*[1], *R. Jansen*[2], *E. de Geus*[3], *D. Boomsma*[3], *B. Penninx*[3], *C. Wijmenga*[1], *G. B. van Ommen*[4], *P. A. C. 't Hoen*[4], *L. Franke*[1];
[1]Department of Genetics, University of Groningen, University Medical Centre Groningen, Groningen, Netherlands, [2]Department of Psychiatry, Netherlands Study of Depression and Anxiety, VU University Medical Center, Amsterdam, Netherlands, [3]Department of Biological psychology, Netherlands Twin Registry, VU University, Amsterdam, Netherlands, [4]Department of Human Genetics, Leiden University Medical Center, Leiden, Netherlands.

Many genetic variants affect gene expression levels, although the exact mechanism through which this works is still mostly unclear. Previously, numerous expression quantitative trait locus (eQTL) mapping studies have been performed using microarray data. Recently, through next generation sequencing gene expression level quantitation has become possible (RNA-seq) and it has shown to be a very powerful approach of quantifying the transcriptome.

However, various RNA-seq strategies have been proposed, but it is still unclear what the best strategy for eQTL mapping is and how to combine eQTL data that has been generated by different technologies.

Here, we used three different types of RNA-seq data: paired-end RNA-seq (56 samples), single-end RNA-seq (64 samples) and deepSAGE data (94 samples). eQTL mapping (FDR = 0.05) on each dataset yielded 1287 unique genes for single-end RNA-seq, 601 unique genes for paired-end RNA-seq and 1188 unique genes for deepSAGE data. We show that a meta-analysis on different types of data can be performed to increase statistical power, permitting us to identify significant associations to 3504 unique genes. We compared the eQTLs that had been identified using RNA-seq and array based data and observed a concordance of 95% in allelic directions, indicating highly consistent results.

Our study indicates that different types of RNA-seq datasets can be well combined and that meta-analysis of RNA-seq is a logical step forward to gain better insight into the genetic regulation of gene expression variation.

P08.14

Alternative splicing in the Fanconi anemia candidate gene FAAP100

J. Kuehl[1], *B. Schuster*[1], *W. Wang*[2], *D. Schindler*[1];
[1]Department of Human Genetics, University of Wuerzburg, Wuerzburg, Germany, [2]Laboratory of Genetics, National Institute on Aging, National Institutes of Health, Baltimore, MD, United States.

Fanconi anemia (FA) is a rare autosomal or X-chromosomal recessive disease that can be regarded as a model for genomic instability, premature aging and tumorgenesis. Each of the 15 genes, whose products are members of the FA/BRCA pathway for genomic maintenance, have been identified to be causative for FA. FAAP100 is an additional member of the FA core complex but has not yet been found to be mutated in FA patients. It forms a subcomplex with FANCL and FANCB and protects both components for proteolytic degradation. After siRNA depletion or gene knockout FAAP100-deficient cells show features comparable to other FA cells defective of FANCD2 monoubiquitination. Because FAAP100 is a FA candidate gene, we screened seven FANCD2 monoubiquitination deficient cell lines by Sanger sequencing of all exons and adjacent introns portions. We detected eight common SNPs registered in the dbSNP database and a non-annotated heterozygous synonymous single-base substitution in exon 9 which cannot be causative for FA. Additionally, we found an alternative splicing event via sequencing cDNA of the FA cell lines. This event occurs because of the presence of a cryptical splice donor and results in skipping of 414 bp (c.1760_2173del414). In order to test an association with FA we examined FAAP100 transcripts in a control cell line. Since we detected the same alternative splicing event in the control it seems not likely to be causative for FA. The alternative transcripts could be involved in cell cycle-dependent or tissue-specific gene regulation, a role that will be studied in further experiments.

Novel method of CNV analysis in FcγR locus and its application to immune-related diseases

A. Zhernakova[1,2], L. Franke[1], A. Ioan[2], G. Trynka[1], K. Fransen[1], R. Weersma[3], S. Rantapää-Dahlqvist[4], P. Gregersen[5], C. Wijmenga[1], T. Huizinga[2], R. Toes[2];
[1]Department of Genetics, University medical centre Groningen, Groningen, Netherlands, [2]Department of Rheumatology, Leiden University Medical Center, Leiden, Netherlands, [3]Department of Gastroenterology and Hepatology, University Medical Center Groningen and University of Groningen, Groningen, Netherlands, [4]Department of Public Health and Clinical Medicine/Rheumatology, Umea University, Umea, Sweden, [5]The Feinstein Institute for Medical Research, North Shore-Long Island Jewish Health System, Manhasset,, New York, NY, United States.

Genetic variants near the FC-gamma receptor (FcγR) locus are associated with several immune-related diseases. However, most FcγR genes are located in complex regions of segmental duplications (SD) and they are therefore not well covered by the genotyping platforms. To be able to identify copy-number variants (CNVs) in this locus, we first developed a method to analyse CNVs using principal component analysis of the raw intensity values of single nucleotide polymorphisms (SNPs) genotyped on the Immunochip platform. This platform includes 1,159 SNPs in the SD block of FcγR genes; of these 1,019 (88%) failed our quality control for SNP analysis but their intensity values are informative for the CNVs estimation. We identified several CNV loci in the FcγR block. Second, we confirmed our results via an independent method - arrayCGH genotyping - and observed a perfect correlation in CNV estimation between both methods. Third, we applied our method to an RA cohort (3,326 cases; 3,397 controls). We found no associations between these CNVs with RA ($p > 0.05$). We are now applying our method to cohorts of celiac disease and inflammatory bowel disease, in total ~20,000 subjects. Fourth, by performing functional studies we observed a correlation between the number of FCGR3A gene copies and FCGR3 (CD16) expression on T-cells.

Conclusion: We have developed a method to accurately estimate CNVs based on SNP intensity data that can be extended to other SD loci in the human genome.

Study allelic variants G-2548A of the gene LEP and G223A gene LEPR in individuals with different levels of the main indicators of lipid profile

L. Kayumova, E. Yakshembitova, R. Kayumova, E. Vorobieva, V. Gorbunova;
Bashkir State Pedagogical University from after M. Akmulla, Ufa, Russian Federation.

It is known that structural and functional properties of lipoproteins are controlled by genetic factors. In this regard, the current association of polymorphic variants of genes with the level of serum lipids are the subject of intense attention. We examined polymorphic variants of the gene G-2548A LEP and leptin receptor gene G223A LEPR leptin in patients with different levels of the major lipid profile.

The material for the study included DNA samples from 434 healthy individuals. Determining the level of the main indicators of lipid profile (total cholesterol, triglycerides, low density lipoprotein, high density lipoprotein, atherogenic index and body mass index) was performed by standard enzymatic methods. Analysis of polymorphic DNA loci of LEP and LEPR was performed by PCR-RFLP.

The study found that significantly more frequent in individuals with high levels of total cholesterol (64,58% vs. 50,82% in the group of individuals with total cholesterol levels within the physiological norm; p=0,0189), triglycerides (55,45% vs. 41,67% in the group of individuals with triglyceride levels in normal; p=0,0408) and body mass index (85,71% vs. 41,67% in group of persons with BMI within the physiological norm; p=0,0524) alleles found LEPR A and LEP A, and in individuals with a level of performance within the physiological norm - alleles of LEP G, LEPR G and the genotype of LEP G/G (23,36% vs. 8,33% in the group of individuals with total cholesterol is normal; p=0,0321).

P08.17

Association of *ACE*, *PPARGC1A* and *PPARA* Genotypes with Footballers Performance

V. Ginevičienė[1], A. Jakaitienė[1], L. Tubelis[2], V. Kučinskas[1];
[1]Department of Human and Medical Genetics, Vilnius, Lithuania, [2]Lithuanian Olympic Sports Centre, Vilnius, Lithuania.

The aim of this study was to determine the impact of *ACE* (I/D), *PPARGC1A* (G/A), *PPARA* (G/C) polymorphisms on footballers performance among 199 Lithuanian professional footballers and 167 sedentary, healthy men (controls). The football players were divided into groups according to the position in the field: forwards (n=44), defenders (n=63), midfielders (n=75), goalkeepers (n=17). The novelty of the study is association analysis of *PPARGC1A*, *PPARA* polymorphisms in combination with *ACE* which is the gene candidate for footballers' performance research by others. Genotyping was performed using the methods of polymerase chain reaction and restriction fragment length polymorphism. The results showed that the *ACE* genotype distribution was significantly different between the total football players group and the controls (II-23.6%,ID-46.7%,DD-29.6% *vs.* II-24.6%,ID-29.9%,DD-45.5%, P=0.002). We revealed that in defenders (P=0.033) and midfielders (P=0.012) the *ACE* ID frequency was higher although DD genotype frequency was lower than in control. According to the analysis of *PPARGC1A* and *PPARA* polymorphisms, significant differences were determined between forwards and controls (*PPARGC1A*: GG-54.6%,GA-29.5%,AA-15.9% *vs.* GG-49.7%,GA-44.3%,AA-6.0%, P=0.044; *PPARA*: GG-52.3%,GC-40.9%,CC-6.8% *vs.* GG-72.4%,GC-24.6%,CC-3.0%, P=0.034). There were no athletes with *PPARGC1A* AA and *PPARA* CC genotype among the researched goalkeepers. In the whole cohort, the odds ratio of [*ACE* ID+*PPARA* GG] being a footballer was 1.69 (95%CI 1.04-2.74), and of [*ACE* ID+*PPARGC1A* GG] 1.93 (95%CI 1.10-3.37), and of [*ACE* II+*PPARA* GC] 2.83 (95%CI 1.02-7.91) compared to controls. In conclusion, the above data suggest that *ACE* I allele in combination with *PPARGC1A* G allele or *PPARA* G allele is associated with football players' ability.

P08.18

HLA class II (DRB1 and DQB1) genes associated in Tunisian patients with idiopathic dilated cardiomyopathy

S. Zarrouk-Mahjoub[1,2], S. Mehri[2], M. Hammami[2];
[1]Faculty of Medicine, Unit of Epidemiology Genetics and Molecular, Tunis, Tunisia, [2]Faculty of Medicine, Biochemistry Laboratory, Research Unit 'Human Nutrition & Metabolic Disorders', Monastir, Tunisia.

There is growing evidence of an important immunologic/ autoimmune component to idiopathic dilated cardiomyopathy (dCMP) disease, with abnormalities in both humoral and cellular response that is becoming the major pathogenic hypothesis for myocardial damage. Owing to the important participation of the immune system in the development of the CMP, genetic factors implied on its onset could include genes located on the Human Leukocyte Antigen (HLA). The present study was the first report to evaluate the relationship between class II HLA genes HLA (DRB1 and DQB1) and the genetic susceptibility to idiopathic dCMP in Tunisian patients. The HLA (DRB1, DQB1) alleles were analyzed in 76 patients with idiopathic dCMP and 111 ethnically matched healthy controls using polymerase chain reaction-sequence specific primers technique. An increased frequencies of HLA-DRB1*0401 (OR = 2.67, $P < 0.001$), HLA-DQB1*0302 (OR = 3.28, $P = 0.001$) and HLA-DQB1*0401 (OR = 6.26, $P = 0.005$) alleles were found in patients compared with healthy controls. Individuals with HLA-DRB1*1301 (OR = 0.24, $P < 0.001$) and HLA-DQB1*0201 (OR = 0.49, $P = 0.002$) alleles have a protective effect against idiopathic dCMP. Two haplotypes were associated with increased risk of idiopathic dCMP: DRB1*0401/DQB1*0302 (OR = 4.53, $P = 0.002$) and DRB1*0401/DQB1*0401 (OR = 9.42, $P = 0.004$). In conclusion, our data suggest that the variation in class II HLA alleles could be a genetic factor involved in the susceptibility to idiopathic dCMP in the Tunisian population.

P08.19

Genetic data fusion: combining sequence and array data for improved genotype calling

J. M. O'Connell[1], J. Marchini[2,1];
[1]Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom, [2]Department of Statistics, Oxford, United Kingdom.

Data sets containing large cohorts of individuals who have been genotyped on microarrays as well as sequenced at low coverage are now becoming available. Whilst the genotype calls coming from modern arrays are of high quality, accuracy and call rate can still be improved by incorporating sequence data into calls. This is particularly true for low frequency variants where very few observations are available to identify clusters for the rare genotypes. Higher quality genotype calls and better call rates will reduce time spent on quality control and decrease Type I and II error in genome wide association studies.

We present a Bayesian mixture model for genotype calling from array allele signal intensities, with parameter estimation and calls augmented by genotype likelihoods from sequence data. The method successfully identifies and discards spurious data and is capable of handling individuals with missing values, for example, a subset of individuals may have only been assayed on an array and not sequenced. This results in genotype calls with greater accuracy and a higher call rate than standard array-only methods. The implementation requires similar computational time to standard software for array-only based genotyping, providing higher quality genotype calls for minimal extra time and effort. We demonstrate these capabilities on 1000 Genomes Phase 1 data which have been genotyped on the Illumina HumanOmni2.5S chip as well as sequenced at 4X coverage.

P08.20

eQTL analysis of glucocorticoid regulated gene expression: new insight in the genetics of mood and anxiety disorders

***J. Arloth**, A. Menke, T. Klengel, B. Müller-Myhsok, E. B. Binder;*
Max Planck Institute of Psychiatry, Munich, Germany.

Abnormal hypothalamic-pituitary-adrenal axis regulation is a key neurobiological characteristic of depression. Glucocorticoid receptor (GR) function has been shown to be disturbed in depression, hence polymorphisms altering the transcriptional effects of GR-activation might be interesting candidates for this disorder.

The aim of this study was to identify SNPs associated with glucocorticoid (GC)-induced gene expression changes (*cis*-eQTLs) in peripheral blood.

160 male Caucasians (69 cases, 91 controls) were genotyped using Illumina Human660W-Quad BeadChips. Imputation was performed using IMPUTE-v2 with HapMap III and 1,000 Genomes Project as reference panels. Baseline and stimulated (1.5 mg dexamethasone) gene expression was analyzed using Illumina Human HT12v3 array. Quality control checks, filtering, batch corrections and linear regression analysis was performed in PLINK and R.

Of a total of 4,395 significant *cis*-eQTLs, 2,364 significant response-eQTLs, namely loci associated with GC-stimulated gene expression variation were identified after multiple testing corrections. Over 44% of response-eSNPs were located >200kb from the probe, indicating long-range regulation of gene expression by GCs. This was accompanied by significant enrichment of GR response elements (GREs) within the response-eQTLs. We also observed differences in the affinity of GREs between the opposite SNP alleles. Further, response-eQTLs were significantly more likely to be associated with unipolar depression susceptibility loci from a recent meta-analysis than baseline eQTLs. Interestingly, the majority of these enriched eSNPs alter the gene expression of more distant genes.

In conclusion our data suggest that GC-stimulated eQTLs could expand our understanding of the genetic basis of stress-related disorders, in which GR-function plays an important pathophysiologic role.

P08.21

Atypical haemolytic uraemic syndrome in a large population with a single CFH (complement factor H) gene mutation: modified penetrance data including a newly discovered family, based on mutation testing and family history.

***F. H. Sansbury**[1,2], G. Bromilow[1], C. J. Shaw-Smith[1,2], C. Bingham[3,2], L. Smyth[3], L. Strain[4], T. H. J. Goodship[5,4], P. D. Turnpenny[1,2];*
[1]Peninsula Clinical Genetics Service, Royal Devon & Exeter NHS Foundation Trust, Exeter, United Kingdom, [2]Peninsula College of Medicine & Dentistry, Universities of Exeter & Plymouth, Exeter, United Kingdom, [3]Renal Medicine, Royal Devon & Exeter NHS Foundation Trust, Exeter, United Kingdom, [4]The Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle, United Kingdom, [5]Newcastle University, Newcastle, United Kingdom.

Atypical haemolytic uraemic syndrome (aHUS) can have high morbidity and mortality. Usually it is due to mutations in the Factor H, Factor I, or membrane cofactor protein genes, which play a role in the alternative pathway of complement activation. The trigger events for an episode of HUS leading to renal failure are unknown. We have previously presented initial penetrance data for four families with over 400 individuals, mainly resident in one region, who carry the same Factor H mutation [c.3643 C>G (p. R1215G)].[1] Previously we knew of three families whom we have been unable to link to date. A fourth branch has now come to light.

We have constructed updated Kaplan-Meier survival curves for this mutation to estimate the penetrance. In the current generation we have a large number of unaffected carriers. We have very few obligate unaffected carriers in previous generations, as consanguinity means we cannot clearly trace the line of descent of the mutation. We have therefore estimated the penetrance by including family members at 50 % and 25 % risk with appropriate weighting. Including such members lowers the penetrance from a lifetime risk of around 2/3 to just under 1/2 (0.45; i.e. 4/9). The penetrance of aHUS by adulthood falls from 1/3 to 1/4. We compare this approach with other methods of estimating historical carrier frequency in less than fully penetrant conditions.

1. Sansbury FH *et al.* J Med Genet 2010:47 (Supplement 1).

P08.22

Analysis of association between age and JAK-STAT signaling pathway gene polymorphism

***V. V. Erdman**, R. S. Somova, T. R. Nasibullin, I. A. Tuktarova, O. E. Mustafina;*
Institute of Biochemistry and Genetics, Ufa, Russian Federation.

Aim of study was to estimate alleles and genotypes frequencies dynamic of STAT5A (rs9889323), JAK1 (rs310216) and JAK3 (rs3212780) genes with age.

Total group (1678 unrelated individuals, from 1 to 109 years, ethnic Tatars from Russia) was divided into young (1-20), middle-age I (21-35), middle-age II (36-55), aged (56-74), senile (75-89) and long-living (90-109) persons. Gene polymorphism was analyzed by PCR-RFLP. For comparison of age groups was used Fisher's two-tailed exact test. Search of genetic markers associations with age was performed using logistic regression analysis (SPSS18.0).

In female there was an increase of JAK3*C/*T genotype frequency in age from 30 until 80 years (p=0.045, OR=1.019). In middle-age I group STAT5A*C/*C genotype frequency was lower than in aged (P=0.005), senile (P=0.005) and long-livers groups (P=0.002). Frequencies of STAT5A*C/*T and STAT5A*T/*T genotypes differed between aged individuals, in one hand, and senile and long-lived persons, on the other (p<0.01). STAT5A*T/*T genotype frequency was decreasing with age in both male (57-98 years, p=0.033, OR=0.971) and female (44-87 years, p=0.005, OR=0.976); also only in female there was increasing of STAT5A*C/*T genotype frequency in 44-87 years (p=0.002, OR=1.029).

Thus, STAT5A (rs9889323) and JAK3 (rs3212780) gene polymorphisms are important for achieve of senile age in both male and female; STAT5A (rs9889323) polymorphic marker may be associated with longevity in male.

Supported by grant RFBR 10-04-0164a.

P08.23

Identifying additional variants associated to celiac disease by imputation-based GWAS

***A. Kanterakis**[1], I. Ricaño-Ponce[2], J. Gutierrez[2], H. Westra[2], L. Franke[2], C. Wijmenga[2], M. A. Swertz[1];*
[1]Genomic Coordination Center, Groningen, Netherlands, [2]UMC Groningen, Groningen, Netherlands.

Celiac Disease (CeD) is a complex immune-mediated disorder caused by an unknown number of genetic variants. To date, 39 non-HLA loci have been identified by GWAS that explain 15% of the heritability. Previous GWAS studies in CeD were limited to directly genotyped SNPs. This study aims to boost the GWAS' power through imputation. Genotyping data for four European CeD collections of cases (3,796) and controls (8,154) used in the previous GWAS study will be imputed with the pilot version of the Genome of the Netherlands (GoNL). GoNL consists of whole genome, high coverage (12), sequencing data from 250 Dutch trios. Additionally, we will assess the added value of using a population specific dataset (GoNL) compared with the multi-ethnic 1000 Genomes Project (1KG) reference. We did obtain our first results with the GoNL pilot data of 48 trio's. Preliminary results in chromosome 20 indicate that GoNL contains genotypes for 99.3% of the HapMap550 SNP-set, whereas 1KG covers only 72%. The imputation R2 values were similar between the two reference panels for common markers (MAF > 5%) but exhibit a significant increase for GoNL in rare variants. We also measured the concordance between imputation with HapMap2 and GoNL and a validation dataset consisting of 1,758 samples genotyped on Immunochip in chromosome 3. GoNL imputation showed an average increase from 97% to 99% in the concordance and showed suggestive association for 4 novel variants in the CRR locus (not present in HM2) that are not in linkage disequilibrium with a previous associated SNP.

P08.24

Evaluation of the performance of several imputation strategies in an admixed sample from Mexico City

***S. Krithika**[1], A. Valladares-Salgado[2], J. Escobedo-de La Peña[3], J. Kumate-Rodríguez[4], M. Cruz[2], E. J. Parra[1];*
[1]University of Toronto Mississauga, Mississauga, ON, Canada, [2]Unidad de Investigacion Medica en Bioquimica, Hospital de Especialidades, Centro Medico Nacional Siglo XXI, Mexico City, Mexico, [3]Unidad de Investigacion en Epidemiologia Clinica, Hospital General Regional 1, Dr Carlos McGregor, IMSS, Mexico City, Mexico, [4]Fundacion IMSS, Mexico City, Mexico.

Background: We explored the imputation performance of the program IMPUTE in an admixed sample from Mexico City (N=1,310). We evaluated the: (a) impact of different reference panels on imputation; (b) potential differences in imputation performance between single-step and two-step approaches; and (c) effect of different INFO score thresholds on imputation performance.

Methods: The samples were genotyped with the Affymetrix 5.0 array. We randomly masked 5% of the markers directly genotyped on chromosome 12 (n=1,046) and compared the imputed genotypes with the microarray genotype calls. The concordance rates between imputed and observed genotypes reflect imputation accuracy and the proportion of non-missing genotypes indicate imputation efficacy.

Results: Using an INFO threshold of 0.9 to define valid genotypes, the single-step imputation approach produced slightly higher concordance rates than the two-step strategy (99.1% vs. 98.4% - HapMap phase II combined panel), but at the expense of a lower proportion of non-missing genotypes (85.5% vs. 90.1%). The 1,000 Genomes panel produced similar concordance rates to the HapMap phase II panel (98.4%), but increased substantially the proportion of non-missing genotypes (94.7% vs. 90.1%). The average INFO scores of alleles with frequencies <1% was much lower than the scores for alleles >5%.

Conclusions: The program IMPUTE had an excellent imputation performance for common alleles. Genotype concordances were higher than 98.4% using all the imputation strategies. The best balance of imputation accuracy and efficiency was obtained with the 1,000 Genomes panel. However, rare alleles were not captured effectively by any of the panels.

Insersion/Deletion Polymorphism of The Angiotensin-Converting Enzyme Gene And Knee Osteoarthritis

S. Yigit[1], *A. Inanir*[2], *S. Akkanet*[1], *O. Cecen*[2], *N. Bozkurt*[1], *A. Rustemoglu*[1];
[1]*Gaziosmanpasa University, Medical Faculty, Department of Medical Biology, Tokat, Turkey,* [2]*Gaziosmanpasa University, Medical Faculty, Department of Physical Medicine and Rehabilitation, Tokat, Turkey.*

Objective/Aim:

Knee Osteoarthritis (OA) is a multi-factorial disease. Various genetic polymorphisms have been reported that they might be associated with OA. Angiotensin converting enzyme (ACE) is a critical component of the renin-angiotensin system, and a large body of evidence indicates its proinflammatory role. The aim of the present study was to examine the possible role of angiotensin-converting enzyme (ACE) insertion/deletion (I/D) gene polymorphism as a risk factor in the development of knee OA.

Meterial and Method:

In this study, we studied 102 (60 women, 42 men) patients with knee OA and 150 (87 women, 63 men) healty control groups. ACE I/D **polymorphism** were analyzed by using PCR (Polymerase Chain Reaction) method.

Findings: DD, DI and II genotype frequencies of ACE I/D polymorphism was detected 27 %, 58%, and 15 % in patient group and 32 %, 50 %, and 18 % in control group, respectively. There were not significant differences in genotype/allele frequencies of ACE gene polymorphism between patients with knee OA and controls (p=0.24).

Result: Our results reflect that ACE I/D polymorphism does not have a role in susceptibility to Knee OA in Turkish patients. Currently, we continue to testing higher number of people in both patient and control groups to obtain more data.

P08.26

Association analysis of the leptin receptor gene haplotypes with cardiovascular risk phenotypes

Ž. Tomas, *M. Zajc Petranović, T. Škarić-Jurić, N. Smolej Narančić;*
Institute for Anthropological Research, Zagreb, Croatia, Zagreb, Croatia.

Aims: Leptin is an adipocyte-derived protein with an important role in regulation of food intake, metabolism, reproductive and immune function. It acts through its specific receptor which is predominantly expressed in hypothalamus. Aim of this study was to investigate association of haplotypes of the leptin receptor gene (LEPR) with several cardiovascular (CVD) risk phenotypes, namely, body mass index, waist circumference, serum lipid, fibrinogen and C-reactive protein levels.

Methods: We selected 43 single nucleotide polymorphisms (SNP) in and near LEPR gene from genome-wide association study data (Human Hap300 Illumina platform) of 986 inhabitants of the island of Vis, Croatia. We used Haploview software to assess linkage disequilibrium (LD) structure in genomic region of LEPR gene and Unphased software for haplotype association analysis.

Results: SNPs were grouped into nine blocks according to LD structure. Although none of the single markers in LD block comprised of six SNPs (rs1782754, rs1171269, rs1022981, rs6673324, rs3790426 and rs1049338) was individually associated with waist circumference, haplotype A-C-A-A-G-A of this LD block showed the strongest association signal, p= 7.085 x 10-22. However, after permutation testing the result was found to be only marginally significant.

Conclusion: Haplotype association analysis of CVD risk phenotypes show marginally significant association of LEPR gene only with waist circumference.

P08.27

Allele-based N-Test in linkage analysis

S. Khan[1], *S. Manzoor*[1], *S. Shah*[2];
[1]*Department of Statistics, Islamia College University Peshawar, Peshawar, Pakistan,*
[2]*Department of Statistics & Operations Research, College of Sciences, King Saud University, Riyadh, Saudi Arabia.*

There are many tests of inheritance based upon sibling information for diseases that have late onset. The N-test (Green et al. 1983) is one of these tests, which utilizes information from affected siblings. The N-test is the count in affected siblings of the most frequently occurring haplotype from the father plus the analogous count from the mother. When applied to haplotypes, the N-test excludes recombinant families from the analysis. In this study we modified the N-test to be based on alleles instead of haplotypes. This modified allele-based N-test can include all families (recombinant as well as non-recombinant). We carried out a simulation study to find the thresholds and powers.

P08.28

A robustness study of parametric and non-parametric tests in Model-Based Multifactor Dimensionality Reduction for epistasis detection

J. M. Mahachie John, *E. S. Gusareva, F. Van Lishout, K. Van Steen;*
Montefiore Institute, University of Liege, Liege, Belgium.

Model-Based Multifactor Dimensionality Reduction (MB-MDR) is data mining technique that enables the fast identification of epistasis, without the need to make restrictive assumptions about the modes of inheritance. The most commonly used implementation of MB-MDR involves testing one multi-locus genotype cell versus the remaining cells. By construction, this procedure creates two imbalanced genetic groups that subsequently need to be compared. To date, for continuous traits, we have adopted a standard F-test to make such group comparisons. However, when either the assumption of normality or homoscedasticity or both are violated, highly inflated type I errors and false positives are to be expected. In this study, we assess, through simulations, the effects of aforementioned model violations on the performance of MB-MDR to detect epistasis signals, and propose remedial measures in order to maintain efficiency. Since important lower order genetic effects can also give rise to inflated type I errors or false positive epistatic effects, we restrict our simulation study to pure epistasis models. In particular, we consider normal, chi-square and t-distributions with constant and non-constant phenotypic variances. In all simulating settings, we apply the standard F-test , as well as a novel implementation based on the Welch's F-test .The original traits were either left untransformed or first transformed into new traits via rank and logarithm transformation, or via a rank-transformation to normality.

In conclusion, when performing MB-MDR screening for gene-gene interactions with quantitative traits, we recommend to first rank-transformtraits to normality, prior to classical F-testing.

Association of TNF polymorphism rs1800629 with Multisomatoform Disorder in a group of German patients and healthy controls

K. C. Harms[1], *K. P. Kapitza*[2,3], *L. Pahl*[1], *M. Karst*[3], *M. Stuhrmann*[1], *M. Bernateck*[3];
[1]*Institute of Human Genetics, Hannover Medical School, Hannover, Germany,*
[2]*Department of Psychiatry and Psychotherapy, University of Luebeck, Luebeck, Germany,*
[3]*Department of Anesthesiology, Pain Clinic, Hannover Medical School, Hannover, Germany.*

Causes of MSD are not sufficiently elucidated yet, but genetic factors are suspected to influence MSD pathogenesis. The main symptom MSD patients suffer from is pain. As prior studies have demonstrated that genetic polymorphisms of different proinflammatory cytokines are associated with pain, our goal was to find out whether cytokine polymorphisms are also associated with MSD. Blood from 148 MSD patients and 149 demographically matched healthy controls was used for genotyping of nine polymorphisms located on seven cytokine genes. Thereafter statistical analysis was performed. In addition to the examination of possible associations with MSD, we searched for correlations with individual thermal and mechanical detection and pain thresholds, which were determined by quantitative sensory testing (QST). Association with MSD was found for alleles and genotypes of rs16944 (interleukin 1β), rs1800629 (tumor necrosis factor α) and rs909253 (lymphotoxin α). Due to multiple testing we corrected the results using Bonferroni method, which caused only the association of rs1800629 with MSD to remain significant. The rare A-allele occurred more often in MSD patients while the G-allele could be found more frequently in the control group (p=0.007). Genotype distribution was in line with those results as genotype GG correlated with being healthy (p=0.004) and AG was associated with MSD (p=0.008). We could not detect correlations for any of the tested polymorphisms with the investigated QST parameters. To conclude, we assume the A-allele of SNP rs1800629 (TNF) to be a risk factor for MSD while the G-allele appears to have a protective effect.

P08.30

The association of the MYF6 gene polymorphism with size and composition of muscle fibers

A. Druzhevskaya[1], *I. Astratenkova*[2], *F. Magi*[3], *D. Caporossi*[3];

[1]*Research Institute of Physical Culture, St. Petersburg, Russian Federation,* [2]*St. Petersburg State University, St. Petersburg, Russian Federation,* [3]*University of Rome „Foro Italico", Rome, Italy.*

Transcription factor myf6 regulates expression of many genes involved in development, maturing and work of human skeletal muscle. The results of our previous studies showed that frequency of MYF6 964TT genotype and 964T allele was significantly higher in endurance athletes in comparison with control subjects. The 964T allele carriers had 5% bigger cross-sectional area (CSA) of m. rectus femoris in comparison with 964CC genotype carries.

In the present study the DNA of 8 young healthy physical active males and 26 elite ice-skaters was genotyped using PCR-RFLP method. Histomorphological and immunohistochemical analyses were conducted. Percentage composition and CSA of muscle fibers were measured.

Average CSA of muscle fibers in young males was almost two times larger among TT genotype carriers (41385 ± 14636 mkm^2) in comparison with CC homozygotes (23065 ± 20691 mkm^2) and heterozygotes (25642 ± 20084 mkm^2), (P < 0.0001). Content of fast muscle fibers in ice-skaters was 40.7 ± 2.4% and content of slow fibers was 66.4 ± 2.5%, which did not differ among MYF6 genotypes. In TT homozygotes average CSA of both types of muscle fibers was larger than in CC homozygotes and heterozygotes (TT - 6278.8 ± 1560.4 mm^2, CC - 5500.7 ± 852.7 mm^2, CT - 5195.4 ± 1278.8 mm^2; P = 0.04).

In conclusion, the results of this study in two independent samples have shown the association of 964TT genotype with larger CSA of muscle fibers. It is necessary to conduct repetition studies of the MYF6 C964T polymorphism in greater samples of elite athletes.

New genes for normal hearing function and age-related hearing loss by genome-wide association and expression studies

G. Girotto[1], *M. Lewis*[2], *A. Buniello*[2], *B. Lorente-Cánovas*[2], *N. Pirastu*[1], *K. P. Steel*[2], *P. Gasparini*[1];

[1]*Med Genet, IRCCS-Burlo Garofolo Children Hospital,Univ.Trieste, (Trieste-Italy), Trieste, Italy,* [2]*Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge-Uk, Hinxton-Uk, United Kingdom.*

Little is known about the molecular bases of normal hearing function and age-related hearing loss (ARHL) or presbycusis. Thus, research still needs to study hearing as a complex trait and to understand genetic factors underlying ARHL. To reach this goal an integrated strategy has been designed based on: A) GWAS on hearing quantitative traits as well as on ARHL qualitative traits, and B) expression studies in wildtype mice (at 4 and 5 days postnatal) using immunohistochemistry and confocal microscopy of genes identified by the GWAS. Up to now, for hearing quantitative traits we have run 2 meta-analyses of GWAS data (one with 6 isolated European populations and 1 adding samples from Caucasus and Central Asia), while for ARHL (qualitative traits) a candidate gene analysis has been performed. Matching all the data we defined a list of 27 candidate genes that have been chosen for expression analysis. 5 candidate genes show strikingly specific expression in the cochlea (e.g at the top of sensory hair cells and in the marginal cells of the stria vascularis) while the other 12 are located in multiple cell types in the cochlea. Additional studies now in progress include the identification of variants in genes confirmed by expression analysis, the development of mouse models, and replication of the data.

In conclusion, preliminary results prove the useful combination of GWAS and expression studies in providing new insights into the molecular basis of hearing function and ARHL, and may suggest new targets for hearing impairment treatment and prevention.

P08.32

Association of FOXE1 in nonsyndromic cleft lip with or without cleft palate in Central European and Mesoamerican populations

A. C. Böhmer[1,2], *K. U. Ludwig*[1,2], *S. Herms*[1,2], *T. AlChawa*[1,2], *E. Nasser*[1,2], *P. Wahle*[1,2], *D. C. Tradowsky*[1,2], *S. Nowak*[1,3], *M. A. Alblas*[1,2], *B. Lippke*[1,2], *S. Barth*[1,2], *H. Reutter*[1], *M. M. Nöthen*[1,2], *A. Rojas-Martinez*[4,5], *M. Knapp*[6], *R. Steegers-Theunissen*[7,8], *E. Mangold*[1];

[1]*Institute of Human Genetics, University of Bonn, Bonn, Germany,* [2]*Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany,* [3]*Department of Oral and Maxillofacial Surgery, University of Göttingen, Göttingen, Germany,* [4]*Department of Biochemistry and Molecular Medicine, School of Medicine, Universidad Autonoma de Nuevo Leon, Monterrey, Mexico,* [5]*Centro de Investigacion y Desarrollo en Ciencias de la Salud, Universidad Autonoma de Nuevo Leon, Monterrey, Mexico,* [6]*Institute of Medical Biometry, Informatics and Epidemiology, University of Bonn, Bonn, Germany,* [7]*Erasmus Medical Center, University Medical Center, Rotterdam, Netherlands,* [8]*Radboud University Medical Center, Nijmegen, Netherlands.*

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is one of the most common birth defects. Its etiology is multifactorial, with both genetic and environmental factors contributing to this craniofacial malformation. Several genes have been suggested to play a role in NSCL/P development. However, only the *IRF6* gene has shown a convincing degree of consistency across studies. Recently, the forkhead box E1 (*FOXE1*) gene on chromosome 9q22 has emerged as promising candidate gene (Moreno et al., 2009). In that study, comprehensive genetic analyses in NSCL/P samples from different ethnicities revealed two markers, located inside a 70 kb LD-block containing *FOXE1*, to be strongly associated with NSCL/P. Also, *Foxe1* knockout-mice show a clefting phenotype, providing further evidence for *FOXE1* being a susceptibility gene for NSCL/P. However, so far, the genetic findings on *FOXE1 i*n NSCL/P have not been convincingly replicated.

In order to further elucidate the contribution of *FOXE1* to NSCL/P, we investigated the two most strongly associated markers of the initial study (rs3758249, rs4460498) in two case-control samples of Central European (949 NSCL/P cases, 1,163 controls) and Mayan Mesoamerican (156 NSCL/P cases, 338 controls) descent. We obtained significant associations for both variants in both samples, with rs4460498 providing the lowest *P*-values (P_{Europe}=6.50x10^{-06}, P_{Mayan}=0.0151). Furthermore, we obtained evidence that the effect size increases for homozygous carriers of the risk alleles, suggesting a recessive effect. Our data conclusively identify *FOXE1* as second confirmed candidate gene for NSCL/P and give rise to further investigations into its underlying functional basis.

P08.33

Analysis of association of polymorphic variants of D5S422 and D5S402 receptor gene gamma-aminobutyric acid GABRG2 with the level of intellectual development of man.

A. Maraleva, *O. Gumerova;*

Bashkir State Pedagogical University name of M.Akmully, Ufa, Russian Federation.

INTRODUCTION: gamma-aminobutyric acid (GABA) is the basic type of inhibitory neurotransmitters in humans, providing a process of inhibition of the central nervous system by using three types of receptors. The gene GABRG2 (5q34) encodes the alpha subunit of the gamma receptor GABA and contains 9 exons. This gene has two polymorphic site (D5S422, D5S402), affecting gene expression and alter the permeability of the membrane for the transmission of nerve impulses. The analysis of polymorphic variants of D5S422 and D5S402 on the GABRG2 gene in individuals with different levels of intellectual development.

METHODS: The polymerase chain reaction (PCR) carried out an analysis D5S422 and D5S402 polymorphisms of the gene receptor gamma-aminobutyric acid GABRG2 in 180 unrelated individuals. The level of intellectual development (IQ) in subjects determined by the method of Cattell. In accordance with the performance IQ subjects were divided into two groups: those with high (above 140 points) and low (below 95 points) level of intellectual development.

RESULTS: Analysis of associations of polymorphic loci studied showed a significant reduction in the frequency of allele D5S422 * 15 (7.61% vs. 21.15% in the group with low IQ; P = 0.0009, x2 = 13.3887), and increased frequency of allele D5S402 * 2 (57.89% vs. 28.84%, P = 0.0031, x2 = 9.3491) in the group with a high level of intellectual development.

Comparison of running time of variance-component based methods for whole genome association analysis

G. R. Svishcheva, *N. M. Belonogova, T. I. Axenovich, Y. S. Aulchenko;*

Institute of Cytology and Genetics, Novosibirsk, Russian Federation.

One of the most flexible and powerful methods of accounting for genetic substructures in genetic association testing is the variance component (VC) approach based on the mixed models. To decrease the computational com-

plexity of this method, it was proposed using a two-stage score test instead of the standard likelihood ratio test. Several fast implementations of the score test, including approximate ones, have been developed recently. These methods differ in their computational speed and the accuracy of the SNP effect estimation. We compared the running time of the different implementations of score test (mmscore, EMMAX, FaST-LMM, GRAMMAR-Gamma), using simulated data. The GRAMMAR-Gamma implementation provides the fastest means to run genome wide association study using mixed models. Compared with EMMAX and the FaST-LMM, GRAMMAR-Gamma achieved a speed-up of more than 30 and 10 times, respectively, for the data studied. The more individuals and genetic markers are analyzed, the larger is the expected speed-up of GRAMMAR-Gamma compared to other methods. While the scenario above assumes use of an SNP array, one of the current challenges in statistical genomics is the analysis of whole-genome re-sequencing data. We investigated a scenario in which 36.5 millions of SNPs in 3,000 people were analyzed. Using GRAMMAR-Gamma method, the analysis of this data set was completed in 38 min.
We conclude that GRAMMAR-Gamma is a fast tool for the analysis of human GWA scans. Its role will increase in the future with the availability of larger sample sizes and increased number of genetic markers.

P08.35

Linkage analysis of quantitative traits with a spike in the distribution

T. I. Axenovich[1]*, I. V. Zorkoltseva*[1]*, C. M. van Duijn*[2]*;*
[1]*Institute of Cytology and Genetics, Novosibirsk, Russian Federation,* [2]*Erasmus Medical Center, Rotterdam, Netherlands.*

Quantitative data coming from proteomics and metabolomics studies often have irregular distribution, characterized by presence of a proportion of observations in the point-mass (spike) at zero and some continuous distribution of non-negative values. Thus these data contain information about both the binary (zero or not) and continuous components. The general approach to simultaneous analyses of these components was proposed by Broman (2003). However, his method focuses on experimental crosses. We introduced Broman's approach in the parametric linkage analysis of pedigree data, which is applicable to large human pedigrees of arbitrary structure. We developed GADS software, which implements this method. Our software package includes not only the programs for parametric linkage analysis, but also the program for complex segregation analysis, which allows the estimation of the model parameters used in linkage. We tested our method on the real data about vertical cup-to-disc ratio, the important characteristic of the optic disc associated with glaucoma, in a large pedigree from a Dutch genetically isolated population. Significant linkage signal was obtained on chromosome 6q23-q24 (LOD = 3.33) with the help of GADS, whereas the analysis of the continiously distributed values demonstrated only a suggestive linkage to this chromosome. Our results support the feasibility of the simultaneous analyses of the point-mass observations and continuous measurements for the QTL mapping. The software GADS is freely available at http://mga.bionet.nsc.ru/soft/index.html

P08.36

Implication of two transforming growth factor-beta1 (TGF-beta) gene polymorphisms in TGF-beta serum levels and susceptibility to acute myocardial infarction

A. Tabatabaei Panah[1]*, R. Akbarzadeh Najar*[2]*, S. Ghaderian*[2]*;*
[1]*Department of Biology, Islamic Azad University, East Tehran Branch, Tehran, Islamic Republic of Iran,* [2]*Department of Medical Genetics, Faculty of Medicine, Shahid Beheshti University of Medical Sciences and Health Services, Tehran, Islamic Republic of Iran.*

Purpose: Transforming growth factor beta-1 (TGF-β1) gene plays an important role in acute myocardial infarction (AMI), however little is known about the relation of variations within the gene and risk of cardiovascular diseases. In this study, we evaluated the influence of TGF-β1 polymorphisms on the onset and progression of AMI.
Methods: Genomic DNA and peripheral blood mononuclear cells (PBMCs) of 900 enrolled patients with AMI and 900 control subjects were extracted. The -509 C/T and 913G/C TGF-β1 polymorphisms as well as mRNA expression and serum levels of TGF-β1 were detected.
Results: The frequency of 'T'allele in -509 C/T and 'C' allele in 913G/C polymorphisms were significantly higher in the patients than control subjects (P<0.001). There were significant differences in circulating levels of TGF-β1 in the patients than in control subjects (34.96±1.74 via 30.46±1.46 respectively, P<0.001) which these concentrations are associated with its gene polymorphism. There was a significant increase in serum levels in the patients who carry the 'T' allele in -509 C/T and 'C' allele in 913G/C, respectively (P<0.001). The mRNA expression levels of TGF-β1 were significantly higher in the patient serums compared with controls (TGF-β1/β-actin, 2.86±1.02 via 1.28±0.89, P<0.001).
Conclusions: Our results confirmed the association between the TGF-β1 polymorphisms and risk of AMI which suggest that genetic polymorphisms in TGF-β1 might be helpful for determining susceptibility to AMI in Iranian patients. There are also significant relationship between serum TGF-β1 and occurrence of AMI and susceptibility to AMI might be related to TGF-β1 gene expression which affects serum levels.

Genetic causes of Primary microcephaly in Iranian population

H. Najmabadi[1]*, L. Musante*[2]*, F. Larti*[1]*, Z. Fattahi*[1]*, M. Garshasbi*[2]*, S. Abedini*[1]*, M. Hosseini*[1]*, A. Tzschach*[2]*, F. Behjati*[1]*, T. Wineker*[2]*, K. Kahrizi*[1]*, H. Ropers*[2]*;*
[1]*Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran,* [2]*Department of Human Molecular Genetics, Max Planck Institute for Molecular Genetics, Berlin, Germany.*

The volume of human brain through evolution has been tripled since the divergence from chimpanzees. This change has resulted in much higher complex wiring and physiology of the human brain. In primary microcephaly, reduction in brain size-without gross abnormalities in brain architecture or gyral formation-results in intellectual disabilities in majority of cases. So far, seven genetic loci (MCPH1-7) with their genes have been mapped and additional four novel genes (CAPN10, CNKSR1, HIST1H4B, and ZBTB40) have been identified by our group for this disorder. Identification of these genes, which result in microcephaly, can explore the understanding of evolution of human brain size.
Total of 114 families with two or more affected individuals with ID and primary microcephaly have been recruited at Genetics Research Center since 2004 of which 18 families had ataxia or other minor neurological symptoms. Short stature was observed in 12 families and the remaining families did not show any additional features. In addition, all the affected individuals with MCPH 5 gene regardless of their mutation had short stature. All the known genes have been excluded and the causative mutation in MCPH genes was detected only in 20% of the families. For the rest large families, autozygosity mapping was performed and one affected from each familiy has been subjected to exome sequencing. So far, we have identified number of novel loci on chromosome 2, 4, 14, 17, and 21. Our results indicate that there are additional genes involved in microcephaly and there is high heterogeneity among the microcephaly families.

P08.38

Analyses of MEFV Mutations in Patients with The Rheumatoid Arthritis

A. Inanir[1]*, S. Yigit*[2]*, A. Habiboglu*[1]*, A. Rustemoglu*[2]*, O. Ates*[2]*;*
[1]*Gaziosmanpasa University Medical Faculty, Department of Physical Medicine and Rehabilitation, Tokat, Turkey,* [2]*Gaziosmanpasa University Medical Faculty, Department of Medical Biology, Tokat, Turkey.*

Objective/Aim: Rheumatoid Arthritis (RA), a systemic, inflammatory, autoimmune disorder, is called a complex genetic disease, meaning that several genes and enviromental factors act in concert to cause pathological events. Immum system genes including MEditerranean FeVer (MEFV) gene may affect the phenotype of RA. Therefore, we aimed to investigate the relationships of MEFV gene mutations (M694V, M680I, V726A, P369S and E148Q and) and Rheumatoid Arthritis in Turkish population.
Material And Method: In this study, we studied 110 (63 women, 47 men) patients with RA and 140 (77 women, 63 men) healty control groups. MEFV mutations were analyzed by using PCR (polymerase chain reaction) and RFLP (Restriction Fragment Length Polymorphisms) methods.
Findings: The frequencies of MEFV gene mutations were detected 27/110 (24.5%) and 15 (10,7 %) in patient group and control group, respectively. Our results showed that there were no significant differences between MEFV gene mutations and Rheumatoid Arthritis (p=0.006).
Result: Our results reflect that MEFV mutations have a role in susceptibility to Rheumatoid Arthritis in Turkish patients. Currently, we continue to testing higher number of people in both patient and control groups to obtain more data.

P08.39

Genome-wide, permutation-based rare variant analysis with INTERSNP-RARE

D. Drichel[1]*, A. Lacour*[1]*, C. Herold*[1]*, V. Schueller*[2]*, T. Vaitsiakhovich*[2]*, M. Leber*[2]*, M. Angisch*[2]*, T. Becker*[1,2]*;*
[1]*DZNE - German Center for Neurodegenerative Diseases, Bonn, Germany,* [2]*Institute for Medical Biometry, Informatics and Epidemiology, Bonn, Germany.*

Due to growing accessibility to comprehensive, genome-wide data, systematic investigation of disease association with rare variants (MAF<5%) becomes increasingly appealing.

We present INTERSNP-RARE, a software for genome-wide rare-variant testing using different testing procedures: CMAT (cumulative minor allele test), COLL (collapsing test, a version of CMC) and FR (Fisher_rare, a version of the Fisher combination test). We offer an implementation of corresponding extensions to variable-threshold (VT) tests using a method based on permutations. Combined with permutation-based determination of p-value, this approach promises maximized power without overcorrection for multiple testing while accounting for LD structure.

All rare-variant tests operate on bins, physically continuous chromosomal segments. Bins can be created algorithmically, using on distance or number of (rare) SNPs. Additionally, creating bins from on user-supplied data in various formats is supported, facilitating binning strategies based on a priori information like LD block structure or genomic function. Various functions for bin modification, like merging and flanking are supported.

Results from our power study using simulated data offer insights into strengths and shortcomings of implemented tests under different conditions. Using 20 to 60 causal, protective or neutral rare SNPs per bin, we find that the single-marker analysis outperforms other approaches in some scenarios, in particular for relatively large MAFs and few causal markers (~10%), while CMAT and COLL have excellent power in models with ~30-50% damaging and up to 20-30% protective variants. FR is well-powered even for a low fraction of causal SNPs (upwards from 10%) and highly robust with increasing number of protective markers.

P08.40

Explore the association between cytokines, cytokine related genes and antidepressant in major depressive disorder: a Bayesian approach

W. Chien[1,2]*, Y. Chang*[3]*, I. Lin*[1]*, Y. Bai*[3]*, M. Lin*[1,4]*;*
[1]*Institute of Public Health, National Yang-Ming University, Taipei, Taiwan,* [2]*Deparment of Life Sciences and Institute of Genome Sciences, National Yang-Ming University, Taipei, Taiwan,* [3]*Department of Psychiatry, Taipei Veterans General Hospital, Taipei, Taiwan,* [4]*Department of Medical Research & Education, Taipei Veterans General Hospital, Taipei, Taiwan.*

With the recent advance in pharmacogenetics, how to combine data of genetic markers and biomarkers to predict treatment response in diseases has become an important issue in population health sciences. This kind of studies generally contain data from a number of subjects, each of whom has been observed on one or more times, with a binary or continuous response and possibly some covariates recorded for each subject on every time. Thus, the issue of the correlation of repeated measures in a single subject has to be taken into account in statistical analysis. For binary outcomes with repeated measurements, one of the most commonly used analysis methods is generalized linear mixed model (GLMM) and the parameter estimation in GLMM typically involves maximum likelihood. However, for small sample sizes, likelihood-based estimation can be unreliable and their variance components are difficult to estimate. To overcome such problems, we apply the Bayesian framework in the GLMM by assigning prior distributions for the fixed effects, random effects as well as for variance components. After deriving posterior distributions of these parameters, we can generate posterior samples by MCMC to make inferences. The performance of the proposed procedures was compared with likelihood-based methods by simulation studies. Finally, we applied our proposed model to a case-control major depression study with twelve week treatment of antidepressants to evaluate whether cytokines and their related genes might play some role in susceptibility to depressive disorders as well as in the treatment response of antidepressant.

Analysis of IL-17 A and IL17F Genetic Polymorphisms as Risk Factors for Allergic Rhinitis

F. Fatahi, H. Khazraei, A. Salehi, ***N. Bagheri****, K. Kihan Ghatreh, M. Hashemzadeh;*
Cell and Molecular Research Center, Shahrekord University of Medical Sciences, Shahrekord, Islamic Republic of Iran.

Background and Aims: The development of allergic rhinitis entails a complex interaction between genetic predisposition and environmental exposure to different factors that allergens are the most important. Responding molecules are; chemokine's and their receptors, interleukins and their receptors, eosinophil peroxidase and leukotriene's, among others. The interleukin-17 cytokines (IL17A and IL17F) are emerging as critical players in host defense responses and inflammatory diseases. This study investigated the association between single-nucleotide polymorphisms (SNP) in IL17A gene promoter (rs2275913, IL17 G152A) and IL17F exon 3(rs763780 IL17F 161His-Arg) and Rhinitis-related traits among the patients in Iran.

Methods: DNA was extracted using standard phenol-chloroform method. The screening of mentioned polymorphisms was performed using PCR-RFLP procedure. A case- control association study was performed (rhinitis group; n=300 and control group; n=160). Chi- square test was performed to compare proportions of subjects with different clinical features among subjects with different genotypes.(All statistical analyses were performed using SPSS).

Result: There was significant association between rs2275913; IL17A and allergic rhinitis (p=0.025) but no association between rs763780; IL17F and cited disease in Chaharmahal va Bakhtiari province was found (p=0.468).

Conclusions: Our data indicated that the IL17A may play an important role in the inflammatory response and promoting allergic rhinitis and rs 763780; 1L17F have no role in rhinitis in Iran.

P08.42

Contribution of APO E allleles and ACE I/D polymorphism in the development of hypertension (HT) in Sleep Apnea-Hipoapnea Syndrome patients

M. Alonso[1]*, J. De Frutos*[2]*, C. Arroyo*[2]*, M. Durán*[1]*, I. Ferandez*[1]*, F. Del Campo*[2]*;*
[1]*IBGM (Instituto de Bioloogía y Genética Molecular), Valladolid, Spain,* [2]*H.U.Rio Hortega, Valladolid, Spain.*

Sleep apnea/hypopnea syndrome (SAHS) is a common condition affecting approximately 0.3-4% of the middle-aged population and is defined on the basis of symptoms of daytime sleepiness and objective measures of disordered breathing

during sleep. . Several studies have identified SAHS as a risk factor for hypertension, but a direct etiologic link between these disorders has not been established definitively.

Aims: Evaluate the influence of polymorphisms on the APO E gene and the I/D polymorphism on ACEI in the presence of hypertension (HT) In Sleep Apnea - Hipoapnea Syndrome patients.

Methods: APO E and ACEI I/D genotypes were obtained from 99 controls and 114 patients with a diagnosis of sleep apnea-hipoapnea sindrome after polysomnography in the Sleep unit of the Rio Hortega Hospital.

Results: There were not any difference in the APO E alleles frequency between patients and controls, but SAHS patients carrying the APO E ε4 allele showed an increased frequency of HT 3,145 higher than ε3 homozygous and ε2 carriers(CI 1.269-7.79). These findings keep significant even after correction for sex . The ACE I/D genotypes were in Hardy-Weinberg equilibrium (p<0.05) and they seem don´t have any influence on the development of HT in these patients (DD OR 0,478 (CI 0,21-1,08)

Conclusions:. Our results demonstrate that the presence of the ε4 allele increases the probability to develop HT in Sleep Apnea patients. We suggested that this allele could be useful as a biological marker for identification of a subgroup of SAHS patients who are more likely to have HT.

P08.43

SVM-based generalized multifactor dimensionality reduction approaches for detecting gene-gene interactions in family studies

Y. Chiu*, Y. Fang;*
Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan.

Gene-gene interaction plays an important role in the etiology of complex diseases, which may exist without a genetic main effect. Most current statistical approaches, however, focus on assessing an interaction effect in the presence of the gene's main effects. It would be very helpful to develop methods that can detect not only the gene's main effects but also gene-gene interaction effects regardless of the existence of the gene's main effects while adjusting for confounding factors. In addition, when a disease variant is rare or when the sample size is quite limited, the statistical asymptotic properties are not applicable; therefore, approaches based on a reasonable and applicable computational framework would be practical and frequently applied. In this study, we have developed an extended support vector machine (SVM) method and an SVM-based pedigree based generalized multifactor dimensionality reduction (PGMDR) method to study interactions in the presence or absence of main effects of genes with an adjustment for covariates using limited samples of families. A new test statistic is proposed for classifying the affected and the unaffected in the SVM-based PGMDR approach to improve performance in detecting gene-gene interactions. Simulation studies under various scenarios have been performed to compare the performances of the proposed and the original methods. The proposed and original approaches have been applied to a real data example for illustration and comparison. Both the simulation and real data studies show that the proposed SVM and SVM-based PGMDR methods have great prediction accuracies, consistencies, and power in detecting gene-gene interactions.

P08.44

The frequency of common α-deletions among β-thalassemia minor individuals and the importance of it in blood indexes change by comparing data in an Iranian population.

***A. Moosavi**, M. Karimipoor;*
Molecular Medicine Department,Biotechnology Research Center,Pasteur Istitute of IRAN, Tehran, Islamic Republic of Iran.

β-thalassemia is the most common monogenic disorder in Iran, and one of the challenges in the screening of the carriers is the coinheritance of alpha thalassemia mutations. Alfa-thalassemia acts as a secondary modifier in clinical manifestations of beta thalassemia. In the view of high prevalence of alfa - thalassemia mutations in many parts of the country, its coinheritance with beta-thal may cause misdiagnosis.

The aim of this study was to determine the carrier frequency of alpha deletions in carriers of beta-thalassemia with known mutations in beta-globin gene and compare some data of them to interpret the importance of these coinheritances.

The study includes families referred from different primary health care centers with microcytic hypochromic anemia [MCV<80fl; MCH<27pg] and A2> 3.5. After providing informed consent, genomic DNA was extracted from peripheral blood leukocytes by salting out method. Allele-specific PCR was exp;oited for common β-mutations. Then common alpha deletions (-α3.7, -α4.2, -α20.5 and

- MED) were screened by multiplex gap PCR.

Among 227 β-thalassemia minor individuals we found alfa thal mutations in 43 cases: 37 heterozygote -α3.7(16.3%), 5 homo -α3.7 (2.2%)and 1 -MED (0.44%).

The results show the high prevalence of the coinheritance of alfa- and beta-thal in a selected Iranian population and the changes are different. Therefore, it is highly recommended that physicians and genetic counselors involved in the screening program of beta-thalassemia major in the country consider this phenomenon.

P08.45

A novel gene-gene interaction: the role of SPRY2 and SPRY4 in tooth agenesis susceptibility

***M. F. Alves-Ferreira**[1], T. Pinho[2], A. Sousa[1,3], J. Sequeiros[1,3,4], C. Lemos[1,3], I. Alonso[1,3];*
[1]UnIGENe, IBMC, University of Porto, Porto, Portugal, [2]CICS, ISCS-N/CESPU, Portugal, Paredes, Portugal, [3]ICBAS, University of Porto, Porto, Portugal, [4]CGPP, IBMC, University of Porto, Porto, Portugal.

Tooth agenesis affects 20% of the world population and agenesis of maxillary lateral incisors (MLIA) is one of the most frequent subtypes, characterized by the absence of formation of deciduous or permanent lateral incisors. Odontogenesis is a complex mechanism regulated by sequential and reciprocal epithelial-mesenchymal interactions. Disturbances in FGF signalling can lead to abnormalities in odontogenesis, resulting in alterations in the formation of the normal number of teeth. Sprouty family members function as a negative feedback regulator of FGF signalling.

Therefore, our aim was to study for the first time the involvement of SPRY2 and SPRY4 genes in MLIA susceptibility and to explore a possible gene-gene interaction.

A case-control study, in a total of 306 individuals, is underway; a case-control ratio of 1:2 was achieved in order to increase the study statistical power. We selected 10 tagging single nucleotide polymorphisms (SNPs), which were genotyped by SNaPshot, using a multiplex approach.

We found that the GA genotype of rs504122 in SPRY2 gene leads to an increased risk in individuals with MLIA (p=0.008). Noteworthy, we uncovered a strong synergistic interaction between these two genes and MLIA liability.

Although the molecular mechanisms involved in tooth agenesis remain unknown, our results provide the first evidence of the involvement of sprouty genes in MLIA susceptibility, leading to a better understanding of the genetic mechanisms underlying this trait.

Polymorphisms in genes involved in the hypoxia-related signaling pathway are associated with abdominal aortic aneurysm and aortoiliac occlusive disease

***E. Strauss**[1], K. Waliszewski[2], R. Staniszewski[2], K. Milanowska[1], R. Slomski[1];*
[1]Institute of Human Genetics the Polish Academy of Sciences, Poznan, Poland, [2]Department of General and Vascular Surgery, Poznan University of Medical Sciences, Poznan, Poland.

The four SNPs in genes involved in the hypoxia-related signaling pathway: *VEGF +405G>C* (rs2010963), *HIF1A 1771C>T (*rs11549465), *1790G>A (*rs11549467) and *HMOX1 -413A>T* (rs2071746) were analyzed in search for the functional differences predisposing either to the aneurysmal or to the occlusive type of arterial diseases.

The case-control study was designed, in which the series of 535 patients with abdominal aortic aneurysm (AAA), 365 patients with aortoiliac occlusive disease (AOID) and 316 persons without symptoms of vascular diseases were analyzed. Associations between studied alleles/haplotypes and the intermediate traits related to the vascular diseases were also examined.

The frequency of *VEGF +405C* allele carriers in the AAA (50,6%) and AIOD (49,3%) groups was 1,4-fold higher than that in the control group (41,6%; p=0,01 and p=0,048, respectively). AIOD patients significantly differ from the other groups in the frequency of *HMOX1 -413T* allele carriers; the observed frequencies were: 61,8% (AIOD) << 71,3% (AAA, p=0,003) < 74,8% (controls; p=0,0004). In patients, weak positive correlations between dose of *HMOX1 -413T* allele and fasting glucose (β=0,074; p=0,037) and triglyceride (β=0,070; p=0,04) levels were found (adjusted for age, gender and type of vascular disease). However those associations should be considered carefully because there was a deviation in *HMOX1* genotype distribution from HWE in two out of three studied groups.

In conclusion, 1) *VEGF +405C* allele is the risk factor of large arteries diseases, 2) *HMOX1 -413T* allele may be involved in AAA pathogenesis by increasing the predisposition to diabetes and dyslipidemia. Supported by the National Science Centre grant NN403_250440.

P09.002

ICAM-1 and CCR5 gene polymorphism and susceptibility to abdominal aortic aneurysm or aortoiliac occlusive disease

***A. Korcz**[1], S. Hryhorowicz[2], O. Zakerska[2], K. Pawlaczyk[3], M. Molinska-Glura[3], G. Oszkinis[3], R. Slomski[1], M. Gabriel[3];*
[1]Polish Academy of Sciences, Poznan, Poland, [2]Adam Mickiewicz University, Poznan, Poland, [3]Poznan University of Medical Sciences, Poznan, Poland.

Abdominal aortic aneurysm (AAA) is a life-threatening condition affecting 4-9% of population with a risk increasing with age. Aortoiliac occlusive disease (AIOD) is characterized by aortoiliac obstruction and is caused by advanced atherosclerosis. Both of these common vascular disorders are considered to have multifactorial etiology with both genetic and environmental risk factors involved. Destructive remodeling of extracellular matrix and histological signs of chronic inflammation associates both of these pathologies.

ICAM1 and chemokine CCR5 are mediators of inflammatory process. The CCR5_32 deletion genetic variant was found to be associated with AAA in Italian population. The ICAM1 (K469E) genetic variant was characterized as potentially affecting the autoimmunity process.The purpose of the present study was to determine if there is an association between the ICAM1 (nt+469) or CCR5_32 deletion gene polymorphisms and susceptibility to AAA or AIOD in Polish patients. Genotyping was performed by PCR and gel electrophoresis for CCR5 and by pyroseqencing for ICAM1 in three selected groups: 300 patients with AAA and 305 patients with AIOD who underwent surgery; 310 individuals from control group. Genotypes were compared with demographic and clinical data of subjects and analyzed in relation to risk factors. No significant differences in genotype distribution and allele frequencies of ICAM1 (nt+469) or CCR5_32 deletion were found between patients with AAA or AIOD and control group. Conclusion: We found no evidence of association of ICAM1 (nt+469) or CCR5_32 gene polymorphisms and AAA or AIOD in Polish patients.

P09.003

Correlation between polymorphism of ACE gene and Insulin-like Growth Factor-I (IGF-1) in malnourished children

***O. C. Marginean**[1], C. Duicu[2], C. Banescu[3];*
[1]Pediatric Department No 1, University of Medicine and Pharmacy Tg. Mures, Romania, Tg. Mures, Romania, [2]Pediatric Department No 2, University of Medicine and Pharmacy Tg. Mures, Romania, Tg. Mures, Romania, [3]Genetic Department, University of Medicine and Pharmacy Tg. Mures, Romania, Tg. Mures, Romania.

Malnutrition is a clinical problem caused by inadequate intake of one or more nutritional elements, and it is one of the most important health problems in developing countries. The aim of this study is to determine the relationship among body weight, concentrations of IGF-1 and ACE gene polymorphisms in malnourished children.

Material and method: The study group consisted of 50 children diagnosed with malnoutrition. Fifty healthy children were enrolled as the control group. All children were genotyped for I/D gene ACE polymorphism.

Results: Three genotypes of 16th intron of ACE gene(D/D,D/I,I/I) were detected. The distribution of ACE DD, ID, and II genotypes in malnourished patients were 32; 50 and 18%, respectively; while for the control group were 44; 44 and 12% respectively. Compared with control subjects, I-allele frequency and I/D+I/I frequency of ACE gene were higher in malnourished children (43% and 68%, respectively; P>0.05).

Malnourished children had significantly lower body weight, height, mid-arm circumference, skinfold thickness, mean serum IGF-1 levels compared with healthy subjects (P<0.05).

Conclusions: There is polymorphism of the ACE gene in healthy and malnourished children. Malnutrition is characterized by the important decreases in the IGF-1 level. ACE polymorphism is not a significant factor for nutritional disorders and does not contribute to the odds of malnoutrition in children.

Ideopathic achalasia is a rare esophageal motility disorder with a lifetime prevalence of 1:10,000. It is a neurodegenerative disorder in which the neurons of the myenteric plexus are lost, leading to dysfunction of the lower esophageal sphincter (LES) and to a derangement of esophageal peristalsis. In the final stage of achalasia, esophageal motility is irreversibly impaired, and complications ensue because of the retention of food that is no longer transported into the stomach. The cause of achalasia is mainly unknown, but autoimmune processes appear to be involved in individuals with a genetic susceptibility. In the present study, we performed the first systematic association analysis for achalasia using Illumina´s Immunochip (Trynka, G. *et al.*, Nature Genetics 2011), enriched for immune-relevant loci. To the best of our knowledge, we analyzed the largest achalasia case-control sample that has been studied so far. The sample consisted of 633 cases with ideopathic achalasia and 2,653 population-based controls from Germany, Belgium, and The Netherlands. After quality control 126,899 markers from the Immunochip remained for association testing and the analysis yielded a total of 24 markers reaching genome-wide significance. All of the associated markers are located within the *HLA* region and the most significant finding (rs1794265; P=7.53x10^{-15}) yielded a stronger signal in females (P=2.83x10^{-15}) than in males (P=1.94x10^{-3}). Further analyses to determine how many independent findings are present in the *HLA* region and to assess the *HLA* alleles that may be involved in the disease process are ongoing and will be presented at the congress.

Adipophilin (ADRP/ADPH/PLIN2): Variability in Exonic Regions and Secretion of Adipophilin into Breast Milk

Z. Splichal[1], *L. Fauveau*[1], *J. A. Bienertova Vasku*[1], *J. Tomandl*[2], *M. Tomandlova*[2], *Z. Hodicka*[3], *P. Ventruba*[3], *A. Vasku*[1], *P. Bienert*[1];
[1]*Department of Pathological Physiology, Faculty of Medicine, Masaryk University, Brno, Czech Republic,* [2]*Department of Biochemistry, Faculty of Medicine, Masaryk University, Brno, Czech Republic,* [3]*Clinic of Gynecology and Obstetrics, University affiliated Hospital, Masaryk University, Brno, Czech Republic.*

Introduction: Adipophilin (ADRP/ADPH/PLIN2), a member of the perilipin (PAT) family of lipid droplet proteins, is believed to play a crucial role in both formation and secretion of milk lipids in mammals. The aim of our study was to determine whether adipophilin is secreted into human breast milk and to associate adipophilin levels in breast milk with the exonic variations of the adipophilin gene.

Material and methods: The total of 20 pregnant women with physiological pregnancy, originating from the Caucasian Central-European population, were enrolled into the study and serum-milk sample duos were collected at the time of birth and at the days 1-3, 12-14, 28-30, 88-90 and 178-180 postpartum and investigated using ELISA-based methodology. The exons 3-7 of the PLIN2 gene were directly sequenced.

Results: Adipophilin was constantly secreted into breast milk during the whole period of the study. The maternal serum circulating levels were extremely low (<0.8 ug/l), while the adipophilin levels in breast milk substantially exceeded serum levels at the given timepoints (p = 0.03). Two SNPs in exonic sequence of PLIN2 gene were identified, synonymous rs2228416 and missense rs35568725 that were not associated with maternal serum / breast milk levels of adipophilin.

Conclusion: This is the first study to demonstrate that adipophilin is secreted into human breast milk during the whole 6 months after the birth. We do not report major association of investigated exonic variations of PLIN2 gene with adipophilin levels in maternal serum / breast milk in the Central-European population.

P09.007

The impact of CFH, ARMS2 and APOE gene polymorphisms in Greek age related macular degeneration patients

M. B. Petersen[1], *I. Skalidakis*[2], *A. Velissari*[3], *M. Apostolopoulos*[2], *M. Stefaniotou*[4], *G. Kitsos*[4], *H. Kokotas*[1], *C. Kroupis*[3];

Gennimatas' Hospital, Athens University Medical School, Athens, Greece,* [3]*Department of Clinical Biochemistry, Attikon Hospital, Athens University Medical School, Athens, Greece,* [4]*Department of Ophthalmology, Ioannina University Medical School, Ioannina, Greece.*

Age related macular degeneration (ARMD) is a degenerative ocular disease, which may lead to serious loss of central vision. Genetic background seems to have an impact on the onset and progress of the disease. The aim of the present study was to assess the association between ARMD and the single nucleotide polymorphisms (SNPs) Y402H (rs1061170) in the CFH gene, A69S (rs10490924) in the ARMS2 gene and APOE2 (rs7412) in the APOE gene. Genotyping was performed on isolated DNAs from peripheral blood samples from 27 patients with ARMD and 34 age-matched controls, all of whom were clinically evaluated with optical acuity measurement and funduscopy. A real-time PCR-melting curve analysis methodology in the LightCycler (Roche) was developed for the Y402H SNP genotyping. Genotyping of the A69S and APOE2 SNPs was performed with PCR-RFLP methods. Statistically significant association was found for Y402H SNP (OR=2.68, p=0.012). The association between ARMD and the A69S and APOE2 SNPs did not reach levels of statistical significance. The present study confirmed the reported association between Y402H SNP and ARMD in the Greek population as well. The potential association of the A69S and APOE2 SNPs with the disease amidst Greek population needs further evaluation on larger samples.

Modelling the genetic risk in age-related macular degeneration

F. Grassmann[1], *L. G. Fritsche*[1], *C. Keilhauer*[2], *I. M. Heid*[3], *B. H. F. Weber*[1];
[1]*Institute for Human Genetics, Regensburg, Germany,* [2]*University Eye Hospital Würzburg, Würzburg, Germany,* [3]*Institute of Epidemiology and Preventive Medicine, Regensburg, Germany.*

Age-related macular degeneration (AMD) is a common sight-threatening disease of the central retina affecting approximately 1 in 30 Caucasians. Besides age and smoking, genetic variants from nine gene loci have reproducibly been associated with this condition and likely explain a large proportion of disease. Here, we genotyped 16 AMD risk variants from 8 gene loci in 986 late stage AMD patients and 796 controls. We developed a risk model for AMD based on a genetic risk score (GRS) calculated from a parsimonious set of thirteen variants from eight AMD loci. The model exhibited good discriminative accuracy (area under the receiver-operating curve = 0.820). We present a five-category risk classification with the relative risk for AMD of individuals in the highest category (GRS >3.44, about 0.5% of general population) being 70.4 compared to subjects with the most common genetic background (GRS -0.05-1.70, 40.2% of general population). Noteworthy, younger AMD patients with an age below 75 years had a significantly higher genetic risk score (1.87, 95% CI: 1.69-2.05) than patients aged 75 and above in the same risk groups (1.45, 95% CI: 1.36-1.54). Our findings underscore the large proportion of AMD explained by genetics particularly for younger AMD patients. Our risk classification could be useful for therapeutic stratification or as screening test once preventive treatment is available.

P09.009

Epigenetic alteration of the dopamine transporter gene in alcohol dependent patients is associated with age

V. Nieratschker[1], *M. Großhans*[1], *J. Frank*[1], *J. Strohmaier*[1], *C. von der Goltz*[1], *O. El Maarri*[2], *S. H. Witt*[1], *S. Cichon*[2,3], *M. M. Nöthen*[2,4], *F. Kiefer*[1], *M. Rietschel*[1];
[1]*CIMH, Mannheim, Germany,* [2]*University of Bonn, Bonn, Germany,* [3]*Research Centre Jülich, Jülich, Germany,* [4]*German Center for Neurodegenerative Disorders (DZNE), Bonn,*

Germany.

Chronic alcohol abuse and dependence are associated with dysfunctional dopaminergic neurotransmission in mesocorticolimbic circuits. Genetic and environmental factors have been shown to modulate susceptibility to alcohol dependence, and both may act through epigenetic mechanisms that can modulate gene expression, e.g. DNA methylation at CpG sites. Recent studies have suggested that DNA methylation patterns may change over time. However, few data are available concerning the rate of these changes in specific genes. A recent study found that hypermethylation of the promoter of the dopamine transporter (DAT) gene was positively correlated with alcohol dependence, and negatively correlated with alcohol craving. The aim of the present study was to replicate these findings in a larger sample of alcohol dependent patients and population-based controls matched for age and sex. No difference in methylation level was observed between patients and controls, and no difference in methylation level was observed before and after alcohol withdrawal in patients. However, patients with more severe craving showed a trend towards lower DAT methylation levels (p=0.07), which is consistent with previous findings. Furthermore, in our overall sample, DAT methylation levels increased with age. Interestingly, a separate analysis of patients suggested that this finding was mainly driven by the patient group. Although the present data do not clarify whether chronic alcohol abuse is responsible for this phenomenon or merely enhances an aging specific process, our findings suggest that hypermethylation in alcohol dependent patients is a consequence, rather than a cause, of the disorder.

Follow-up study of a genome-wide association scan in alopecia areata: IL13 and KIAA0350 as new susceptibility loci supported with genome-wide significance

S. Redler[1], *D. Jagielska*[2], *F. F. Brockschmidt*[1,3], *C. Herold*[4], *S. Pasternack*[1], *N. Garcia Bartels*[5], *S. Hanneken*[6], *S. Eigelshoven*[6], *M. Refke*[1], *K. A. Giehl*[7], *R. Kruse*[8], *G. Lutz*[9], *H. Wolff*[7], *B. Blaumeiser*[10], *M. Böhm*[11], *U. Blume-Peytavi*[2], *T. Becker*[4,12], *M. M. Nöthen*[1,3], *R. C. Betz*[1];

[1]Institute of Human Genetics, University of Bonn, Bonn, Germany, [2]Clinical Research Center for Hair and Skin Science, Department for Dermatology, Berlin, Germany, [3]Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany, [4]German Center for Neurodegenerative Diseases (DZNE), Bonn, Bonn, Germany, [5]Clinical Research Center for Hair and Skin Science, Department for Dermatology, Charité-Universitätsmedizin Berlin, Berlin, Germany, [6]Department of Dermatology, University of Düsseldorf, Düsseldorf, Germany, [7]Department of Dermatology, University of Munich, Munich, Germany, [8]Dermatological Practice, Paderborn, Paderborn, Germany, [9]Dermatological Practice Hair & Nail, Wesseling, Wesseling, Germany, [10]Department of Medical Genetics, University of Antwerp, Antwerp, Belgium, [11]Department of Dermatology, University of Münster, Münster, Germany, [12]Institute for Medical Biometry, Informatics and Epidemiology, University of Bonn, Bonn, Germany.

Alopecia areata is a common genetic complex hair loss disorder which affects approximately 1-2% of the general population, including both sexes and all age groups. Although the scalp is the most commonly affected site in AA, all hair-bearing areas of the skin, including the eyebrows and eyelashes, may be affected. Recently, the first genome-wide association study (GWAS) of alopecia areata (AA) was performed in a North American sample, and this identified eight susceptibility loci surpassing genome-wide significance. The aim of the present follow-up association analysis was to determine five of these eight loci (SNPs from the *CTLA4*, *IL-2RA*, and the HLA regions were not included due to previous own findings) and to test 12 other loci from the GWAS which did not surpass the threshold for genome-wide significance. Twenty three SNPs from the 17 loci were investigated using a sample of 1,702 Central European AA patients and 1,723 controls. Of the five loci with previously reported genome-wide significance, association was confirmed for all of these: *ULBP3/ULBP6*, *PRDX5*, *IL-2/IL-21*, *STX17*, and *IKZF4/ERBB3* (P-value <16 0.05). To detect robust evidence for association among the 12 other loci, a meta-analysis of the present association data and the data of the recent GWAS was performed. Genome-wide significant association was found for rs20541 (Pcomb=7.52*10-10; OR=1.30 [1.23-1.38]) and rs998592 (Pcomb=1.11*10-1119; OR=1.28 [1.21-1.36]), thus establishing *IL-13* and *KIAA0350/CLEC16A* as two new susceptibility loci for AA. Interestingly, *IL-13* and *KIAA0350/CLEC16A* are susceptibility loci for other autoimmune diseases, supporting the hypothesis of shared pathways of autoimmune susceptibility.

P09.011

Association of CALHM1 Gene Polymorphism with Late Onset Alzheimer Disease

J. Gharesouran[1], *M. Mohaddes Ardebili*[1], *M. Rezazadeh*[1,2,3];

[1]Department of Medical Genetics, Faculty of Medicine, Tabriz University of Medical Sciences, tabriz, Islamic Republic of Iran, [2]Genetic Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran, [3]Research Student Committee, Education Development Centerand Talented Students Office, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran.

Late-Onset Alzheimer disease (LOAD) is the most common form of AD that affecting people over 65 years old. The etiology of LOAD is complex that has strong genetic heterogeneity. The studies show that the different regions on chromosome 10(CALHM1) has concordant to LOAD in linkage analysis. CALHM1 encodes a transmembrane glycoprotein that controls cytosolic Ca2+ concentrations and Aβ levels. The previous studies reported that that P86L polymorphism in this gene is significantly associated with LOAD.

Our main objective was to determine the relationship between this polymorphism and the risk of LOAD in 160 AD patients and 163 healthy controls of Azerbaijan population. DNA was extracted of blood specimens that collected of these groups. The genotype and allele frequencies were determined in test and control goups using PCR/RFLP method.

Analysis of acquired data with statistical methods of allele and genotype frequency distribution of P86L genotype showed slight significant difference between the two study groups, that we concluded that T allele (mutant) has a protective role and is nearly significant between two groups (p= 0.026).

Genetic testing of Alzheimer's Disease associated polymorphisms using biochip-based assay

I. I. Nizamutdinov[1], *T. V. Andreeva*[2,3], *A. Y. Goltsov*[3], *S. S. Kunijeva*[2,3], *E. I. Rogaev*[2,3], *A. S. Zasedatelev*[1], *T. V. Nasedkina*[1];

[1]Engelhardt Institute of Molecular Biology RAS, Moscow, Russian Federation, [2]Vavilov Institute of General Genetics RAS, Moscow, Russian Federation, [3]Research Center of Mental Health, RAMS, Moscow, Russian Federation.

Late-onset Alzheimer's disease (AD) is the most common form of dementia in the elderly. The presence of an *APOE* epsilon4 allele is a well-established genetic risk factor for AD, with a higher percentage of epsilon4 allele in patients with AD comparing to general population. Recent genome-wide association studies also have identified the other loci of interest including *CLU*, *TOMM40*, *EXOC3L2*, *GAB2*, *A2M*, *CR1*, *BIN1* and *PICALM*, as putative genetic determinants of the late-onset form of AD. The aim of the work was to develop biochip for simple and rapid genetic tests of allelic variations in these genes in population and AD cohorts. The genotyping assay has been developed employing multiplex PCR and allele-specific hybridization of the amplicon probes on low-density gel-based biochips. In total, set of 235 case-control subjects of Russian origin have been tested to validate the sensitivity and specificity of the biochip. The genotype data are in agreement with described associations in both Russian and other European origin populations showing association of *APOE* epsilon4 allele and *CLU* C-allele (rs11136000) in AD (OR = 2.34, 95%CI= 1.22-4.47, p=0.01 and OR = 1.6, 95% CI=1.06-2.4, p = 0,024, respectively). Additionally, protective effect for the *APOE* epsilon2 allele has been observed (OR = 0.28, 95% CI=0.13-0.63, p = 0,001).

The work was supported by Ministry of Science and Education of Russian Federation (State contract # 02.527.11.0006) and EU 7-th Framework Programme (Grant Agreement # 242257).

Association study between *APOE* and *TNF- α* gene variations and sporadic Alzheimer's disease in Iranian population

N. Safavi naini, *S. Momeni, K. Kamali, M. Ohadi, M. Karimloo, H. Khorram Khorshid;*

Genetic Research Centre, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran.

Introduction: Amyloid ß (Aß) peptide deposits and Neurofibrillary tangles have key roles in pathogenesis and progression of the late-onset Alzhimer's disease. Likewise it has been shown that inflammatory reactions play a significant role as well. Inflammatory mediators such as complement, chemokines and cytokines activators and inhibitors can release from activated microglia and astrocytes, causing neuronal dysfunction and death. One of the most important cytokines is tumor necrosis factor-α (TNF-α). This study was designed and carried out to determine the association between sporadic Alzheimer's disease and the human *TNF- α* and *APOE* gene variations in Iranian population.

Materials and Methods: In this case - control study, the role of *TNF-α* gene polymorphism was determined in 167 sporadic AD patients and 163 healthy controls. Genomic DNA was extracted and *TNF-α* -850C/T promoter polymorphism was genotyped using PCR/RFLP technique. Comparing the genotype and allelic frequencies were analyzed using chi-square and logistic regression tests by SPSS 11.5.

Results: The obtained results indicated that the frequency of *TNF-α* -850 heterozygote genotype (CT) was significantly higher in AD patients comparing healthy controls (p=0.038). Although no significant difference were observed in *TNF-α* -850 homozygote genotype (TT) and T allele between the

studied groups. No interaction was shown between *TNF-α* -850 and *APOE* gene polymorphisms as well.
Conclusion: These data suggests the role of *TNF-α* -850 TC genotype as a risk factor for AD in Iranian population. Although to show the effects of homozygote genotype (TT) and T allele, a study with a larger sample size maybe indicated.

The effect of AVPR1B gene polymorphisms on personality traits in healthy individuals from Russia

Y. Suleymanova[1], *A. Kazantseva*[2], *S. Malykh*[3], *E. Khusnutdinova*[1,2];
[1]*Bashkir State University, Ufa, Russian Federation,* [2]*Institute of Biochemistry and Genetics, Ufa, Russian Federation,* [3]*Psychological Institute, Moscow, Russian Federation.*

Since the role of arginine vasopressin in modulation of social behaviors was established, we aimed to define a single genotype and haplotype effect of AVPR1B (rs28632197 and rs33911258) gene polymorphisms on personality traits assessed with TCI-125.
We recruited1018 healthy individuals (68% women) of Caucasian origin (Russians-357, Tatars-549, Chuvashs-112) from Russia (mean age: 19.53±2.24 years) without any history of psychopathologies. Genotyping of two polymorphisms was performed using PCR-RFLP. Statistical analysis was conducted with SPSS 13.0, PLINK v.1.07, Haploview 4.1.
ANOVA demonstrated an association of AVPR1B rs33911258 and Cooperation in males (p=0.003;F=8.77) occurred mainly due to the lower Cooperation in Tatar males bearing G-allele (p=0.028;F=4.90) compared to A/A-genotype-carriers. Subsequent haplotype analysis revealed an association of AVPR1B A*G-haplotype (rs28632197 and rs33911258, respectively, D'=0.87) and higher Self-transcendence (ST) (p=0.008; R2=0.6%) and G*A-haplotype and lower scores on ST (p=0.003; R2=0.7%) in the total group. The same effect of G*A-haplotype on ST was observed in Chuvashs (p=0.007; R2=6.6%), mainly caused by haplotype effect in Chuvash females (p=0.002; R2=12.1%).
Our findings indicate that AVPR1B gene has larger impact on character- than on temperament traits (according to TCI-125). Moreover,ethnicity mediated the main and haplotype effect of AVPR1B gene polymorphisms on sociability-related character traits.
Study was supported by Russian Foundation for Basic Research (#11-04-97032-r_povolzhye_a).

Array comparative Genomic Hybridization (array-CGH) as a clinical diagnostic tool in syndromic and nonsyndromic Congenital Heart Defects

A. Syrmou[1], *M. Tzetis*[1], *S. Kitsiou-Tzeli*[1], *H. Fryssira*[1], *K. Kosma*[1], *V. Oikonomakis*[1], *K. Giannikou*[1,2], *E. Kanavakis*[1];
[1]*Department of Medical Genetics, University of Athens, «Aghia Sophia» Childrens Hospital,Greece, Athens, Greece, Greece,* [2]*Alexander S. Onassis Public Benefit Foundation, Athens, Austria.*

•**Aim:** Congenital Heart Diseases (CHD) are often associated with other congenital anomalies, peculiar facies and developmental delay and only few cases of chromosomal abnormalities are detected by conventional cytogenetic techniques. The microarray Comparative Genomic Hybridization analysis (array CGH) allows the identification of submicroscopic genomic rearrangements. This study describes for the first time in Greece, the application of array CGH, as a diagnostic tool for the investigation of patients with congenital heart disease.
• **Materials- Methods:** During the last 3 years, a total of 330 patients were studied, of whom 55 had CHD of unknown aetiology plus at least one additional indication of abnormal chromosomal phenotype but with normal conventional karyotype. High resolution 1x244K Agilent arrays were used in this study (> 236.000 probes average resolution of 8.9 Kb).
• **Results** Submicroscopic genomic rearrangements (CNVs) ranging in size from 0.08 to19.01 Mb were detected in 37/55 patients (67%). In 29 of these (52.7%) the following genes associated with heart disease were identified:*DVL1, CHRD, DISP1, ETS1, KCNJ5, SCN3B, WNT7B, SCO2, ELN, GATA5, COL4A1, ADAMTS1, ADAMTS5, TBX1, DGCR8, KCTD13, TBX6, EMILIN2, MRCL2, MRCL3, MYOM1, LPIN2, LAMA1, CIDEA, KCNG2, TOP3B, TOP3B2, HIC2, CACNA1B, EHMT1, BAG3, NKX1-2, RBFOX1, EDN1, DTNBP1, MYLIP, KCNT1, NOTCH1, MAML1, FLT4, PRKAG3, WNT6, CYP27A1, NEXN, KCNQ1, ADAMTS13, CTNNA3, CACNB2, IGLL3, SLC29A.*
• **Conclusions** In patients with CHD and / at least one additional indication of abnormal chromosomal phenotype array CGH analysis is mandatory to detect possible submicroscopic chromosomal abnormalities and provide proper genetic counseling.

P09.016

The challenges of molecular genetic testing in Arrhythmogenic Right Ventricular Cardiomyopathy

J. M. Taylor[1], *C. Willoughby*[1], *S. Reid*[1], *K. Thomson*[1], *E. Blair*[2];
[1]*Oxford Medical Genetics Laboratory,, Oxford, United Kingdom,* [2]*Department of Clinical Genetics, Oxford, United Kingdom.*

Arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D) is characterised by fibrofatty replacement of the RV myocardium and a marked predisposition to ventricular arrhythmias; it is clinically and genetically heterogeneous. ARVC/D is generally considered to be an autosomal dominant trait. The incomplete penetrance and variable disease expression seen in this condition suggests a complex aetiology. Approximately 50% of patients are reported to have variants in genes encoding components of the cardiac desmosome; with 4-8% of index cases having more than one desmosomal gene variant. The difficulties in interpreting the clinical significance of variants in these genes are highlighted in the literature and the utility of genetic diagnosis in this condition the subject of debate.
Since 2008, Oxford Medical Genetics Laboratory has provided a diagnostic service for the four most commonly associated desmosomal genes: *PKP2*, *DSP*, *DSG2*, and *DSC2*. >175 individuals referred with a clinical or probable clinical diagnosis of ARVC/D have been analysed to date. Probable/possible disease causing variants were identified in ~46%. The majority of variants were detected in *PKP2* (27%), followed by *DSP* (12%), *DSG2* (11%) and *DSC2* (6%). 12% of index cases who had variants thought highly likely to be pathogenic also harboured at least one other desomosomal gene variant.
The results of genetic testing in our cohort will be compared to the literature. The challenges in unravelling the molecular aetiology of ARVC/D in a family will be discussed and the utility of genetic testing in this disorder examined.

P09.017

Anti-leukotriene therapy with Montelukast reduce expression of *IL12B* genes, which are overexpressed in children with asthma

P. Perin[1,2,3], *U. Potočnik*[1,2];
[1]*University of Maribor, Faculty of Chemistry and Chemical Engineering, Maribor, Slovenia,* [2]*University of Maribor, Faculty of Medicine, Maribor, Slovenia,* [3]*University of Maribor, Faculty of Health Science, Maribor, Slovenia.*

Single nucleotide polymorphisms (SNPs) in the cytokine gene cluster on 5q31-33 region, that includes genes *IL12B* and *IL13*, was associated with asthma development. However, the role of those SNPs in asthma behavior and response to therapy is poorly characterized. The aim of our study is to analyze the role of *IL13*, *IL12B* and *IL23R* genes in asthma pathogenesis and determinate their role in response to diferent therapies. We have included 288 children with asthma and 186 healthy individuals. Genotyping was performed by PCR-RFLP technique. Gene expression was measured by TaqMan assay using real-time PCR. The data were statistically analyzed. We were the first to found that *IL12B* gene is overexpressed in asthmatics compared to the control group (p<0.001). After treatment with anti-leukotriene drug montelukast the expression of *IL12B* was reduced (p=0.015). Montelukast affect the expression of *IL23R* gene, which significantly increased after the therapy. In eQTL analysis, we found that the expression of *IL12B* is significantly higher in carriers of at least one allele of SNP rs6887695 G, which was in preliminary studies identified as a risk factor for chronic immune-mediated diseases. In our study, we were the first to found an impact of allele G on airway obstruction in asthma (p=0.006). The finding of a higher *IL12B* expression in asthmatics may in future serve as diagnostic marker for asthma and the finding that montelukast decrease its expression may become an important fact in choice of therapy.

P09.018

Association of GRIA1 gene polymorphisms with asthma in Bashkirs from Russia

Y. Fedorova[1], *A. Karunas*[1], *B. Yunusbaev*[1,2], *N. Ramazanova*[3], *E. Galimova*[3], *E. Etkina*[3], *S. Zagidullin*[3], *E. Khusnutdinova*[1];
[1]*Institute of Biochemistry and Genetics, Ufa Scientific Centre of RAS, Ufa, Russian Federation,* [2]*Estonian Biocentre, Tartu, Estonia,* [3]*Bashkir State Medical University, Ufa, Russian Federation.*

Asthma is a complex disease that is influenced by many genes and environmental factors. Genome-wide association studies have identified many candidate loci for a number of complex traits, including asthma. For the first time, we performed GWAS of asthma in the Volga-Ural region of Russia. The study involved 358 unrelated patients with asthma and 369 control subjects of different ethnicity. DNA samples were genotyped using an Illumina Human 610 quad array as a part of the GABRIEL project. After QC filters, 550 915 SNPs genotyped in 330 cases (141 Russians, 120 Tatars, 69 Bashkirs) and 348 controls (145 Russians, 111 Tatars, 92 Bashkirs) were used for testing the association of SNPs to asthma. Some markers on chromosome 5q33 showed the most significant association with asthma in Bashkirs (p<5xl0-7). The maximum association was at the SNP rs9324750 (p=4,25x10-7) in the second intron of GRIA1. Eight linked SNPs (rs495703, rs480726, rs726877, rs726876, rs1463747, rs17114771, rs9324750, rs10041179) located within second intron GRIA1 were selected for haplotype analysis. The haplotype GTGCGGAT was found to be overrepresented in Bashkirs with asthma (p=3,0x10-4). GRIA1 encodes a subunit of the AMPA receptor, a tetrameric ligand-gated ion channel that transmits glutamatergic signals in the brain. It has recently been shown that glutamate not only has a role as a neurotransmitter, but also as an immunomodulator. These results suggest that GRIA1 gene play an important role in susceptibility to asthma in Bashkirs from the Volga-Ural region of Russia. Supported by a contract from the European Commission (018996).

P09.019

Immune-response modifying gene polymorphisms and susceptibility to asthma and *Opisthorchis felineus* helminth invasion

I. V. Saltikova[1], *E. Y. Bragina*[2], *L. M. Ogorodova*[1], *V. P. Puzyrev*[2,1], *M. B. Freidin*[2];
[1]Siberian State Medical University, Tomsk, Russian Federation, [2]Research Institute of Medical Genetics, Tomsk, Russian Federation.

It has been shown that common genetic variants of cytokine and cytokine signal transduction genes, especially *IL13* and *STAT6*, predict risk of asthma and allergy, as well as the intensity of helminth invasion by *Ascaris* and *Schistosoma* species.

Opisthorchis felineus is a common helminth infection in Siberian region of Russia. So far, no information on genetic component of susceptibility for this infection was published. To investigate whether the same genes are involved in predisposition to asthma and O. *felineus* invasion, we analyzed 10 single-nucleotide polymorphisms (SNP) of immune-response modifying genes in 107 asthma patients, 103 individuals infected by O. *felineus*, 100 persons with combination of asthma and O. *felineus* infection, and control group of 126 healthy people.

The *PIAS3* rs12756687:G/G genotype was associated with symptomatic O. *felineus* infection (P = 0.02), while the C/C genotype was associated with asthma (P = 0.033). The *SOCS5* rs6737848:C/C genotype and the *IFNG* rs2069705:C/T genotypes were associated with asthma (P = 0.006 and 0.032, respectively) alone.

Thus, the *PIAS3* rs12756687 polymorphism demonstrates the inverse association between asthma and *O. felineus* invasion clinical manifestation. This suggests that the gene-environmental interaction between the *PIAS3* and *O. felineus* modifies the risk of development of asthma in the helminth endemic region. At the same time, the studied *SOCS5* and *IFNG* polymorphisms are likely independent risk factors of asthma susceptibility.

P09.020

Evaluation of gene expression normalization strategy for real-time qPCR in leukocytes from asthmatic patients before and after treatment.

C. E. P. Kozmus[1,2], *U. Potočnik*[1,3];
[1]Center for Human Molecular Genetics and Pharmacogenomics, University of Maribor, Maribor, Slovenia, [2]Institute for Molecular and Cell Biology, University of Porto, Porto, Portugal, [3]Laboratory for Biochemistry, Molecular Biology and Genomics, University of Maribor, Maribor, Slovenia.

The aim of this study was to identify the most suitable reference genes to normalize gene expression data obtained by qPCR from asthmatic patients. We analyzed 7 candidate reference genes (*18S rRNA*, *ACTB*, *B2M*, *GAPDH*, *POL2AR*, *RPL13A* and *RPL32*) previously reported as being the most stable in blood samples, in asthmatic patients before and after anti-asthma treatment, and control subjects. Variance of Cq values was analyzed and gene stability determined with geNorm. The influence of normalization strategy on *ORMDL3*, *PSMD3*, *GSMD3*, *MAP3K2*, *SLC22A5*, *TRIM35* and *EPHX2* gene expression was analyzed. Cq values of *ACTB*, *B2M* and *GAPDH* were shown to be stable across samples obtained before and after treatment and also the top-ranking genes determined by geNorm. These produced the most consistent results of the target gene expression. When samples obtained before treatment were analyzed alone, *POLR2A* and *B2M* where shown to be the best selection. Gene expression of *ORMDL3* was shown to be significantly increased, and *PSMD3*, *SLC22A5*, *MAP3K2* and *TRIM35* were decreased in asthmatic patients before and after treatment compared to healthy controls. *GSDMB* was significantly decreased only in asthmatic patients after treatment. When comparing samples obtained before and after treatment, gene expression of *PSMD3* and *MAP3K2* was significantly decreased. In conclusion, a different combination of reference genes should be used according to whether changes in gene expression are being analyzed in samples from asthmatic patients before receiving treatment or together with samples obtained after anti-asthma treatment.

P09.021

Association between *VEGF* polymorphisms and asthma treatment response

M. Balantic[1], *M. Rijavec*[1], *M. Skerbinjek Kavalar*[2], *S. Suskovic*[1], *M. Silar*[1], *M. Kosnik*[1], *P. Korosec*[1];
[1]The University Clinic of Pulmonary and Allergic Diseases Golnik, 4204 Golnik, Slovenia,
[2]University Clinical Centre Maribor, 2000 Maribor, Slovenia.

Background_ Asthma affects around 300 million people worldwide. Vascular endothelial growth factor (VEGF), a regulator of angiogenesis, is elevated in asthma patients. VEGF contributes to airway responsiveness and remodelling. Treatment of asthma patients decreased VEGF levels and inhibiting VEGF in mice diminished asthma symptoms. Therefore, polymorphisms in *VEGF* might be associated with asthma treatment response.

Methods: This study enrolled 131 children with asthma. They were treated with inhaled corticosteroid (ICS) fluticasone propionate or leukotriene receptor antagonist (LTRA) montelukast. We analyzed association between improvement of lung function, assessed by measurement of FEV1 – % of predicted, FEV1/FVC after 6 and 12 months of treatment and asthma control after 12 months of treatment, and polymorphisms, rs2146323 and rs833058, in the *VEGF* gene.

Results: Polymorphism rs2146323 A>C in *VEGF* was associated with response to ICS. Patients with the AA genotype had a greater improvement in FEV1 – % of predicted compared to the AC or CC genotype (*p* = 0.01). Conversely, the AA genotype in rs2146323 was associated with uncontrolled asthma in patients regularly receiving LTRA (*p* = 0.02). Polymorphism rs833058 C>T was associated with treatment response to episodically used LTRA. A subgroup of patients with the TT genotype had improvement in FEV1 – % of predicted compared to no improvement in patients with the CT or CC genotype (*p* = 0.03).

Conclusions: Our results showed that treatment response to commonly used asthma therapies, ICS or LTRA, is associated with polymorphisms rs2146323 and rs833058 in *VEGF*, what makes *VEGF* a potent pharmacogenetic marker.

P09.022

Genetic polymorphisms of glutathione S-transferases M1, T1 and P1 and susceptibility to oxidative stress and atherogenesis

I. I. Grubisa[1], *P. Otasevic*[2], *N. Dimkovic*[3], *V. Dedic*[4], *J. Milasin*[5], *N. Vucinic*[1];
[1]Department of Human Genetics and Prenatal Diagnostics, Zvezdara University Medical Center, Belgrade, Serbia, [2]Dedinje Cardiovascular Institute and Faculty of Medicine, University of Belgrade, Belgrade, Serbia, [3]Faculty of Medicine, University of Belgrade and Clinical Department of Renal Diseases, Zvezdara University Medical Center, Belgrade, Serbia, [4]European Center for Peace and Development Established by United Nations University of Peace, Belgrade, Serbia, [5]Institute of Human Genetics, School of Dentistry, University of Belgrade, Belgrade, Serbia.

A persistent oxidative stress has been implicated in the pathogenesis of various diseases, among others atherosclerosis. Glutathione S-transferases (GSTs) provide protection against oxidative stress by detoxifying the end-products of lipid peroxidation. Polymorphic deletion variants in the *GSTM1* and *GSTT1* genes produce either a functional protein (non-deletion alleles or heterozygous deletion) or result in the complete absence of the protein (homozygous deletion-null genotype) while *GSTP1 Ile105Val* functional polymorphism influences protein catalytic activity and stability. We investigated the association between these polymorphisms and susceptibility to oxidative stress in 60 angiographically documented patients with manifest atherosclerotic disease and 100 control individuals from Serbia. Genomic DNA was isolated from peripheral blood cells and genotyping was performed using polymerase chain reaction followed by restriction fragment length polymorphism (PCR-RFLP) analysis for *GSTP1* and multiplex-PCR or Real-time PCR methods for *GSTM1* and *GSTT1* gene variants. We observed significant association of *GSTM1* null (OR=2.0, 95%CI=1.05-3.86, P=0.03) and *GSTT1* null (OR=2,26, 95%CI=1,06-4,81, P=0.03) genotypes with atherosclerosis. Combined analysis of the two null genotypes demonstrated significant increase in risk (OR=15, 95%CI=3,09-73,3, P<0.0001), too. *GSTP1 Val105* allele (OR=0,63, 95%CI=0,39-1,03, P=0.06), *Ile/Ile* (OR=0,53, 95%CI=0,27-1,05, P=0.07) and *Ile/Val* (OR=0,41, 95%CI=0,12-1,43, P=0,16) genotypes showed a nonsignificant 1.6, 1.9 and 2,44 fold decrease in the risk of atherosclerosis, respectively. Our data provide evidence that both *GSTM1* and *GSTT1* null genotypes, alone or in combination, are associated with increased oxidative stress and atherogenesis. A larger study group is needed to establish true relationship between potentially protective allele *Val105* and disease.

Toll-like receptor genes variants and atopic dermatitis in Volga-Ural region of Russia

G. F. Gimalova[1], *E. Prans*[2], *A. S. Karunas*[1], *Y. Y. Fedorova*[1], *E. R. Gumennaya*[3], *S. V. Levashova*[4], *A. R. Biktasheva*[4], *E. I. Etkina*[4], *S. Koks*[2], *E. K. Khusnutdinova*[1];
[1]Institute of Biochemistry and Genetics, Ufa Scientific Centre, Russian Academy of Sciences, Ufa, Russian Federation, [2]Faculty of Medicine, Institute of Physiology, University of Tartu, Tartu, Estonia, [3]Dermatovenerologic dispensary of Bashkortostan Republic, Ufa, Russian Federation, [4]Bashkir Medical State University, Ufa, Russian Federation.

Atopic dermatitis is the common chronic inflammatory disorder with cutaneous hyperreactivity to environmental triggers and is often the first step in the atopic march. Recent studies have shown an association between toll-like receptor genes variations and allergic diseases development. We have screened 4 SNPs in TLR1 (rs4833095, rs5743604, rs5743571, rs2101521) and 6 SNPs in TLR10 (rs4331786, rs4129009, rs11096957, rs11466617, rs10004195, rs4543123) genes, both map closely together on chromosome 4. The AD group consisted of 318 AD patients from Volga-Ural region of Russia (Russians, Tatars, Bashkirs and individuals of mixed origin). The control group included 262 non-atopic individuals of the same ethnic origin. Genomic DNA was isolated by phenol-chloroform extraction. The genotyping of SNPs was performed by real-time PCR.
The AD patients have significantly higher TLR1 gene polymorphisms alleles rs5743604*A, rs5743571*C and rs2101521*G frequencies when compared with control group (p=0.036, p=0.020, p=0.0378 respectively). The frequencies of the TLR10 gene variants alleles rs10004195*T and rs4543123*A was also significantly higher in AD patients than in healthy donors (p=0.0091 and p=0.0156). The haplotype analysis revealed that the most frequent haplotype is TTATAC (rs11466617-rs10004195-rs4543123-rs4833095-rs5743604-rs5743571), with statistically significant difference between patients and controls (69% and 63% respectively; p=0.05), besides AD patients have significantly higher TTACAC (p= 7.0E-4) and lower TAGCGT (p= 0.0083) haplotype frequencies compared with controls.
The results of our investigation show that TLR1 and TLR10 genes polymorphisms are important risk factors of atopic dermatitis in the Volga-Ural region of Russia.

P09.024

Genetic dissection of atrial septal abnormalities: integrating QTL mapping and genomic technology

M. Moradi Marjaneh[1,2], *E. P. Kirk*[2,3], *T. B. Doan*[1], *P. C. Thomson*[4], *I. C. A. Martin*[4], *C. Moran*[4], *R. P. Harvey*[1,5];
[1]Victor Chang Cardiac Research Institute, Sydney, Australia, [2]School of Women and Children's Health, Faculty of Medicine, University of New South Wales, Sydney, Australia, [3]Department of Medical Genetics, Sydney Children's Hospital, Sydney, Australia, [4]ReproGen - Animal Biosciences Group, Faculty of Veterinary Science, University of Sydney, Sydney, Australia, [5]St. Vincent's Clinical School, Faculty of Medicine, University of New South Wales, Sydney, Australia.

The formation of the atrial septum during cardiac development is a complex process being vulnerable to a wide range of dysmorphogenesis. A genetic link and anatomical continuum between secundum atrial septal defect (ASDII) and patent forame ovale (PFO) have been suggested by murine and human studies. While ASDII and PFO occur commonly and represent a significant burden to health resources, the genetic complexity of such conditions is not fully known. PFO incidence in inbred mice, as we reported earlier, is strongly correlated with quantitative parameters of atrial septum. We previously mapped quantitative trait loci (QTL) underlying such parameters using F2 intercross between QSi5 and 129T2/SvEms, parental strains with extremes of septal dysmorphogenesis. Subsequently, breeding of parental strains continued for 12 further generations to establish an advanced intercross line (AIL). We genotyped 150 single nucleotide polymorphism (SNP) markers at an average interval of 2cM in 400 F14 mice. AIL confirmed the F2 QTL and significantly improved confidence intervals of the QTL. Afterward, we performed whole genome sequencing of the parental strains and identified variations between the sequences. The genome was partitioned into high and low SNP rate intervals and the genes within high SNP rate regions of the QTL confidence intervals were identified. As a confirmatory method, we used mouse HapMap imputation genotype resource. The list of candidate genes was prioritized according to sequence and expression profiles. In conclusion, integrating QTL mapping and genomic technology form a powerful approach to dissect genetic complexity underpinning atrial septal abnormalities.

P09.025

The GABAergic hypothesis in the etiology of attention-deficit/hyperactivity disorder in the Portuguese population: a family-based association study

A. Marques[1], *J. Boavida*[2], *S. Nogueira*[2], *C. Alfaiate*[2], *M. Almeida*[2], *A. M. Ambrósio*[1,3];
[1]Clinical and Molecular Genetics Unit of National Institute of Legal Medicine, Coimbra, Portugal, [2]Child Development Center of Coimbra Children's Hospital, Coimbra, Portugal, [3]IBILI-Faculty of Medicine of University of Coimbra, Coimbra, Portugal.

Attention-deficit/hyperactivity disorder (ADHD) is one of the most common neuropsychiatric disorders diagnosed during childhood and several studies demonstrated that ADHD is a highly heritable disorder with a strong genetic basis. However the identification of genes that may predispose to ADHD has been difficult. Several lines of evidence suggest that changes in genes from GABAergic system and particularly the GABA A receptors might be involved in ADHD, but this hypothesis remains unexplored by genetic studies. Therefore, the aim of this study was to investigate the role of a GABRB2 gene polymorphism (C1412T) in the etiology of ADHD, in the Portuguese population through a family-based association strategy.After obtaining informed consent, blood samples were collected from trios, composed by parents and respective offspring, diagnosed with DSM-IV-TR and genomic DNA was isolated from peripheral leukocytes using an enzymatic method. The GABRB2 C1412T polymorphism was investigated with polymerase chain reaction-restriction fragment length polymorphism technique. We performed both haplotype relative risk (HRR) and transmission disequilibrium test (TDT) and found no association between the GABRB2 C1412T polymorphism and ADHD (HRR: $\chi^2 = 0.199$, df = 1, P = 0.656; TDT: $\chi^2 = 0.182$, df = 1, P = 0.670). The preliminary results obtained with HRR and TDT analyses do not support the hypothesis that the C1412T polymorphism of GABRB2 gene contributes with a minor effect to the expression of ADHD in the Portuguese population. However further studies with larger samples are in course in order to confirm or refute these results.

P09.026

Identifying phenotypes and exploring genetic aetiology of autism spectrum disorders : a 87 patient study.

E. Landais[1], *N. Golovkine*[2], *R. Dard*[1], *F. Lempp*[1], *N. Bednarek*[1], *S. Godet*[2], *R. Senezuk*[2], *A. Lannoy*[1], *P. Jonveaux*[3], *M. Beri*[3], *C. Bonnet*[3], *M. Valduga*[3], *J. Motte*[1], *G. Schmit*[2], *D. Gaillard*[1], ***M. Doco.Fenzy***[1];
[1]CHU-Reims, Reims, France, [2]Centre de Ressource Autisme, Reims, France, [3]CHU-Nancy, Nancy, France.

Autism is characterized by limited verbal communication, lack of reciprocal social interaction, and stereotypical behaviour affecting preferentially Boys. Mental retardation and or seizures coexists in two-thirds of patients. Autistic spectrum disorders are complex multifactorial disorders involving various genes, and many aetiologic diagnosis remain unravelled.
We report a collaborative study between our Genetic Department and the Autism Center (CRA). A population of 87 children with autism was selected. We identified 5 different phenotypic groups (8-32 children per group), using the behaviour and the intellectual efficiency evaluation criteria from the following tests PER-R, CARST, and ADIR.
Among them 45 patients (6 -14 per group) were negative for FMR1 amplification and then tested by array-CGH (180K) to search for deleterious chromosomal rearrangements. The Array-CGH analysis showed the presence of 49 copy number variants (CNV) not referred as polymorphisms in 28 children with an average of 2 CNV per patient. A deleterious CNV was found in 5 children from 4 different groups. A parental study was done in 10 families for 14 aberrations : 12 rearrangements were inherited and 2 were de novo with a 6q26 deletion (gene PACRG) and an isochromosome Yp (deletion of NLGN4Y) both considered of uncertain clinical significance (VOUS). Five CNVs were previously reported in autism: 1q21.1,3p26.3q26.2 (CNTN4), 15q13.3 (CHRNA7), 16p11.2 and Xp22.31. Three aberrations in 3p26 (dup) and Xp22 (del/dup) seemed more specific to autism as not present in our cohort of 400 patients with intellectual disability.
In conclusion, the aetiologic diagnosis was found in 11% of autistic children.

P09.027

A 3- year- old patient with autism and microdeletion in the *KIAA0442* (*AUTS2*)- gene

C. Huebner[1], *D. Steinemann*[2], *J. Schmidtke*[1], *M. Arslan-Kirchner*[1];
[1]Institute of Human Genetics, Hannover Medical School, Hannover, Germany, [2]Institute for Cellular and Molecular Pathology, Hannover Medical School, Hannover, Germany.

A 2 10/12- year- old boy with bilateral cleft lip and cleft palate as well as developmental delay was presented to our genetics clinic. He is the first child of non-consanguineous healthy parents. He shows behavioural patterns of the autism spectrum which include avoiding eye contact, no response to his name, playing alone and stereotyped movements when listening to music. His postnatal chromosomal analysis revealed a normal male karyotype 46,XY.

Array-CGH analysis showed a microdeletion of 170 kb: arr (7q11.22)(70,077,607-70,247,036)x1 dn. This part of the chromosome contains exons 6-15 of the 19 exons spanning the *AUTS2*- gene. His parents do not carry this microdeletion, indicating that it was a de novo event.

Autism spectrum disorder (ASD, OMIM 209850) encompasses different forms of autism with a broader phenotype. Two-thirds of all patients with ASD suffer from mental retardation. Among the genes involved, *AUTS2*-disruption has been described in 7 patients with ASD and mental retardation. In all of these seven patients translocations with different breakpoints between exon 1 and 7 and different translocation partners were the underlying mechanism of the disruption. Additionally other genes were disrupted according to the breakpoint of the partner chromosome. Our patient shares the same symptoms as the 7 patients with translocation, indicating that disturbed function of *AUTS2* and not the truncated translocation partner causes the clinical presentation of the patients.

P09.028

Contribution of rare and common variants of the *PTCHD1* gene to Autism Spectrum Disorder and Intellectual Disability

Autism is a severe neurodevelopmental disorder, characterized by impaired verbal communication, limited reciprocal social interaction, restricted interests and repetitive behavior, often accompanied by intellectual disability (ID). Although it is one of the most heritable neuropsychiatric disorders, the underlying genetic factors remain largely unknown.

A recent study reported rare mutations in the X-linked gene *PTCHD1* (patched domain-containing protein 1)in patients with autism spectrum disorder (ASD) and ID (Noor *et al.* 2010), suggesting a possible role of this gene in cognitive development. *PTCHD1* is highly expressed in brain regions and encodes a transmembrane protein containing a patched-related domain. It has been suggested that *PTCHD1* plays a role in the hedgehog signaling pathway.

In this study we aimed to investigate the possible contribution of common variants in *PTCHD1* to ASD through a case-control association study. The study sample consisted of 595 Caucasian autistic patients (270 Spanish, 247 Dutch and 78 German) and 680 gender-matched controls (320 Spanish, 269 Dutch and 82 German). Twenty-eight tagSNPs were selected on the basis of linkage disequilibrium (LD) patterns. A significant association, that overcame the Bonferroni correction for multiple testing and permutations was obtained with the marker rs7052177 (p= 6.13e-4). Furthermore, in order to evaluate the possible participation of *PTCHD1* rare variants in ASD and ID, we are currently performing a mutation screening in the Spanish ASD cohort, and in an additional sample of 200 individuals with ID. The preliminary results of this study support the involvement of this gene in autism and cognitive impairments.

Autism Spectrum Disorders (ASD) is a group of neurodevelopmental disorders characterized by distinct patterns of social deficits and communication impairment, rigid ritualistic interests and stereotypical behaviors. Recent genetic studies have shown that some synaptic genes, including *NRXN1, NLGN3, NLGN4X, CNTNAP2* and *SHANK3*, are associated with ASD. To study these 5 genes in 5 Thai multiplex families with ASD, the target regions of these candidate genes were enriched from total DNA samples using NimbleGen microarrays. The enriched DNA fragments from each index case were sequenced using 454 Genome Sequencer FLX Titanium. Sequences were aligned and compared with reference sequence UCSC hg18 using Newbler software. Variant annotations were focused on the exons and exon-intron boundaries, then novel variants were validated by Sanger sequencing. One novel variant, c.2047C>G (p.E683Q) in the exon 13 of *CNTNAP2*, was identified in a boy with ASD. The variant was transmitted from his mother but it was not present in his father and younger brother with ASD. This variant was not found in the 170 control alleles. Bioinformatic analysis showed that the glutamic acid (E) in CNTNAP2 protein was highly conserved across different species and the glutamine (Q) variant affected on secondary structure of CNTNAP2 protein. However, further studies involving a larger set of ASD samples (i.e. association studies) are necessary to determine the potential disease relevance of the p.E683Q in *CNTNAP2*. Otherwise, functional analysis of CNTNAP2 protein with p.E638Q isoform can give us the best conclusion.

Mirror effects for Autism Spectrum Disorder due to gene dosage at 10q11.22 affecting GPRIN2 gene, a regulator of neurite outgrowth and PPYR1 gene involved in energy homeostasis.

V. Disciglio[1], *M. Fichera*[2,3], *R. Ciccone*[4], *M. Mucciolo*[1], *E. Ndoni*[1], *A. Fernández-Jaén*[5], *O. Galesi*[2], *M. Vinci*[2], *P. Failla*[2], *M. A. Mencarelli*[1], *C. Lo Rizzo*[1], *F. Mari*[1], *O. Zuffardi*[4], *C. Romano*[2], *A. Renieri*[1];

[1]Medical Genetics Unit, Biotechnology Department, University of Siena, Siena, Italy, [2]Laboratory of Genetics Diagnosis, IRCCS Oasi SS Maria,, Troina, Italy, [3]Medical Genetics, University of Catania, Catania, Italy, [4]Biologia Generale e Genetica Medica, Universita' degli Studi di Pavia, Pavia, Italy, [5]Unidad de Neurología Infanto-juvenil Hospital Universitario Quirón Centro CADE., Madrid, Spain.

We recently reported that a small duplication on 10q11.22 including GPRIN2 gene, a regulator of neurite outgrowth, and PPYR1, a gene involved in energy homeostasis is a candidate modifier for Rett syndrome. Specifically, duplications were found in the Zappella variant, the Rett variant with recovery of speech, and lacking the typical growth delay, underweighting and autistic features. Since PPYR1 knockout mice display underweight and reduced white adipose tissue an overexpression of PPYR1 due to gene duplication may be responsible for the higher body weight characterizing Zappella variant. We concluded that duplication at 10q11.22 may play a role in protecting from both underweighting and autistic features in Rett patients. We now report more convincing evidences that dosage balance at GPRIN2 locus plays a role in autism spectrum disorders (ASD). We observed 6 patients affected by ASD with an overlapping small deletion including the two genes (and extending to MAPK8 in one patient). We then compared a group of 164 ASD patients with a group of 180 syndromic and non syndromic intellectual deficit (SID/NSID) patients and 160 controls. Seven deletions were identified in the ASD group. On the contrary, no deletion has were found in SID/NSID nor in control group (p=0,005 and p=0,008). We are currently extending this study to a second cohort including about 100 ASD patients and 135 SID/NSID. Overall, these data suggest that gene dosage at 10q11.22 affecting GPRIN2 gene may have mirror effects being duplication protective and deletion prone to ASD.

Whole-genome methylation profile in BEN patients

R. G. Staneva[1], *I. Dimova*[1], *P. Dimitrov*[2], *V. Simeonov*[3], *M. Polenakovic*[4], *V. Stefanovic*[5], *R. Cukuranovic*[5], *V. Djonov*[6], *S. Lalchev*[1], *D. Toncheva*[1];

[1]Department of Medical Genetics, Medical University of Sofia, Sofia, Bulgaria, [2]National Center of Public Health Protection, Sofia, Bulgaria, [3]Vratza District Hospital, Vratza, Bulgaria, [4]Macedonian Academy of Sciences and Arts, Skopje, The Former Yugoslav Republic of Macedonia, [5]Faculty of Medicine, Institute of Nephrology, University of Nis, Nis, Serbia, [6]Institute of Anatomy, University of Bern, Bern, Switzerland.

BACKGROUND: Balkan endemic nephropathy (BEN) represents a chronic progressive interstitial nephritis in striking correlation with uroepithelial tumors of the upper urinary tract. The disease has endemic distribution in the Danube river regions in several Balkan countries.

DNA methylation is a primary epigenetic modification that is involved in major processes such as cancer, genomic imprinting, gene silencing etc. Epigenetic tests can prove to be the bridge between environmental factors and genetic background in BEN development.

MATERIALS AND METHODS: Age matched pools of 45 female BEN patients and 45 healthy controls were created. We've performed high-resolution genome-wide methylation array analysis. We've analyzed the methylation status of 27 800 CpG islands of both groups to identify significant methylation profile differences.

RESULTS: Our experiments show significant disparity of the methylation status of several group of genes. Significant hypomethylation in the patient group was discovered for the following genes: ADRA2A, B3GNT4, BTBD6, C1orf183, GCH1, KCNK12,NEO1, REXO1, SHROOM2, SSPO, TTC9B.The genes ADNP, C11orf63, ACTG1, RNF187, C4orf32, MIR153-2, TM6SF1, SSR4, HNRNPH1, EVI5L, TAL1, EBF3, C3orf21, IQSEC1, MSL2, FAM123A, RBMY1B, RBMY2EP showed significantly higher level of hypermethylation in patients.

CONCLUSIONS: Data obtained from our experiments suggest that dysregulation of cytoskeletal proteins, transcription factors, transmembrane ion channels as well as proteins involved in secretion processes, cell adhesion, DNA-splicing and cell proliferation can be key mechanism in BEN pathogenesis. These results are in unison with the key pathological alterations in BEN and further elucidate the precise mechanism behind BEN development.

De novo copy number variation in bipolar affective disorder

E. Rees[1], *J. Moran*[2], *K. Chambert*[2], *L. Georgieva*[1], *S. Purcell*[3,4,2], *P. Sklar*[5,6,7], *S. McCarroll*[2], *M. O'Donovan*[1], *M. J. Owen*[1], *G. Kirov*[1];
[1]Cardiff University, Cardiff, United Kingdom, [2]Stanley Center for Psychiatric Research, Broad Institute, Cambridge, MA, United States, [3]Psychiatric and Neurodevelopmental Genetics Unit, Department of Psychiatry, Massachusetts General Hospital and Harvard Medical School, Boston, MA, United States, [4]Center for Human Genetics Research, Massachusetts General Hospital, Boston, MA, United States, [5]Department of Genetics and Genomic Sciences, Mount Siani school of Medicine, New York, NY, United States, [6]Department Psychiatric , Mount Siani School of Medicine, New York, NY, United States, [7]Department of Neuroscience, Mount Siani school of Medicine, New York, NY, United States.

An increased rate of de novo copy number variants (CNVs) has been found in several neuropsychiatric disorders, such as schizophrenia, autism and developmental delay. In this study we wanted to identify de novo CNVs in bipolar affective disorder (BD). We used Illumina OmniExpress microarrays to genotype 119 BD offspring from 114 complete parent-offspring families passing strict QC criteria. CNVs were called by PennCNV. We excluded CNVs <10kb, covered by <10 probes, overlapping segmental duplications and with a frequency >1%.

The initial analysis identified 41 putative novo CNVs. Subsequent validation by a Z-Score calling algorithm, and manual inspection of the logRratios of the trios, reduced this to seven de novos in six probands. This rate of 5% is higher than the reported rates in controls (~1-2%), but similar to studies in schizophrenia and BD. The median size of de novo CNVs was 189kb. Two of the de novo CNVs did not intersect any genes. We find one de novo deletion intersecting an exon of *DLG2,* and one large duplication intersecting 27 genes at 16p11.2, both regions having been implicated in de novo CNV studies of schizophrenia and BD. The remaining three CNVs are also potential novel de novo CNV loci for BD: a 448kb deletion at 2q31.1 that intersects 5 genes including the nicotinic acetylcholine receptor *CHRNA1,* a 160kb duplication intersecting *PCDH15* at 10q21.1, and a 186kb deletion at 9q21.3 intersecting *ELAVL2*.

The bladder exstrophy-epispadias complex (BEEC) represents an anterior midline defect with variable expression of phenotype comprising a spectrum of malformations involving the abdominal wall, pelvic floor, urinary tract, genitalia, and occasionally the anus and spine. Most of the BEEC cases are classified as non-syndromic, and the etiology is still unclear. The overall birth prevalence for the complete BEEC spectrum in children of European descent has been estimated to be 1 in 10 000. In this study, we aimed to identify copy number variantions (CNVs) that contribute to BEEC. An array-based molecular karyotyping, utilizing 1,134,514 SNPs (single nucleotide polymorphisms), was performed to screen 75 individuals with BEEC for causative de novo events. SNP fluorescence intensity was analyzed with QuantiSNP using an Objective-Bayes Hidden-Markov model for calling putative CNVs. The SNPs were filtered according to various criteria by use of the Cartagenia Bench software, by in-silico-analysis, and by comparison with 531 healthy controls. A de novo microduplication on chromosome19p13.12 was detected in a patient with isolated bladder exstrophy. The size of the duplication is 0.9 Mb and harbors 23 RefSeq genes. Whole-mount in situ hybridization studies of the genes within the region of rearrangement were performed in order to prioritize genes according to their expression during E9.5 to E10.5. WISH data of mice embryos showed specific expression of CASP14, NOTCH3, WIZ and CYP4F22. According to the function of these genes WIZ becomes the most promising candidate to be systematically sequenced in the complete sample to identify high-penetrance mutations involving small sequence changes.

P09.034

The gene encoding Kit ligand associates with Bronchopulmonary dysplasia

J. M. Huusko[1], *M. Mahlman*[1], *M. K. Karjalainen*[1], *T. Kaukola*[1], *R. Haataja*[1], *M. Rämet*[2], *P. M. Lavoie*[3], *M. Hallman*[1];
[1]Department of Pediatrics, Institute of Clinical Medicine, University of Oulu, Oulu, Finland, [2]Department of Pediatrics, Tampere University Hospital, Tampere, Finland, [3]Child & Family Research Institute of British Columbia, Vancouver, BC, Canada.

Background. Bronchopulmonary dysplasia (BPD) is one of the most common chronic lung diseases associated with very preterm birth. Major risk factors are lung immaturity and inflammatory lung injury. As a result of improved treatment methods, increased infant survival has arisen the "new" BPD among the most immature infants. Based on twin studies, genetic factors play an important role in BPD susceptibility. However, the genetic background is still poorly understood.

Aims. Because glucocorticoids are important in the process of lung maturation, the genes encoding glucocorticoid receptor (*NR3C1*) and Kit ligand (*KITLG*, involved in hematopoiesis and cell migration) were investigated as candidates for BPD.

Materials and methods. Total of 259 infants with gestational age <31 weeks born in Oulu University Hospital during 1997-2010 were studied. Of these, 61 were diagnosed with BPD. All infants were of Finnish origin. Eight *KITLG* and 23 *NR3C1* tagging SNPs were genotyped.

Results. Six SNPs of *KITLG* (rs11104906, rs10858753, rs17424193, rs4842477, rs11104948, rs869408) associated with BPD. The frequencies of two haplotypes including all the 8 SNPs were significantly different between infants with BPD and those without BPD. There was no association with *NR3C1* SNPs and BPD.

Conclusion. We are the first to show evidence that the polymorphisms of *KITLG* associate with susceptibility to BPD. This raises the possibility that transcription products of *KITLG,* expressed in endothelial cells or lung fibroblasts, are important in early lung growth. Present results remain to be confirmed.

P09.035

Association of leukocyte telomere length and cardio-vascular fitness: Results of the Austrian Stroke Prevention study.

P. Freudenberger[1], *A. Sen*[1], *M. Schallert*[2], *C. Nagl*[1], *N. Watzinger*[3], *R. Zweiker*[3], *R. Schmidt*[2], *H. Schmidt*[4];
[1]Institute of Molecular Biology and Biochemistry, Centre of Molecular Medicine, Medical university, Graz, Austria, [2]Clinical Section of Special Neurology, Department of Neurology, Graz, Austria, [3]Clinical department of cardiology, Medical university, Graz, Austria, [4]Institute of Molecular Biology and Biochemistry, Centre of Molecular Medicine, Centre of Molecular Medicine; Clinical Section of Special Neurology, Department of Neurology, Graz, Austria.

Background: Telomeres are short repetitive sequences protecting the ends of the chromosomes. Leukocyte telomere length (LTL) is related to age, inflammation, oxidative stress and life-style factors. Physical activity has been indicated to exert beneficial effects on LTL. This study investigates the effect of cardio-respiratory fitness (CRF) on LTL.

Methods: Relative LTL was measured by quantitative Real Time PCR in 907 participants of the Austrian Stroke Prevention Study, a community-based cohort study on brain aging.

CRF was estimated by exercise ECG in 794 subjects. The measured variables included diastolic and systolic blood pressure, heart rate during resting, peak and recovery phase. VO2max was calculated by the formula

15*weight[kg]*maximum/resting heart rate. The associations between each of the CRF variables and LTL were analyzed using multiple linear regression by adjusting for age and sex (Model 1) and additionally for hypertension, diabetes, cardiac disease and BMI (Model 2).
Results: We observed a significant association between LTL and maximum achieved heart rate (MHR) (Model 1 β=-0.002; p=0.022). Additional adjustment for vascular risk factors did not alter the effect size and the strength of this association (Model 2 β=-0.02;p<0.018). All other CRF variables were not significantly associated with LTL. The association was confined to subjects above the age of 65(Model2β=--0.003;p=0.005), to men (Model2β=-0.002; p=0.043) and to normotensives(Model2β=-0.004; p=0.018).
Conclusion: This is the first study investigating the association between CRF and LTL in a healthy elderly population. Our results suggest a protective role of MHR on LTL, which is present particularly in elderly, men, and normotensives.

Expression analysis of celiac disease candidate genes in the 6q22 GWAS peak

C. Bondar[1]*, L. Plaza-Izurieta*[2,3]*, N. Fernandez-Jimenez*[2,3]*, I. Irastorza*[4]*, C. E. G. E. C.*[5]*, C. Wijmenga*[6]*, F. Chirdo*[1]*, J. C. Vitoria*[4,2]*, J. R. Bilbao*[2,3]*;*
[1]*University of La Plata, La Plata, Argentina,* [2]*University of the Basque Country, Leioa-Basque Country, Spain,* [3]*BioCruces Research Institute, Barakaldo-Basque Country, Spain,* [4]*Cruces University Hospital, Barakaldo-Basque Country, Spain,* [5]*Spanish Consortium for Celiac Disease Genetics, (SEEC), Spain,* [6]*University Medical Center Groningen, Groningen, Netherlands.*

Celiac disease (CD) is an immune mediated, multigenic disorder where HLA-DQ2/DQ8 contributes about 35% to genetic risk. GWAS have found more than 26 regions for CD susceptibility, and several potentially functional candidate genes have been located within. Recently, the IMMUNOCHIP genotyping array discovered additional 13 regions of susceptibility. The GWAS signal in chromosome 6:128.0-128.4 kb pointed to THEMIS and PTPRK as possible candidate genes, both with immune-related function. The signal was narrowed to the PTPRK region in the subsequent study, but functional confirmation is pending.
The aim of this work was to determine the influence of associated SNPs on THEMIS and PTPRK gene expression in the intestinal mucosa of active and treated CD patients and controls.
We assessed the correlation between qPCR expression levels and SNP genotypes of the top SNPs in both studies (rs802734, rs55743914 and rs72975916) and those most strongly associated in our CEGEC population (rs10484718 and rs9491896).
THEMIS showed higher expression in active CD compared to treated patients and controls, while PTPRK showed lower expression. Our study confirmed an association of this region with CD in the local population, although only rs802734 genotype showed any influence in THEMIS expression. Interestingly we found a significant positive correlation between THEMIS and PTPRK mRNA levels in CD patients but not in controls.
Our results suggest a possible role for both candidate genes in CD pathogenesis although further investigation is needed to clarify the impact of the associated SNPs on their expression.

P09.037

Association of *FUT2* (rs601338) with celiac disease in Finnish patients

A. S. Parmar[1]*,* **N. Alakulppi**[2]*, E. Einarsdottir*[1]*, K. Kaukinen*[3]*, K. Kurppa*[4]*, M. Mäki*[4]*, K. Lindfors*[4]*, J. Partanen*[2]*, K. Aranko*[2]*, J. Mättö*[2]*, P. Wacklin*[2]*, P. Saavalainen*[1]*;*
[1]*Research Program for Molecular Medicine and Department of Medical Genetics, Haartman Institute, University of Helsinki, Helsinki, Finland,* [2]*Finnish Red Cross Blood Service, Helsinki, Finland,* [3]*Department of Gastroenterology and Alimentary Tract Surgery, Tampere University Hospital and School of Medicine, University of Tampere, Tampere, Finland,* [4]*Pediatric Research Center, University of Tampere and Tampere University Hospital, Tampere, Finland.*

Intestinal microbiota plays an important role in human health, and its composition is determined by several factors, such as diet and host genotype. However, host genes determining the intestinal microbiota composition are largely unknown. Recently, we (Wacklin et al. 2011) and Rausch et al. (2011) have showed that polymorphism in *FUT2,* which defines the expression of ABH and Lewis histo-blood group antigens in intestinal mucus and other secretions, affects intestinal microbiota composition. The *FUT2* gene encodes fucosyltransferase 2 enzyme. Non-functional enzyme resulting from nonsense mutation (rs601338, NM_000511.5:c.461G>A) in *FUT2* gene leads to the non-secretor phenotype (AA). Celiac disease is chronic inflammatory enteropathy occurring in genetically predisposed individuals after dietary gluten consumption. It is classically manifested in gastrointestinal tract (diarrhoea, malabsorption), but extra-intestinal symptoms, such as dermatitis herpetiformis (DH) are also common. In spite of several well-known genetic risk factors for celiac disease, environmental factors, e.g. microbiota, are suggested playing role in development of celiac disease. Interestingly, *FUT2* association with celiac disease was detected by Dickey et al. (1994), but not by Heneghan et al. (1996). Thus, it is possible that host genes could indirectly via microbiota composition be involved in manifestation of disease. We studied 1025 celiac disease patients and 2738 controls using Taqman assay for rs601338. We found suggestive associations at level of genotype (Cases and controls: f(AA) = 18.0%, 14.7%; f(AG) = 42.4%, 47.6%; f(GG) = 39.5%, 37.8%; p = 0.006) and recessive model (Cases and controls: f(AA) = 18.0%, 14.7%; f(AG/GG) = 82.0%, 85.3%; p = 0.011).

Expression of TLR signalling-related miRNAs (mir-21, mir-146a, mir-155) in celiac disease

L. Plaza-Izurieta[1,2]*, N. Fernandez-Jimenez*[1,2]*, I. Irastorza*[3]*, J. C. Vitoria*[3,1]*,* ***J. R. Bilbao***[1,2]*;*
[1]*University of the Basque Country, Leioa-Basque Country, Spain,* [2]*BioCruces Research Institute, Barakaldo-Basque Country, Spain,* [3]*Cruces University Hospital, Barakaldo-Basque Country, Spain.*

BACKGROUND: MicroRNAs have emerged as important regulators of gene expression by decreasing target mRNA levels. A trio of microRNAs, mir-21, mir-146a and mir-155, have been proven to be of considerable interest in relation to TLR signalling, and their dysregulation may be involved in many inflamatory diseases, including celiac disease (CD)
AIM: To evaluate the expression and relationship with disease status of these 3 microRNAs in the pathogenesis of celiac disease.
PATIENTS AND METHODS: Biopsy specimens from distal duodenum were obtained from 30 paediatric celiac patients at diagnosis and after 2 years on gluten free diet, and 18 non-celiac controls. miRNA expression was determined by RT-PCR, using commercially available mature-microRNA TaqMan assays. Experiments were run in triplicate in an ABI-PRISM 7900HT and results were normalized to RNU48 endogenous control. Groups were compared using parametric and non-parametric tests.
RESULTS AND CONCLUSIONS: mir-21 and mir-146a were upregulated in both groups of CD patients (debut and after 2 years on gluten free diet) when compared to controls, while mir-155 was only upregulated in active CD mucosa. The same tendency has been found in other immune related diseases, such as rheumatoid arthritis and systemic lupus erythematosus, and functional analysis of their target genes and proteins must be done to assess their role in the disease.

P09.039

Exploring the NFkB signalling pathway in celiac disease

N. Fernandez-Jimenez[1,2]*, A. Castellanos-Rubio*[1,2]*, I. Irastorza*[3]*, L. Plaza-Izurieta*[1,2]*, J. C. Vitoria*[1,3]*, J. R. Bilbao*[1,2]*;*
[1]*University of the Basque Country, Leioa-Basque Country, Spain,* [2]*BioCruces Research Institute, Barakaldo-Basque Country, Spain,* [3]*Cruces University Hospital, Barakaldo-Basque Country, Spain.*

The NFkB transcription factor family regulates a large array of genes involved in immunity, inflammation and cell survival. Previous work of our group showed constitutive activation of NFkB in the intestinal mucosa of patients with untreated celiac disease (CD), suggesting a pivotal role in the perpetuation of the inflammatory process.
Using RT-PCR in a custom Taqman Low Density Array, we analyzed the expression of 93 NFkB cascade genes in biopsies from 16 active celiac patients, 16 treated celiac patients on gluten-free diet and 16 non-celiac controls lakking inflammation of the gut at biopsy.
Twenty-two genes were significantly overexpressed in mucosa from both active and treated celiac patients compared to controls, and only one was downregulated, confirming the overall upregulation of NFkB pathway in CD. Most of those genes have central regulatory functions in the cascade and are clustered in Apoptosis and Toll-like Receptor (TLR) signalling KEGG pathways. In contrast, of the 10 genes upregulated only in mucosa from active CD patients, most were located in the periphery of the NFkB route, including activating ligands and receptors. The expression signature of each patient group, extracted using Correlation-based Feature Selection and Principal Component Analysis highlighted several deregulated genes and a substantial set of TLR-related genes. These preliminary results point to several specific response pathways as key activators of NFkB in CD.

P09.040

Effect of SOCS3 SNP rs4969170 in celiac disease

L. Plaza-Izurieta[1,2]*, L. M. Medrano*[3]*, N. Frnandez-Jimenez*[1,2]*, A. Lopez-Larios*[3]*, G. Gutierrez*[2]*, I. Irastorza*[4]*, C. E. G. E. C.*[5]*, C. Nuñez*[3]*, J. R. Bilbao*[1,2]*;*
[1]*University of the Basque Country, Leioa-Basque Country, Spain,* [2]*BioCruces Research*

Institute, Barakaldo-Basque Country, Spain, [3]Hospital Clínico San Carlos-IdISSC, Madrid, Spain, [4]Cruces University Hospital, Barakaldo-Basque Country, Spain, [5]Spanish Consortium for Celiac Disease Genetics, SEEC, Spain.

BACKGROUND: Celiac disease (CD) is defined as a Th1-mediated gluten-sensitive enteropathy. Recent studies have shown that Th17 cells may also contribute to disease pathogenesis. *SOCS3* is known to be a negative regulator of the Th17 response, and has been considered a candidate gene in CD. A SNP in *SOCS3* (rs4969170) has been recently associated with CD.
AIM: To study the expression of *SOCS3* in affected tissue in relation to rs4969170 genotype and to replicate the genetic association.
PATIENTS AND METHODS: Gene expression was analyzed in 29 CD biopsy pairs, taken at diagnosis and after 2 years on gluten free diet, and 12 controls. SNP rs4969170 was genotyped in 512 celiac patients and 607 controls from the CEGEC collection. TaqMan gene expression and genotyping assays were employed.
RESULTS: Gene expression showed statistically significant differences when comparing celiac patients before and after treatment, and also with healthy controls. *SOCS3* is downregulated in active disease, compatible with an increased Th17 response. No effect of the rs4969170 genotype on gene expression was detected, nor was the genetic association for this SNP replicated in our sample.

	Replication set (CEGEC)	
	CD	**Controls**
	(N=512)	(N=607)
GG	221 (43.2)	236 (38.9)
AG	229 (44.7)	283 (46.6)
AA	62 (12.1)	88 (14.5)

AA genotype; p = 0.266
CONCLUSION: Although SOCS3 could be a functional player in celiac disease, changes in expression are observed only in active mucosa, and seem to be a consequence of the inflammatory response rather than a primary effect of the associated variant.

P09.041
Association of the matrix metalloproteinases, disintegrin and metalloprotease 33 and the tissue inhibitors of metalloproteinases genes polymorphic markers with chronic obstructive pulmonary disease

***G. Korytina**[1], O. Tselousova[1], L. Akhmadishina[1], E. Viktorova[2], T. Victorova[1,3];*
[1]Institute of Biochemistry and Genetics, Ufa Scientific Center, Ufa, Russian Federation, [2]George-August University of Goettingen, Goettingen,, Germany, [3]Bashkortostan State Medical University, Ufa, Russian Federation.

The contribution of the polymorphic markers of the matrix metalloproteinases MMP1 (-1607 G>GG, rs1799750; -519 A>G, rs494379), MMP2 (-735C>T, rs2285053), MMP3(-1171 5A>6A, rs35068180), MMP9 (-1562C>T, rs3918242; 2660A>G, rs17576), MMP12 (-82 A>G, rs2276109), the disintegrin and metalloprotease 33 ADAM33 (12418A>G, rs2280091; 13491 C>G, rs2787094), the tissue inhibitors of metalloproteinases TIMP2 (-418G>C, rs8179090), TIMP3 (-1296T>C, rs9619311) genes to chronic obstructive pulmonary disease has been assessed. For this purpose, PCR-RFLP analysis of the gene polymorphisms in case (N=391) and control (N=514) groups has been performed. The 6A6A genotype of the MMP3 -1171 5A>6A polymorphism was associated with significantly high risk of chronic obstructive pulmonary disease (OR=2.490, Padj=0.003979 adjusted for age, sex, smoke pack-years, ethnos). Analysis showed an association of the G-G haplotype of 13491 C>G and 12418A>G ADAM33 gene polymorphisms (OR=0.39, Padj=0.0012) with chronic obstructive pulmonary disease. We found a significant interaction of the smoking status and ADAM33 12418A>G (Pinteraction=0.026) and TIMP3 -1296T>C (Pinteraction=0.044). The relationship between the GG genotype of the ADAM33 13491 C>G and emphysema risk was found (OR=1.74, Padj=0.013, Pcor=0.117). Severity of chronic obstructive pulmonary disease was modified by MMP9 -1562C>T in additive model (OR=1.883, Padj=0.028). The MMP3, MMP9, ADAM33, TIMP3 genes polymorphism may be an important risk factor for the development and progression of chronic obstructive pulmonary disease, important gene and environmental interactions were determined.

P09.042
Colorimetric Assay For Medium-High Resolution HLA-DQ2/DQ8 Typing For Coeliac Disease Predisposition Analysis

***H. Joda**[1], V. Beni[2], I. Katakis[1], N. Alakulppi[3], J. Partanen[3], K. Lind[4], L. Strömbom[4], C. K. O´Sullivan[1,5];*
[1]Departament d'Enginyeria Quimica, Universitat Rovira i Virgili, Tarragona, Spain, [2]Department of Physics, Chemistry and Biology, Linköping, Sweden, [3]Finnish Red Cross Blood Service, Helsinki, Finland, [4]TATAA Biocenter AB, Göteborg, Sweden, [5]Institucio Catalana de Recerca i Estudis Avançats, Barcelona, Spain.

Coeliac disease (CD) is a small intestinal inflammation disorder, triggered by the intake of gluten protein that present in certain cereals [1]. The prevalence of CD is about 1% in the European population [2].
CD has been shown to affect only genetically predisposed individuals; strong relation between this disease and Human Leukocyte Antigens (HLA) has been proved, with 95% of the CD patients carrying HLA DQ2 heterodimer and ca. 5% carrying DQ8 heterodimer [3]. DQ2 and DQ8 negative individuals have been shown to be very unlikely to develop CD[4].
Herein we present a colorimetric assay, based on enzyme-linked oligonucleotide assay (ELONA) technology in combination with reverse dot-blot *Sequence Specific Oligonucleotide Probes (SSOP)* approach, for rapid, easy to use and cost effective HLA typing of CD associated genes.
Multiplex colorimetric assay for medium to high resolution HLA typing of the DQ2 and DQ8 genes is demonstrated. Probes with high specificity for the cd associated alleles (DQA1*02:01, DQA1*03:01, DQA1*05:01/DQA1*05:05, DQB1*02:01/DQB1*02:02 and DQB1*03:02) were designed and tested by ELONA and surface plasmon resonance techniques (SPR).
Assay condition studies, performed by SPR and ELONA, revealed that detection can be performed in 25 minutes if operation temperature was set to 37 ºC.
Finally, the performances of the developed typing platform were validated by the analysis of a series of real patient samples.

P09.043
Searching for a causative mutation in a four-generation family with celiac disease using next-generation sequencing

***I. Ricaño-Ponce**, A. Szperl, C. C. van Diemen, C. Wijmenga;*
Department of Genetics, University Medical Center Groningen, University of Groningen, Groningen, Netherlands.

Celiac disease (CeD) is a common food intolerance, caused by a dysregulated immune respone to dietary gluten. It is strongly associated to the HLA-DQ2/DQ8 genes, which explain 35% of the heritability. Genome-wide association studies for CeD identified a further 39 non-HLA loci that explain another 5%. To identify more risk genes, we performed whole-genome linkage in a four-generation Dutch family segregating for CeD. We mapped a dominantly inherited linkage region at chromosome 9p21-13 and another region at 6q25 using a model-free approach.
We hypothesize that these regions may contain causal mutations for CeD and applied whole-exome sequencing to two affected individuals from the family to look for mutations. As CeD segregates in the dominant-like matter, we looked for heterozygous changes present in both individuals. We selected all non-synonymous, nonsense and splice-site changes of unknown or low frequency (MAF<5%) using datasets from 1000 Genomes, an NHLBI exome-sequencing project, and a set of 500 Dutch controls.
Two missense variants, on chromosomes 9p21-13 and 6q25, were further investigated and were both predicted to be damaging. However, the 6q25 variant was also present in one spouse and the family grandmother, both of whom did not carry the risk haplotype. The 9p21-13 variant showed perfect co-segregation in the family and is in a gene of largely unknown function, although it is highly expressed in epithelial tissue. This opens up the exciting possibility that it might be involved in barrier function. Further studies should investigate the gene function and its involvement in CeD pathogenesis.

P09.044
SNP association of *CNTN4, CNTN5, CNTN6, CHL1* and *GRIN2B* corroborates and extends copy number variation data in autism

***M. Poot**, C. G. de Kovel;*
Department of Medical Genetics, Utrecht, Netherlands.

Research into the genetics of neurobehavioral disorders such as autism spectrum disorder (ASD) is caught within the dichotomy of rare variants with a high phenotypic impact, such as copy number variations (CNVs), vs. common variants with a low effect size. To overcome this (false) dichotomy and to find missed heritability we performed an association study on candidate genes, which we had previously identified by SNP array-based CNV analyses in ASD patients (Neurogenetics (2011) 12, 315). Within these CNVs, genes with clear expression in the brain were selected. In total we examined 2,042 SNPs, spanning 16 Mb of genomic DNA, which were located within or immediately bordering these genes. We compared a cohort of 74 ASD patients without relevant CNVs with a population-based cohort of 132 healthy individuals that were not related to the ASD families. After Bonferroni correction for multiple testing we found significant association for one SNP within intron 11 of *CNTN4* (rs1420021), two SNPs within intron 7 and 9 of *CNTN5* (rs6590473 and rs11222599), one SNP within intron 1 of *CHL1* (rs17329247), one SNP within intron 1 of *CNTN6* (rs9878022), and 5 SNPs flanking exon 4 of *GRIN2B*. Our data corroborate involvement of contactins in ASD as indicated by our previous CNV study and indicate that certain genes may harbour variants with both high penetrance and with a smaller degree of effect for the same phenotype.

P09.045

An association between JAK3, STAT3 and CCL2 gene variants and myocardial infarction

***Y. R. Timasheva**, V. A. Matveeva, T. R. Nasibullin, O. E. Mustafina;*
Institute of Biochemistry and Genetics Ufa Science Centre Russian Academy of Science, Ufa, Russian Federation.

Systemic inflammation is considered to be an important factor in the development of coronary artery disease. The aim of the current study was to investigate candidate genes in the inflammatory molecular pathways involved in the progression of atherosclerosis. To achieve this goal, we replicated SNPs in *JAK1*, *JAK3*, *STAT3* and *CCL2* genes in the study group consisting of patients with MI and control subjects.

The group of MI patients of Russian ethnic origin (N=277), when compared to he control group (N=145), has demostrated increased *JAK3*T/*C* genotype frequency (44.23% vs. 32.2% respectively, P=0.032) and decreased *JAK3*C/C* genotype frequency (50% vs. 63.56% respectively, P=0.015). Increased prevalence of *STAT3*C/*C* and *CCL2*G/*G* genotypes was observed in MI patients of Tatar ethnicity (N=220) (16.59% vs. 8.82%, P=0.031, and 5.12% vs. 6.88%, P=0.014 respectively).

In our study, we have detected an association between MI and *JAK3* rs310216 in Russians, *STAT3* rs2293152 and *CCL2* rs3917887 in Tatars. *JAK3**T/*C was associated with increased risk of MI (OR= 1.67, CI: 1.06 - 2.64), while *JAK3**C/*C was found to be protective (OR= 0.57, CI: 0.34 - 0.90). In Tatars, *STAT3**C/*C and *CCL2**G/*G carriers demonsrated higher risk of MI (OR= 2.05, CI: 1.08 - 3.92, and OR= 2.43, CI: 1.21 - 4.90, respectively). Further investigations are needed to confirm these results and to understand the mechanisms underlying the associations.

P09.046

New genes and coronary artery disease

***M. Ghassibe-Sabbagh**[1], J. Cazier[2], S. Saade[1], D. Gauguier[2,3], D. E. Platt[4], P. A. Zalloua[1,5];*
[1]Lebanese American University, School of Medicine, Beirut 1102 2801, Lebanon, [2]The Wellcome Trust Centre for Human Genetics, University of Oxford, Roosevelt Drive, Headington, Oxford OX3 7BN, United Kingdom, [3]INSERM UMRS872, Centre de Recherche des Cordeliers, 75006 Paris, France, [4]IBM T. J. Watson Research Center, Yorktown Hgts, NY, United States, [5]Harvard School of Public Health, Boston, MA, United States.

Genome wide association studies and their replications that have associated DNA variants with myocardial infarction (MI) and/or coronary artery disease (CAD) are predominantly based on populations of European or Eastern Asian descent. Replication of the most significantly associated polymorphisms in populations with distinctive genetic backgrounds and lifestyles is crucial to the understanding of the pathophysiology of a multifactorial disease like CAD.

We have used our Lebanese cohort to perform a replication study of nine previously identified CAD/MI susceptibility loci (LTA, CDKN2A-CDKN2B, CELSR2-PSRC1-SORT1, CXCL12, MTHFD1L, WDR12, PCSK9, SH2B3, and SLC22A3), and 88 genes in related phenotypes. The study was conducted on 2,002 patients with detailed demographic, clinical characteristics, and cardiac catheterization results. One marker, rs6922269, in MTHFD1L was protective against MI (OR=0.68, p=0.0035), while the variant rs4977574 in CDKN2ACDKN2B was associated with MI (OR=1.33, p=0.0086). Associations were detected after adjustment for family history of CAD, gender, hypertension, hyperlipidemia, diabetes, and smoking. The parallel study of 88 previously published genes encompassed 20,225 markers, three quarters of which with imputed genotypes. The study was based on our genome-wide genotype data set, with imputation across the whole genome to HapMap II using HapMap CEU population as a reference. Analysis was conducted on the genotyped and imputed variants in the 88 regions covering selected genes. This approach replicated HNRNPA3P1-CXCL12 association with CAD and identified new significant associations of CDKAL1, ST6GAL1, and PTPRD with CAD.

Our study provides evidence for the importance of the multifactorial aspect of CAD/MI and describes genes predisposing to their etiology.

Systematic identification of genetic factors influencing the thickness of the cerebral cortex

***T. W. Mühleisen**[1,2], C. Herold[3], F. B. Siedek[1,2], S. Caspers[4], C. Roski[4], S. Lux[4], D. Drichel[3], S. Herms[1,2], P. Hoffmann[1,2], M. M. Nöthen[1,2,3], T. Becker[3,5], K. Zilles[4,6,7], K. Amunts[4,6,8], S. Cichon[1,2,4];*
[1]Institute of Human Genetics, University of Bonn, Bonn, Germany, [2]Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany, [3]German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany, [4]Institute of Neuroscience and Medicine (INM-1, INM-2), Research Center Juelich, Juelich, Germany, [5]Institute of Medical Biometry, Informatics, and Epidemiology, University of Bonn, Bonn, Germany, [6]JARA-BRAIN, Juelich-Aachen Research Alliance, Juelich, Germany, [7]C. and O. Vogt Institute for Brain Research, Heinrich-Heine-University Düsseldorf, Düsseldorf, Germany, [8]Department of Psychiatry, Psychotherapy, and Psychosomatics, RWTH Aachen University, Aachen, Germany.

The human cortex is structurally and functionally segregated. It varies more than any other part of the brain between subjects. The identification of gene variants contributing to this inter-subject variability will help to elucidate molecular mechanisms underlying brain functions.

In the present study, we focused on cortical thickness which is a heritable quantitative trait. Moreover, it is undergoing changes in many neuropsychiatric disorders. We analyzed 98 healthy volunteers using a 3T magnetic resonance imaging scanner, obtained T1-weighted images, and performed genome-wide genotyping (HumanOmniExpress/HumanOmni1S). Thickness data were extracted using the FreeSurfer software. To determine those data which explain most of the thickness variability, we applied a principal component analysis (PCA) on the pooled data from all cortical regions. We selected the first 15 principal components which together explained 80% of the total variance and performed genome-wide association studies (GWAS) on each component. Across PCA GWAS, SNP P-values were combined using a meta-analysis approach. Overall, 31 SNPs showed P-values of less than 1E-04. The most significant finding was a SNP on chromosome 16q23.2 (P=9.48E-06). Results of the individual GWAS of the first principal component, which explains 43% of the observed variability in thickness, will also be presented.

Several common genetic variants with suggestive evidence for association with cortical thickness were identified. We are currently analyzing the genes and available knowledge of their function and we have initiated a replication study in two independent samples to follow-up our results.

P09.048

Role for the assemblage of centrosome-derived structures in the pathogenesis of non-syndromic craniosynostosis

*C. Bernardini[1], M. Geloso[1], M. Barba[1], M. Puglisi[1], L. Massimi[2], G. Tamburrini[2], F. Michetti[1], C. Di Rocco[2], **W. Lattanzi**[1];*
[1]Insitute of Anatomy and Cell Biology, Università Cattolica S. Cuore, Rome, Italy, Rome, Italy, [2]Pediatric Neurosurgery, Università Cattolica S. Cuore, Rome, Italy, Rome, Italy.

This study attempted to clarify the molecular and cellular mechanisms underlying the premature ossification of calvarial sutures in non syndromic craniosynostoses (NS-CRS), highly prevalent craniofacial malformations with an unclear etio-pathogenesis. Calvarial specimens of patent and fused sutures were collected from 8 patients during surgery. Total RNA and calvarial cells were isolated from tissues. RNAs from matched samples of each patient was used for comparative microarray analysis using exon arrays enabling both gene- and exon-level analyses. Gene-level analysis allowed identifying 114 significantly modulated genes, mainly involved in cell adhesion, cell-matrix interaction, matrix mineralization, osteogenesis, and tissue development. Exon-level analysis produced a list of over 150 genes with significant differentiallly expressed exons suggesting tissue-specific alternative splicing events occurring at the dysmorphic site. These showed selected splice variants of the ciliopaties-associated genes that were differentially expressed in fused-versus-unfused suture calvarial tissues. Interesting the list included IFT88 and BBS9 genes which are associated with ciliopathic conditions in craniofacial disorders.

Calvarial cells isolated in primary culture from the suture specimens were analyzed morphologically using confocal microscopy. Fused suture-derived cells displayed a constitutive tendency towards the osteogenic commitment, increased growth kinetics, reduced primary cilia and abnormally orientated mitotic spindles. These resembled tumor-like features, confirmed in vitro by demonstrating a higher clonogenicity and a higher invasiveness in vitro of fused suture-derived cells. These suggest that a somatic alteration of centrosome-derived structures in the osteo-progenitor cells, could underlie the overworking osteogenic process at the site of calvarial suture fusion.

P09.049

Association analysis of OXTR and AVPR1B genes gene in criminal violence

A. R. Valiullina[1], *R. F. Kanzapharova*[1], *A. G. Zainullina*[2], *E. K. Khusnutdinova*[1,2];
[1]*Bashkir State University, Ufa, Russian Federation,* [2]*Institute of Biochemistry and Genetics Ufa Scientific Center of RAS, Ufa, Russian Federation.*

Human aggression and violence are, unfortunately, ubiquitous phenomena with substantial costs to society. Aggression - defined as hostile, injurious, or destructive behavior. It is known, that both oxytocin (OXT) and vasopressin (AVP) systems dysfunction is associated with social behavior. The physiologic effects of OXT and AVP are mediated through its specific receptors (OXTR and AVPR). The aim of the present study was to investigate the association OXTR and AVPR1B genes with criminal violence in Russian population. 177 violent offenders (convicted of murder or rape) were included in the study. The control group consisted of 301 voluntaries. Two SNPs (rs53576 and rs2254298) of the OXTR gene and two SNPs (rs33911258 and rs28632197) of the AVPR1B gene were genotyped using PCR/RFLP methods. For pairwise linkage disequilibrium and haplotype analysis, the Haploview 4.1 program was used. Odds ratios (OR) with 95% confident intervals (CI) were calculated. The only association we observed was an allele association between OXTR rs2254298 and criminal violence: G was significantly overrepresented in violent offenders group as compared to controls ($p=0.001$; $OR=2.93$, 95%CI: 1.43-4.03). There were no allele or genotype associations between the AVPR1B SNPs or the OXTR rs53576 and criminal violence. There was an evidence of the strong pairwise linkage disequilibrium (D‘ values between 0.89 to 0.99) between markers within the investigated genes. However, analysis of distribution of the estimated haplotype frequencies revealed no significant differences between violent offenders and control.

This work was supported by grant of the Russian Foundation for Humanities (11-06-00554a).

Higher post surgical opioid requirement in Crohn’s disease - expression profiling of small intestine biopsies

K. Hühne[1], *T. Münster*[2], *T. Rau*[3], *T. Foertsch*[4], *R. Croner*[4], *A. Ekici*[1], *B. Rautenstrauss*[5,6], ***A. Winterpacht***[1];
[1]*Institute of Human Genetics, University Hospital Erlangen, Erlangen, Germany,* [2]*Department of Anaesthesiology, University Hospital Erlangen, Erlangen, Germany,* [3]*Department of Patholgy, University Erlangen, Erlangen, Germany,* [4]*Department of Surgery, University Hospital Erlangen, Erlangen, Germany,* [5]*Medical Genetics Center, Munich, Germany, Erlangen, Germany,* [6]*Friedrich-Baur-Institut, München, Germany.*

Crohn’s disease (CD) is a painful inflammatory bowl disease with complex polygenic inheritance. It has been shown that a number of CD patients require significantly higher post operative opioid doses than patients undergoing comparable abdominal surgery. We recently demonstrated that this is not due to the most common variants in components of opioid metabolism. CD, therefore, may be a suitable model for the identification of novel pain susceptibility genes. In order to further investigate the molecular and genetic basis of this difference in pain perception within CD patients, we focused our attention on the affected tissue. RNA was extracted from sections of inflamed and non-inflamed small intestine tissue of 3 CD patients with high and 3 patients with low postsurgical opioid requirement. Expression profiling of all 12 tissues was performed using Affymetrix U133 Plus2.0 microarrays. Expression profiles were compared between inflamed and non-inflamed tissue of CD patients with high and low postoperative opioid consumption. We identified 18 transcripts (fold change of >2; p-value <0.05) which showed a significantly altered expression in tissue from high versus low consumers independent of the inflammation status. This includes genes already known to be involved in pain perception and/or inflammation as well as genes with yet unknown function. This is the first study investigating intestine tissue from CD patients with respect to their post surgical opioid requirement. Further investigation of the identified genes, their expression in normal and affected tissue, as well as their role in opioid metabolism and/or pain perception is currently in progress.

P09.051

Study of allelic variants in patients with CRPS from Samalanca (Spain)

M. López Bartolomé[1,2], *D. Fernández García*[1], *S. Lobato*[1], *C. Muriel Villoria*[2,3], *R. González Sarmiento*[1];
[1]*Unit of Molecular Medicine. Department of Medicine. University of Salamanca, Salamanca, Spain,* [2]*Cátedra Extraordinaria del Dolor. Grünenthal Foundation, Salamanca, Spain,* [3]*Unit of Pain. Anesthesia Service. Hospital Clínico de Salamanca, Salamanca, Spain.*

Background: Complex regional pain syndrome (CRPS) is a chronic pain condition that is believed to be the result of dysfunction in the central or peripheral nervous systems.

The existence of individual differences in response to painful stimuli suggests that genetic factors can be involved in its modulation. The aim of our study was to investigate the genetic variation of 16 genes involved either in nervous system pathways or in drug metabolism, in patients from Salamanca (Spain), diagnosed CRPS.

Methods: Genomic DNA was extracted from peripheral blood by standard techniques. We selected 16 non-synonymus SNPs. Studies were performed using TaqMan probes (Applied biosystems) for the analysis of the polymorphisms in the following genes: TRPV, GSTP1, CYP2D6, COMT, PTGS2, HTR2A, SLLC6A4, OPRD, OPRM, OPRK, CNR1, DRD2, GABRA1, GABRA6, PPARG, EDN1. Statistical analysis was performed comparing the different allelic variants of the genes in subgroups of patients: patients with a VAS below and over 50.

Results and conclusion: Preliminary analysis has shown significant differences in genotyping distribution ($p<0.05$) comparing both groups of patients in the EDN1 and PTGS2 genes. When we split groups according sex, we find significant differences in EDN1 and IL1B for men, and in PTGS2, GABRA1, TRPV and GSTP1 for women.

That support the hypothesis that genetic variants could be associated with increased susceptibility to suffer pain.

Cystic fibrosis (CF) is the most common lethal autosomal recessive disease with prevalence of 1:2500 newborns. The cause of death in 90% is respiratory insufficiency due to chronic inflammation caused by bacterial infections.

Mannose-binding lectin (MBL) protein is an important mediator component of the innate immune defense system. It has been shown that *MBL2* variant alleles causing low MBL serum levels are associated with an increased risk of infections. In exon 1, three single nucleotide polymorphisms (SNPs) and one in promoter region cause independently low MBL serum levels. We therefore investigated whether *MBL2* gene variants are associated with pulmonary function or susceptibility to infection in Slovak CF patients.

DNA polymorphisms were typed by single base primer extension assay (SNaPshot) in 91 patients and 100 controls. The concentrations of protein were determined in 34 patients by a sandwich enzyme-linked immunosorbent assay, also spirometric and microbiological data were collected from medical records.

In this study we found that *MBL2* genotypes were associated neither with earlier acquisition of bacterial infection nor with reduced pulmonary function among patients. Although *MBL2* genotypes were associated with the MBL2 protein serum level, results were statistically significant only for polymorphisms in exon 1, with $p=0.0008$.

The role of the *MBL2* gene in lung disease severity in CF patients represents a very complex phenomenon where both genetic and environmental factors play an important role. Understanding this complexity requires further studies based on a broader scale of genetic factors involving both a whole-genome approach and a larger patient cohort.

Analysis of *TCF7L2* gene polymorphism in CF Russian patients with and without diabetes.

T. A. Vasilyeva[1], *V. A. Samoylenko*[2], *G. J. Babadjanova*[2], *N. V. Petrova*[1];
[1]*Research Centre for Medical Genetics, Russian Academy of Medical Sciences, Moscow, Russian Federation,* [2]*Research Center of Pulmonology Healthcare Ministry of Russian Federation, Moscow, Russian Federation.*

Diabetes is an important complication of cystic fibrosis (CF), a multisystem genetic disease caused by mutations in the cystic fibrosis conductance regulator gene (*CFTR*). Diabetes risk increases with age and is associated with a significantly worse CF prognosis. Recent studies indicate that variants in *TCF7L2* gene, transcription factor 7 like 2, or the type 2 diabetes susceptibility gene, modifies risk of diabetes in CF. Analysis of three polymorphisms in *TCF7L2* gene (rs7903146, rs12255372, rs11196205) was carried out in two groups of adult Russian CF patients: 47 patients with diabetes (mean age 22,6 years; 25 males : 22 females); 55 patients without diabetes (mean age 22, 8 years; 28 males : 27 females). The difference of the allele and genotype distribution at rs11196205 polymorphism in *TCF7L2* gene between two analyzed groups of CF patients was revealed. The frequency of C allele at rs11196205 is significantly lower in CF patients with diabetes than in CF patients without diabetes (0,394 versus 0,558; p=0,02). Allele C is associated with decreasing risk of diabetes in CF patients (OR=0,51 (95%CI 0,29-0,91); p=0,02).

Background: Of patients with diabetes mellitus (DM), 20%-40% develop diabetes nephropathy (DN) which belongs to one of the most frequent causes of hemodialysis therapy. The process of hemodialysis (HD) itself is not without the influence on patient´s immune system, additionally impaired immune functions are documented in DM patients. Elevations of cell-free DNA (cfDNA) concentrations during HD sessions were reported in numerous studies regardless of an applied therapeutic protocol. In this study, we focus on methylation status of promoter of immune response genes at the level of plasma cfDNA and their changes iniciated by the process of hemodialysis in DN patients.
Methods: We isolated plasma cfDNA from 20 patients with DN before and after a HD session. The extent of promoter methylation of 24 genes involved in immune response was examined using the Methyl Profiler DNA Methylation PCR Array System and cluster analysis (SABiosciences, Qiagen).
Results: We discovered significant changes in methylation profiles that were promoted in consequence of patient´s blood contact with artificial surfaces of dialyzer. According to the character of methylation profiles it seems that Th17 cells related immunity may play role in the response of DN patients to HD.
Conclusion: The method provides the new tool for evaluation of immune system activity in HD patients and its results can be further correlated with clinical data to bring new insights in the complex pathogenesis.

Locomotor dysfunction and hypotonia in Down syndrome mouse models for the Stch-App region as a consequence of dosage sensitive genes controlling muscular metabolism and mitochondrial function

V. Brault[1], *S. Pothion*[2], *M. Karout*[1], *I. Sahun*[3], *J. Bizot*[4], *C. Borel*[5], *F. Trovero*[6], *D. Dembele*[1], *S. E. Antonarakis*[5], *M. Dierssen*[7], *Y. Herault*[1,8,9];
[1]*IGBMC, Illkirch, France,* [2]*CNRS UPS44 TAAM, Illkirch, France,* [3]*Center for Genomic Regulation, Barcelona, Spain,* [4]*Key-Obs, Orleans, France,* [5]*University of Geneva Medical School, Geneva, Switzerland,* [6]*Key Obs, Orleans, France,* [7]*Center for Genomic regulation, Barcelona, Spain,* [8]*CNRS UPS44 TAAM, Orleans, France,* [9]*ICS, Illkirch, France.*

Aneuploidies of human chromosome 21 (Down syndrome and monosomy 21) lead to variable physiological abnormalities, with constant mental retardation and delayed locomotor skills. Delayed motor performance, weak muscle strength and exercise limitation observed in individuals with Down syndrome are not yet understood and remain a challenging issue. They have been attributed to impaired coordinated input due to cerebellar dysfunction, but might have a more complex origin. Phenotypic investigation of mouse models of trisomy (Ts2Yah) and monosomy (Ms3Yah) for the *Stch-App* region revealed the existence in this region of genes sensitive to dosage that are controlling muscle strength, motor function and endurance. A transcriptome analysis of skeletal muscle in Ms3Yah mice revealed up-regulation of genes implicated in mitochondrial function and in the oxidative phosphorylation pathway, a finding that was confirmed by the visualization of increased number of oxidative fibers. The opposite down regulation was observed in Ts2Yah mice, although with less effect. In addition, myopathy-like muscle fiber and mitochondria damage was observed in the Ms3Yah model. Our findings demonstrate that one or more gene(s) present within the *Stch-App* region are implicated in the regulation of muscle energy metabolism and integrity, and point at a defect in the mitochondrial respiratory chain. We propose that locomotor deficits observed in Down syndrome are the results, not only of a central nervous system defect, but also have a peripheral origin ant that the *Stch-App* region contributes to those. Candidate genes for this new phenotype are currently under investigation.

Aging alters DNA methylation level in the genes involved in common diseases

H. Kitajima[1,2], *K. Ohnaka*[3], *R. Takayanagi*[2], *K. Yamamoto*[1];
[1]*Division of Genome Analysis, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan,* [2]*Department of Medicine and Bio-Regulatory Science, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan,* [3]*Department of Geriatric Medicine, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan.*

Aging affects various physiological processes and increases susceptibility to diseases. Whether aging alters DNA methylation level and how the aging-related epigenetic change influences disease traits are of great interest. To settle this matter, we performed epigenome-wide association study by analyzing approximate 450K DNA methylation sites using the blood sample of total 288 subjects in Japanese general population. We conducted multistage association analysis between DNA methylation level and age by adjusting with sex and body mass index using general linear model for 96 subjects in each step. We identified 15 methylation sites of 11 genes associated with age which showed P-value < 0.001 in every three sets and showed P-value $1.0 \times 10^{-29} \sim 1.0 \times 10^{-9}$ in combined set. The functional information of these genes are as follows; 3 sites in one of the susceptibility loci of Diabetes Mellitus, 2 sites related to fatty acid metabolism, 2 sites in the coactivator of the androgen receptor, 1 site in proapoptotic pathway, 1 site related to atherosclerosis development, 1 site affected putative deubiquitinase and 1 site of plasma membrane sodium and calcium exchanger. Our results suggest that aging may alter epigentic status in the genes involved in common diseases such as diabetes, dyslipidemia, cardiovascular disorder and cancer.

Androgenetic alopecia is a common hair loss disorder which occurs in both sexes. The disorder is termed male-pattern baldness (AGA) in men, and female pattern hair loss (FPHL) in women. Although the precise etiopathogenesis of FPHL remains unknown, one likely hypothesis is that sex steroid hormones are crucial for the development of FPHL. However, we could not demonstrate significant association for any of the 32 genotyped variants of the hormone receptor genes aromatase-gene (CYP19A1), progesterone receptor (PGR), steroid-5-alpha-reductase alpha polypeptide 1 and 2 (SRD5A1, SRD5A2) and estrogen receptors 1 and 2 (ESR1, ESR2). Another likely hypothesis is that FPHL and AGA share common disease-causing mechanisms and a common genetic background. The two major susceptibility loci for AGA are the X-chromosomal locus AR/EDA2R; and a locus on chromosome 20p11. We performed a fine mapping study of AR/EDA2R and genotyped five SNPs from the chromosome 20p11 region that reached genome-wide significance in a recent GWAS of AGA. No significant association was obtained for any of the 20p11 variants, assuming that this locus do not influence susceptibility to FPHL. At AR/EDA2R, seven markers showed significant association in the subgroup of early affected UK patients, suggesting that the AR/EDA2R locus may be specifically involved in the pathogenesis of early-onset FPHL. Enlargement of the collective of 230 patients (145 UK; 85 German) and 329 controls (179 UK; 150 German) as well as a genome-wide association study might help to understand the role of AR/EDA2R and to identify further genes contributing to the development of FPHL.

Clínico S. Carlos, Instituto de Investigación Sanitaria San Carlos (IdISSC), Madrid, Spain.

Genome-wide association studies have identified 26 non-HLA risk loci for celiac disease (CD), a common autoimmune disorder. The SNPs in most of these loci are in very high linkage disequilibrium, which makes fine-mapping difficult. To refine the association signals we used Immunochip, a custom-made array that includes common and rare variants with a dense coverage of known immune-related loci. We were able to fine-map more than 50% of CD loci and identified 13 new risk loci. The most significant signal mapped to an intronic region of 70 kb in the LPP gene (rs2030519, p-value 3x10-49). Upon conditional analysis on this SNP, the association within this locus disappeared, indicating association to a single common haplotype.

Our aim was to refine the associated region in the LPP locus by comparing the risk haplotype across four independent populations of European origin, using the Cross test, a haplotype association algorithm. We have shown that risk haplotypes in the four populations are derived from the same common ancestor and thus might carry the same causal variant in all four populations. By comparing risk haplotypes to non-risk haplotypes, we were able to narrow down the region from 70 kb to 18 kb.

To investigate functional regulatory elements at this region, we used ENCODE annotation to indicate the most likely candidate variants. We suggest that deregulation of transcription factor binding properties might be a causal mechanism underlying the association of the LPP region to celiac disease. These variants should be studied further by functional means.

FTO levels affect RNA modification and the transcriptome

T. Berulava[1], *M. Ziehe*[2], *L. Klein-Hitpaß*[3], *E. Mladenov*[4], *J. Thomale*[3], *U. Rüther*[5], *B. Horsthemke*[1];
[1]Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany, [2]Analytical and Environmental Chemistry, Humboldt-Universität zu Berlin, Berlin, Germany, [3]Institut für Zellbiologie (Tumorforschung), Universitätsklinikum Essen, Essen, Germany, [4]Institut für medizinische Strahlenbiologie, Universitätsklinikum Essen, Essen, Germany, [5]Institut für Entwicklungs- und Molekularbiologie der Tiere (EMT) Heinrich-Heine-Universität, Düsseldorf, Düsseldorf, Germany.

A block of single nucleotide polymorphisms (SNPs) within intron 1 of the *FTO* (fat mass and obesity associated) gene is associated with variation in body weight. Previous works suggest that increased expression of *FTO*, which encodes a 2-oxoglutarate-dependent nucleic acid demethylase, leads to increased body weight, although the underlying mechanism has remained unclear. To elucidate the function of FTO we examined the consequences of altered FTO levels in cultured cells and murine brain. We show that a knockdown of *FTO* in HEK293 cells affects the transcripts levels of autophagy related genes, whereas overexpression of *FTO* affects the transcript levels of genes involved in RNA processing and metabolism. Subcellular localization of FTO further strengthens the latter notion. Using immunocytochemistry and confocal laser scanning microscopy, we detected FTO in nuclear speckles and - to a lesser and varying extent - in the nucleoplasm and nucleoli of HEK293, HeLa and MCF-7 cells. Moreover, RNA modification analyses revealed that loss of FTO affects the 3-methyluridine/uridine and pseudouridine/uridine ratios in total brain RNA, which mostly consists of rRNAs. We conclude that altered levels of FTO have multiple and diverse consequences on RNA modifications and the transcriptome and that the links between autophagy, RNA modifications and obesity need to be further explored. At present, we are trying to identify the RNA(s) that is(are) modified by FTO.

P09.061

The FTO gene polymorphisms are associated with obesity in the Chinese postmenopausal women

M. Lin[1,2], *C. Hwu*[3], *L. Chen*[1], *L. Hsiao*[3], *H. Wu*[4], *J. Fuh*[5], *L. Ho*[3];
[1]Institute of Public Health, National Yang-Ming University, Taipei, Taiwan, [2]Department of Medical Research and Education, Taipei Veterans General Hospital, Taipei, Taiwan, [3]Section of Endocrinology and Metabolism, Department of Medicine, Taipei Veterans General Hospital, Taipei, Taiwan, [4]Department of Radiology, Taipei Veterans General Hospital, Taipei, Taiwan, [5]Department of Neurology, Taipei Veterans General Hospital, Taipei, Taiwan.

Obesity is an important risk factor for type 2 diabetes and cardiovascular diseases. The fat mass and obesity-associated gene (FTO) was recently identified as a susceptibility locus for both obesity and type 2 diabetes by genome-wide association studies in several European populations. To investigate the association between FTO gene polymorphisms and obesity in the Chinese postmenopausal women, we genotyped three single nucleotide polymorphisms (SNP) of the FTO gene (rs1421085, rs9939609, and rs9930506) in 424 postmenopausal women recruited from a health survey at the clinics of General Medicine and Metabolism in a university teaching hospital. Among these women, 56 of them were obese (BMI>=27), 108 with overweight (24=<BMI<27) and 260 with normal weight (BMI<24). We found the rs9930506 SNP was significantly associated with obesity in our postmenopausal cohort (p = 0.041). The women carrying with the GG or GA genotypes of the rs9930506 was associated with increased risk of obesity as compared with those with the AA genotype (42.9% v.s. 26.9%, *p* = 0.014). After adjustment for age and physical inactivity, the association between rs9930506 and obesity remains statistically significant (OR=2.02, 95%C.I.:1.13-3.62, p-value=0.019). In conclusion, our results suggest the polymorphisms of the FTO gene are significantly associated with obesity in postmenopausal women. We replicated previous finding of the association between FTO gene polymorphisms and obesity in our Chinese postmenopausal women population.

P09.062

Opisthorchis felineus liver fluke modifies genetic risk of bronchial asthma and serum IgE levels

M. B. Freidin[1], *I. V. Saltikova*[1], *E. Y. Bragina*[1], *L. M. Ogorodova*[2], *V. P. Puzyrev*[1,2];
[1]Research Institute of Medical Genetics, Tomsk, Russian Federation, [2]Siberian State Medical University, Tomsk, Russian Federation.

Gene-environmental interactions (GxE) are in focus of contemporary studies of allergic diseases and traits. Helminth invasion is recognised as an important factor influencing atopic disease risk. Earlier, we revealed that liver fluke *Opisthorchis felineus* invasion has a significant impact on epidemiological portrait of allergic diseases and immunological status in atopy in Siberian populations (*Parasitol Res. 2007;101(4):1165-8*). We now set out to investigate if the helminth invasion is an environmental factor modifying genetic risk of allergy.

Twenty one single nucleotide polymorphisms (SNP) of immune-response genes were analysed in 222 healthy people and 207 bronchial asthma (BA) patients with established status of *O. felineus* invasion. Linear regression models were built using the interaction of the SNPs and *O. felineus* invasion as a predictor of BA and total IgE levels.

Three significant GxE models were found for BA, including rs2069705 (*IFNG*; $P_{int} = 0.010$), rs2066807 (*STAT2*; $P_{int} = 0.015$), and rs673848 (*SOCS5*; $P_{int} = 0.004$) SNPs. Odds ratios for the significant GxE terms indicated approximately 2-times higher or lower risk of BA in corresponding groups. Two significant GxE models were obtained for total serum IgE, and included rs2069705 (*IFNG*; $P_{int} = 0.046$) and rs167769 (*STAT6*, $P_{int} = 0.032$). In both models, the presence of the helminth invasion associated with lower IgE levels. The results lacked the significance after correction for multiple testing, likely, due to small sample size. However, the data is the first indication of the importance of *O. felineus* invasion as an environmental factor modifying genetic risk of BA and atopy.

P09.063

Suicide and glutamatergic system: NMDAR1 gene

M. Alves[1], *B. Silva*[2], *C. Cordeiro*[2], *C. Marques*[2], *J. Fonte Santa*[2], *D. N. Vieira*[2,3], *A. M. Ambrósio*[1,4];
[1]Clinical and Molecular Genetics Unit of NILM, Coimbra, Portugal, [2]National Institute of Legal Medicine, Coimbra, Portugal, [3]Faculty of Medicine of University of Coimbra, Coimbra, Portugal, [4]IBILI-Faculty of Medicine of University of Coimbra, Coimbra, Portugal.

Suicide is one of the leading causes of mortality in many countries and is caused by a combination of genetic and environmental factors. Alterations in glutamate neurotransmission and particularly the ionotropic glutamate receptors have long been suggested to play a crucial role in the etiology of suicide. However, no genetic studies have been performed with NMDAR1 gene in order to explore the hypothesis of glutamatergic system in suicide susceptibility. The aim of this study was to test the potential involvement of single nucleotide polymorphism G1970A of NMDAR1 gene in the etiology of suicide in the Portugese population. Peripheral blood was collected from suicide victims and controls in the National Institute of Legal Medicine, Portugal and using a standard method, genomic DNA was extracted. The polymorphism G1970A in the coding region of NMDAR1 gene was investigated by RFLP-PCR. The PCR product was digested with MspI enzyme at 37ºC and after digestion, the fragments were separated by electrophoresis on a 3% agarose gel.

For the G1970A polymorphism of NMDAR1 gene, there was no significant differences either in allele frequency or genotype frequency between two groups (p> 0,05). In this study no evidence of association was found between the G1970A polymorphism of NMDAR1 gene and suicide in our sample and these results suggest that this polymorphism does not play a major role in the susceptibility to suicide.

P09.064

Genetic predisposition to tuberculosis in native and immigrant Siberian populations

***A. Rudko**[1], M. Freidin[1], E. Bragina[1], N. Babushkina[1], A. An[2], A. Garaeva[1], V. Puzyrev[1,2];*
[1]Research Institute of Medical Genetics, Tomsk, Russian Federation, [2]Siberian Medical University, Tomsk, Russian Federation.

There is a difference in prevalence of tuberculosis (TB) among ethnically divergent Siberian populations with highest rates of disease among aboriginal Asian populations. Given the similar environment, differential genetic background can be responsible for distinguished TB liability in native and immigrant Siberian populations. We addressed this issue in a study of common polymorphisms of twelve immune-response modifying genes in Siberian populations of Russians (304 patients, 265 controls), Tuvinians (238 patients, 263 controlss), and Yakuts (150 patients, 135 controls). Both ethnic specific and common association between the genes and TB were identified. The rs12756687 (*PIAS3*), rs3760903 (*PIASY*), rs167769 (*STAT6*), rs1024611 (*MCP1*), and rs2069705 (*IFNG*) polymorphisms were associated with TB in Russians. The rs7572482 (*STAT4*), rs3760903 (*PIASY*), and rs167769 (*STAT6*) were linked to disease in Tuvinians. The rs16967593 (*STAT5B*), rs3760903 (*PIASY*), rs17880053 (*IFNGR2*), rs1024611 (*MCP1*) were associated with TB in Yakuts. The *PIASY* gene was associated with TB in all studied populations suggesting it as a cosmopolitan TB gene. However, while in Russians the common allele was protective against the disease (OR=0.67, P = 1E-6), in Tuvinians and Yakuts it increased the risk of TB (OR = 1.41, P = 0.032; OR = 1.67, P = 0.035, respectively). *STAT6* gene common allele was protective in Russians and predisposing in Tuvinians; while in case of *MCP1* gene, common allele was predisposing in Russians and protective in Yakuts. This finding suggests specificity in allelic effects predisposing to TB in Asians and Russians of Siberia. Molecular mechanisms of these inverse effects are to be investigated.

Genome-wide association study identifies sequence variants associated with hematological traits in Asian population

***J. OH**, Y. Kim, Y. Kim, Y. Cho;*
Korea National Institute of Health, Chungcheongbuk-do, Korea, Republic of.

To identify genetic loci influencing hematological traits, we conducted a genome-wide association study (GWAS) of 8,842 subjects recruited from population-based cohorts in Korea. Replication from independent population (N=7,861) to validate GWAS results revealed SNPs reaching genome-wide significance for selected hematological traits. We identified significant associations between platelet count and genetic variants in four regions on chromosome 4p16.1 ($P_{combined} = 1.46 \times 10^{-10}$, in *KIAA0232*), 4q25 ($P_{combined} = 6.68 \times 10^{-12}$, in or near *EGF*), 12q24.12 ($P_{combined} = 1.11 \times 10^{-15}$, in *SH2B3*) and 6p21 ($P_{combined} = 1.69 \times 10^{-7}$, in *BAK1*). GWAS for WBC showed strong evidence of genetic association on 17q21.1a ($P_{combined} = 1.1 \times 10^{-16}$) which contains *CSF3* gene. Blood hemoglobin concentration was significantly associated with one region on 22q12.3d ($P_{combined} = 2.2 \times 10^{-8}$) localizing to *TMPRSS6* that is required to sense iron deficiency. Two SNPs were detected for their association with RBC from GWAS (RBC data not available in replication subjects). One ($P = 8.6 \times 10^{-9}$) is located on 6p21.1f in *MED20* encoding a component of the mediator complex. The other ($P = 3.3 \times 10^{-12}$) localizes to 4q12 surrounded with several genes (*CHIC2/GSX2/PDGFRA/KIT*). Interestingly, One locus located on 6q23.3a near *MYB* showed strong association with WBC ($P_{combined} = 5.7 \times 10^{-7}$), RBC ($P = 3.8 \times 10^{-25}$) and hematocrit ($P_{combined} = 5.1 \times 10^{-9}$). This locus is known to play an important role in proliferation and differentiation of hematopoietic progenitor cells. Our findings might enhance to unravel molecular mechanisms underlying these hematological traits.

P09.066

The estimation of Heritability analyses for BMI of Genome-wide Association studies based on Korean cohort

***j. Lee**, Y. Kim, Y. Kim, N. Kim, J. Oh, B. Han, J. Lee;*
NIH, Korea, chungwon, Korea, Republic of.

Many Single nucleotide polymorphisms were significant for various risk factors, but these SNPs account for small fraction. We estimated heritability from the number of risk alleles related on BMI and analyzed linear model. For population and twin-family based on cohort in Korea, we predicted and compared the heritability for BMI using various methods. The aim of this study was to estimate variation and their heritability for BMI including genotype information. We have constructed community and twin-family based on cohort, which is an ongoing prospective studies and surveyed samples were drawn from the Korean Genome and Epidemiology Study and Korea Genome Analysis Project in Korea. From Twin-Family cohort, we selected 2,473 subjects in twin-family cohort and surveyed their zygosity using the self-report questionnaires about 2,000 items and genotyped using Affy 6.0. From community-based cohort(KARE; Korea Association REsource), we selected 8,842 subjects and surveyed their self-report questionnaires about 1,400 items and genotyped using Affy 5.0. We estimated heritability for BMI using SOLAR, GCTA, GENABEL. These were estimated and optimized Quantitative genetic analysis adjust age and sex. The estimation value of heritability for BMI based on twin-family cohort, was 0.67(p=5.21E-86) using SOLAR(including only epidemiological data) and was 0.44(p<0.000) using GCTA and was 0.44(p<0.000) using GENABEL(including epidemiological and genotype data) . The estimation value of heritability for BMI based on KARE, was 0.15(p=1.13E-04) using GCTA and was 0.18(p<0.000) using GENABEL. The estimation difference of heritability between Twin-Family and KARE cohort, it depends on sampling error and related/unrelated structure.

Estimated heritability of the metabolic syndrome components in the Tehranian families: Tehran Lipid and Glucose Study (TLGS)

***M. Zarkesh**[1], M. Daneshpour[1], B. Fam[1], M. Fallah[2], N. Hosseinzadeh[1], K. Guity[1], F. Hosseinpanah[1], A. Momenan[3], F. Azizi[3];*
[1]Obesity Research Center, Research Institute for endocrine sciences Shaheed Beheshti University of Me, Tehran, Islamic Republic of Iran, [2]Kowsar Research Center of Human Genetic, Tehran, Islamic Republic of Iran, [3]Endocrine Research Center, Research Institute for Endocrine Sciences, Shahid Beheshti University, Tehran, Islamic Republic of Iran.

Introduction: Growing evidence suggests that the metabolic syndrome has both genetic and environmental bases. To evaluate the possibility of further genetic analysis, this study estimated the heritability of the metabolic syndrome (MetS) components in the families with metabolic syndrome among from Tehran Lipid and Glucose Study.

Methods: We investigated 904 nuclear families with two biological parents and at least one offspring (1565 parents and 2448 children), aged 3-90 years of Tehran Lipid and Glucose Study, whom metabolic syndrome information was available and had at least two members of family with metabolic syndrome. MetS was defined in adults according to the Joint Interim Statement (JIS) criteria and for offspring as Cooks guide lines. Variance component methods were used to estimate age and sex adjusted heritability of the metabolic syndrome component using SOLAR software.

Results: The heritability of waist circumference (WC), HDL-C, triglyceride (TG), fasting blood sugar (FBS), systolic blood pressure, and diastolic blood pressure as continuous traits after adjusting for age and gender, were 27, 46, 36, 29, 25, and 26%, respectively. When the metabolic syndrome components were analyzed as discrete traits, the estimates of age and gender adjusted heritability for abdominal obesity, low HDL-C, high TG, high FBS, and high blood pressure varied to 22, 40, 34, 38, and 23%, respectively (p <0.05).

Conclusion: We clearly demonstrated a significant heritability of MetS components among TLGS families. The results strongly encourage efforts to identify the underlying susceptibility genes.

P09.068

Association of HIF1A gene Pro582Ser polymorphism with strength athlete status and strength performance in children

***R. T. Gabbasov**[1], A. A. Arkhipova[1], A. V. Borisova[1], A. M. Hakimullina[2], D. N. Gavrilov[2], A. V. Kuznetsova[1], A. G. Williams[3], S. H. Day[3], I. I. Ahmetov[1,2];*
[1]Kazan State Medical University, Kazan, Russian Federation, [2]St Petersburg Research

Institute of Physical Culture, St Petersburg, Russian Federation, [3]Institute for Performance Research, Manchester Metropolitan University, Crewe, United Kingdom.

Hypoxia-inducible factor 1-α (HIF-1α; encoded by HIF1A gene) controls a number of genes that are implicated in various cellular functions including glycolysis, cell proliferation and differentiation. The 582Ser allele of the Pro582Ser (rs11549465 C/T) polymorphism in the HIF1A gene increases protein stability and transcriptional activity, and therefore, improves glucose metabolism. The aim of our study was to investigate the association between the HIF1A Pro582Ser polymorphism, elite strength athlete status and strength related phenotypes in 225 middle school-age children (116 boys and 109 girls; aged 11±0.4). A total of 208 Russian strength athletes (122 weightlifters and 86 wrestlers) of regional or national competitive standard and 1,413 controls were genotyped using PCR-RFLP method. We found that the frequency of the HIF1A 582Ser allele was significantly higher in weightlifters (13.1%, P = 0.0031), as well as in wrestlers (15.7%, P = 0.0002) compared to controls (7.5%). Additionally, the highest (21.1%; P = 0.0052) frequency of the 582Ser allele was found in a group of elite strength athletes. Furthermore, the carriers of the HIF1A 582Ser allele among boys demonstrated the best results of handgrip strength testing than Pro/Pro homozygotes (Pro/Pro - 13.4 (3.1) kg, Pro/Ser - 16.5 (2.5) kg; P = 0.049). Thus, our study provides evidence for the association between the HIF1A gene Pro582Ser polymorphism, elite strength athlete status and strength performance in children. Although more replication studies are needed, the preliminary data suggest an opportunity to use the analysis of HIF1A polymorphism along with other gene variations in athletic talent identification.

P09.069

Replication of functional serotonin receptor type 3A and B variants in bipolar affective disorder: a European multicenter study

***C. Hammer**[1], S. Cichon[2,3,4], T. W. Mühleisen[2,4], B. Haenisch[2,4], F. Degenhardt[2,4], M. Mattheisen[2,4,5], R. Breuer[6], S. H. Witt[6], J. Strohmaier[6], L. Oruc[7], F. Rivas[8], G. Babadjanova[9], M. Grigoroiu-Serbanescu[10], J. Hauser[11], R. Röth[1,12], G. Rappold[1], M. Rietschel[6], M. Nöthen[2,4,13], B. Niesler[1,12];*

[1]Department of Human Molecular Genetics, University of Heidelberg, Heidelberg, Germany, [2]Life &Brain Center, Department of Genomics, University of Bonn, Bonn, Germany, [3]Institute of Neuroscience and Medicine (INM-1), Research Center Juelich, Jülich, Germany, [4]Institute of Human Genetics, University of Bonn, Bonn, Germany, [5]5Department of Biostatistics, Harvard School of Public Health, Boston, MA, United States, [6]Central Institute of Mental Health, Department of Genetic Epidemiology in Psychiatry, University of Mannheim, Mannheim, Germany, [7]Psychiatric Clinic, Clinical Center of the University of Sarajevo, Sarajevo, Bosnia and Herzegovina, [8]Civil Hospital Carlos Haya, Malaga, Spain, [9]Russian State Medical University, Moscow, Russian Federation, [10]Alexandru Obregia Clinical Psychiatric Hospital, Biometric Psychiatric Genetics Research Unit, Bucharest, Romania, [11]Laboratory of Psychiatric Genetics, Department of Psychiatry, Poznan, Poland, [12]nCounter Core Facility, Institute of Human Genetics, University of Heidelberg, Heidelberg, Germany, [13]German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany.

Serotonin type 3 receptors (5-HT3) are involved in learning, cognition, and emotion, and have been implicated in various psychiatric phenotypes. However, their contribution to pathomechanisms remains elusive. Three SNPs in the HTR3A and HTR3B genes have been associated with bipolar affective disorder (BPAD) in pilot studies, and all of them are of functional relevance. We performed a European multicenter study to confirm previous results and provide further evidence for the relevance of these SNPs for neuropsychiatric disorders. This involved analysis of the distribution of the three SNPs among 1804 BPAD cases and 2407 healthy controls. A meta-analysis revealed a pooled odds ratio of 0.881 (P = 0.009, 95% CI = 0.802 - 0.968) for the non-synonymous functional SNP HTR3B p.Y129S (rs1176744), thereby confirming previous findings. In line with this, the three GWAS samples BOMA-BD, WTCCC-BD and GAIN-BD, including more than 3500 patients and 5200 controls in total, showed an over-representation of p.Y129 in patients. Remarkably, meta-analysis revealed a P-value of 0.048 (OR = 0.934, fixed model).

Expression analyses to gain further insights into the distribution of HTR3A and HTR3B mRNA in the human brain detected HTR3A and HTR3B in all investigated brain tissues with the exception of the cerebellum, and large differences in the A:B subunit ratio were observed. Interestingly, expression of the B subunit was most prominent in the brain stem, amygdalae, and frontal cortex, regions of relevance to psychiatric disorders.

In conclusion, the present study provides further evidence for the presence of impaired 5-HT3 receptor function in BPAD.

Hyperuricemia has been generally classified into uric acid (urate) “overproduction type,” “underexcretion type,” and “combined type” based on only renal urate excretion, without considering an extra-renal pathway such as gut excretion. We recently showed that ABCG2/BCRP is a high-capacity urate exporter and that its dysfunction is a major cause of hyperuricemia and gout. Here we evaluated how ABCG2 dysfunction affects urate excretion pathways.

Clinical parameters for urate handling including urinary urate excretion were examined in 644 male outpatients with hyperuricemia. Severity of ABCG2 dysfunction in them was estimated by genotype combination of two common *ABCG2* variants, nonfunctional Q126X (rs72552713) and half-functional

Q141K (rs2231142). We investigated the relationship between ABCG2 dysfunction and urinary urate excretion, and evaluated urate excretion pathways between Abcg2-deficient and wild-type mice treated with uricase inhibitor, oxonate.

Unexpectedly, urinary urate excretion was inversely associated with ABCG2 excretion function. Mild, moderate and severe ABCG2 dysfunctions significantly raised the risk of overproduction hyperuricemia (overproduction type and combined type). In abcg2-deficient mice, serum urate levels and renal urate excretion were increased, while intestinal urate excretion was decreased, compared to those of wild-type mice.

Together with high extra-renal ABCG2 expression, these results suggested that a decrease in extra-renal urate excretion, especially in intestinal excretion, by dysfunctional ABCG2 is a common mechanism of hyperuricemia, often misunderstood as urate “overproduction.” Thus, “overproduction” hyperuricemia in the current classification should be renamed “renal overload” hyperuricemia, which is caused by two mechanisms, “extra-renal urate underexcretion” and genuine “urate overproduction.”

P09.072

Contribution of Genetic Profiles to the Risk for Inflammatory Bowel Disease Patients in Slovenian Population

***U. Potočnik**, K. Repnik;*

Medical faculty, Maribor, Slovenia.

More than 40 genome wide association studies (GWAs) and subsequent meta-analysis in Inflammatory bowel disease (IBD) patients revealed more than 150 IBD associated single nucleotide polymorphisms (SNPs). The single SNP has a limited contribution to disease risk as most of the reported odds ratio (OR) values do not exceed 1.5. This study tested if genetic profiles composed of different numbers of most significant SNPs included in genetic profiles could better describe contribution to disease risk.

We have genotyped 650 Slovenian IBD patients and 400 healthy controls for 34 SNPs previously reported in GWA studies to be most significantly associated with IBD. We confirmed 21 SNPs associated with at least one disease sub-phenotype in our patients, including 5 SNPs associated exclusively with refractory Crohn disease and 4 with ulcerative colits. The highest calculated OR for the genetic profiles reached values between 10-12 for the profiles composed from 10-20 SNPs with more than 90% of disease aleles in tested SNPs included in profiles. The predictive models using combination of 10-12 associated SNPs with highest OR showed above 95% specificity in patients with 90% disease alleles however only a few patients would have 90% disease alleles resulting in low sensitivity usually below 20% of such genetic test. On the other hand, most of the patients would have between 50%-60% of disease alleles however the specificity of genetic test in this case would be less than 15%. These results suggest more complex predictive models need to be developed for better risk prediction in IBD.

P09.073

Association of IRF6 gene polymorphisms with nonsyndromic cleft lip with or without cleft palate

I. Kempa[1,2], I. Akota[2], B. Barkane[2], A. Krumina[1], J. Klovins[1], B. Lace[1];
[1]Latvian Biomedical Research and Study Centre, Riga, Latvia, [2]Riga Stradins University, Riga, Latvia.

Background: Cleft lip and palate is most common congenital malformation with prevalence of approximately 1 in 700 live births worldwide, the frequency also differs by laterality - there is a 2:1 ratio of left to right sided clefts among unilateral cleft lip cases. Mutations in *IRF6* gene cause Van der Woude syndrome and it has been reported that polymorphisms in *IRF6* gene are associated with nonsyndromic CL/P.

The aim of the study was to evaluate the relevance of *IRF6* gene in etiology of nonsyndromic clefts.

Materials and methods: Seven SNPs were analyzed for allelic association with nonsyndromic clefts. The data set consisted of 116 nonsyndromic cleft lip/palate samples and 148 control samples. Out of all cleft cases, 28 had CP and 88 had cleft lip with palate or cleft lip only (CLP).

Results: CP patient group showed the stongest association with rs658860 ($p=0.873x10^{-7}$, OR=0.093, 95% CI=0.033-0.264). In patient group with CLP two SNPs showed significant association (rs642961, p=0.011, OR=1.844, 95% CI=1.148-2.962; rs658860, $p=0.24x10^{-5}$, OR=0.376, 95% CI=0.249-0,568). Similar results we found according to cleft lip side: patient group with CL on left side (n=45) showed strong association with rs658860 (p=0.485x10-4, OR=0.332, 95% CI=0.192-0.574) and patients group with CL on right side (n=18) - with rs642961 (p=0.014, OR=2.589, 95% CI=1.187-5.644).

Conclusion: The results of this study suggest that *IRF6* gene contributes to etiology of nonsyndromic clefts. Our data provide evidence that some variations in *IRF6* gene showed decreased risk to nonsyndromic clefts and futher studies have to be made to clear it.

P09.074

The genes in irritable bowel syndrome research network Europe (GENIEUR)

B. Niesler;
Institute of Human Genetics, Heidelberg, Germany.

Irritable bowel syndrome (IBS) is a highly prevalent functional gastrointestinal (GI) disorder with a major impact not only on the healthcare system but also on the patient's quality of life. Genetic factors contributing to the pathogenesis of IBS have not further been specified and knowledge is still poor. The search for genetic factors in IBS is mainly hampered by the fact that only a few groups worldwide have just recently started to perform genetic analyses in small cohorts.

Consequently, contradictory results have been reported due to low statistical power. The GENIEUR network will foster the establishment of a pan-European, interdisciplinary network with the major goal being the creation of guidelines for patient / control recruitment as well as phenotypic characterization by defining quantitative traits as intermediate phenotypes for the following identification of genetic factors in the pathogenesis of IBS. The network will not only focus on genetics but also epigenetics and microbiomics. In line with this, a biobank will be established in which we collect patient material (blood, saliver, colon biopsies, stool samples) for detailed analyses. This represents a solid basis for novel diagnostic and herapeutic approaches and will significantly improve the insight into IBS pathophysiology, and, hence, help identify new targets for treatment with the ultimate goal of increasing quality of life of affected patients.

Molecular characterization of the KCNA5 gene in Pulmonary Arterial Hypertension Spanish patients

G. Pousada[1], A. Baloira[2], C. Vilariño[3], D. Valverde[1];
[1]Dpto. De Bioquímica, Genética e Inmunología, Facultad de Biología, Universidad de Vigo, Campus As Lagoas Marcosende s/n, 36310, Vigo, Spain, [2]Servicio de Neumología del Complejo Hospitalario de Pontevedra, Pontevedra, Spain, [3]Servicio de Neumología del Complejo Hospitalario de Vigo, Vigo, Spain.

Pulmonary arterial hypertension (PAH; OMIM 178600) is a rare and progressive vascular disorder characterized by pulmonary vascular resistance increase, vascular remodelling and right heart failure. Approximately 75% of patients with the familial form of PAH have a mutation in the gene encoding bone morphogenetic protein receptor type II (BMPR2). However, some other candidate genes have been advocated, including the KCNA5 gene that codifies for a potassium voltage-gated channel. This gene is located on chromosome 12p13, with a single exon of 2865 bp and 613 aminoacidic residues.

We included 30 patients with PAH and 50 controls. The DNA extraction was performed with the Qiagen DNA kit FlexiGene. The KCNA5 gene was amplified by PCR and sequenced.

A total of 10 sequence changes were identified in 11 of the 30 patients with PAH, and none were detected in a panel of 100 chromosomes from normal individuals. From all the mutations and polymorphisms found in this analysis, eight of them had not been previously described. Five of the mutations are missense (p.L42H, p.P46T, p.P169R, p.R184P, p.R577K). Also found a nonsense mutation (p.E208X) and one synonymous change (p.L159L). We found three different mutations in the KCNA5 gene 3´UTR region, which do not produce changes in the structure of the protein (c.2093T>G, c.2123T>G, c.2579A>T).

In conclusion, the mutations in KCNA5 gene indicated that this gene is the second most important gene implicated in the development and worsening of PAH familiar, idiopathic and secondary.

Circulating phospholipids are associated with telomere length in a Dutch family-based study

A. Demirkan[1], L. Broer[1], V. Codd[2], P. Ugocsai[3], G. Liebisch[3], G. Schmitz[3], B. A. Oostra[1], N. J. Samani[2], A. Isaacs[1], C. M. van Duijn[1];
[1]Genetic Epidemiology Unit, Departments of Epidemiology and Clinical Genetics, Erasmus MC, Rotterdam, Netherlands, [2]Department of Cardiovascular Sciences, University of Leicester, Glenfield Hospital, Leicester, United Kingdom, [3]Institute for Clinical Chemistry and Laboratory Medicine, University Hospital Regensburg, Regensburg, Germany.

Telomeres are necessary for both successful DNA replication and maintenance of chromosomal integrity. Telomere length (TL) declines with age and, these decreases are associated with increases in coronary artery disease, obesity and insulin resistance. Both TL and various lipid particles have been associated with longevity. Here, we study the relationship between TL in white blood cells, measured by quantitative PCR, and plasma levels of 24 sphingomyelins (SPM), 9 ceramides, 57 phosphatidylcholines (PC), 20 lysophosphatidylcholines (LPC), 27 phosphatidyletanolamines (PE) and 16 PE-based plasmalogens, assessed using mass spectrometry. A total of 784 persons were included from the Erasmus Rucphen Family Study and analysed using variance component analyses (SOLAR version 4.3.1), adjusting for age, sex and batch effects. After Bonferroni correction, TL was strongly associated with 11 PC species (smallest P-value = 2.31 x 10-09, with PC 40:3), SPM 23:0, SPM 23:1 (P-value = 1.16 x 10-04 and 2.39 x 10-04), LPC 22:0 (P-value = 3.16 x 10-09) and PE 42:7 (P-value = 1.81 x 10-04). Results remained significant after adjusting for plasma HDL-C and LDL-C. Backward regression analyses showed that four of the initial fifteen lipid species (LPC 22:0, PC 38:1, PC O 42:6, PE 42:7) were independently associated with TL. Our findings suggest a link between TL and phospholipid metabolism that may help to explain the role of fatty acids and lipids in longevity as showed in animal and family-based studies.

P09.077

A comprehensive phenotypic and genetic analysis of centenarians from 13 Villages located in the Sardinian region of Barbagia-Mandrolisai

S. A. M. Urru[1], L. Ferreli[2], G. Zedda[2], N. Curreli[2], M. Piras[2], M. Lobina[2], M. Marongiu[2], M. Floris[1], S. Sanna[2], V. Orrù[2], E. Fiorillo[2], R. Galanello[3], A. Atzeni[4], A. Pani[4], F. Cucca[2];
[1]CRS4, Pula (Cagliari), Italy, [2]Istituto di Ricerca Genetica e Biomedica (IRGB) CNR, Cagliari, Italy, [3]Ospedale Regionale Microcitemie ASL8, Cagliari, Italy, [4]Nefrologia e Dialisi, Azienda Ospedaliera G. Brotzu, Cagliari, Italy.

About 30% of longevity is genetically endowed, and there have been repeated observations that long life clusters in families. Presently, it is still unclear whether long life results

1) from the absence in some individuals of genetic variants that would predispose to a range of diseases;

2) or in addition or instead, from a set of alleles that positively and specifically promote healthy old age.

Genetic studies in cosmopolitan populations have been at best inconclusive in addressing these questions: perhaps the major reason is that "centenarians" are rare, and it is reasonable to suppose that alleles involved in conferring longevity are rare as well. These analyses would be simplified by focusing on isolated founder populations, having a high prevalence of centenarians and hence most likely enriched in powerful pro-longevity and "anti-frailty" alleles.

At the geographic centre of Sardinia is located a mountainous, hilly isolated region named Barbagia-Mandrolisai, where many centenarians live and continue to be active. We focused our attention on about 250 healthy 90-year-olds, from a cluster of 13 villages. Presently, we have been collecting their blood samples and measuring over 300 quantitative traits (endophenotypes or quantitative risk-related genetic or environmental factors). Traits of special interest include cardiovascular risk factors, anthropometric measurements, blood test values, facets of personality and a comprehensive panel of immunological traits. With this cohort, genetic studies with batteries of hundred thousand of single-nucleotide markers - and in selected cases with direct sequencing of complete genomes - will be conducted.

P09.078
Susceptibility variants on chromosome 7p21.1 suggest HDAC9 as a new candidate gene for male-pattern baldness

Male-pattern baldness (androgenetic alopecia, AGA) is the most common form of hair loss among humans. Numerous studies have unequivocally identified two major genetic risk loci: the X-chromosomal *androgen receptor* (*AR*)/*ectodysplasin A2 receptor* (*EDA2R*) locus and the *paired box 1* (*PAX1*)/ *forkhead box A2* (*FOXA2*) locus on chromosome 20. Although these loci explain a significant fraction of the overall genetic risk for AGA, additional genetic risk factors still await identification. Here, we performed a GWAS using a German sample of 581 severely affected cases and 617 partially unaffected controls. The best association signal was obtained for rs756853, located intronically in the *histone deacetylase 9* (*HDAC9*) gene on chromosome 7p21.1. A fine mapping analysis within the case-control sample and a family-based analysis revealed rs756853 and rs2249817, respectively, as primary associated SNPs. The association finding for rs2249817 was confirmed within an independent Australian sample (P=0.026). A combined analysis of severely affected German and Australian cases (N=639) and unaffected controls (N=384) for rs2249817 revealed a strong association signal of P=9.09x10-8, odds ratio 1.63 [1.36-1.95]. Tissue expression studies demonstrated *HDAC9* expression in various tissues, including AGA relevant tissues. Genotype-specific expression as well as splice studies revealed no strong genotypic effects, although smaller effects cannot be excluded. Pathway analyses however support the hypothesis that *HDAC9* plays a functional role in AGA via interaction with the *AR* gene. The genetic data of the present study thus provide strong evidence that *HDAC9* is the third AGA susceptibility gene.

P09.080
Migraine susceptibility factors: the role of GABA genes in females' liability

M. Quintas[1], *J. L. Neto*[1], *J. Pereira-Monteiro*[1,2,3], *J. Barros*[2,3], *J. Sequeiros*[1,2], *A. Sousa*[1,2], *I. Alonso*[1,2], *C. Lemos*[1,2];
[1]UnIGENe, IBMC - Universidade do Porto, Porto, Portugal, [2]ICBAS, Universidade do Porto, Porto, Portugal, [3]Neurology Department - CHP, Porto, Portugal.

Migraine is a chronic disorder characterized by episodes of headache and autonomic and neurological symptoms. Several studies showed that migraine is influenced by genetic and environmental factors. The female-to-male ratio of migraine prevalence is 3- to 4-fold higher among women than men.
The role of common variants of GABA genes in the X-chromosome in migraine susceptibility was assessed, aiming to explain the differences in disease frequency between males and females.
An association study with 188 unrelated cases and 287 migraine-free controls age- and ethnic matched was performed. The case-control ratio was 1:1.5.
Candidate genes were selected based on their possible role in pathophysiology of migraine. Twenty-one tagging SNPs were selected in three genes (*GABRE, GABRA3* and *GABRQ*) and genotyping was performed by SNaPshot.
Allelic, genotypic and haplotypic frequencies were compared between cases and controls and multiple testing corrections were performed. Also, gene-gene interactions were analyzed.
The results for allelic associations revealed five nominal significant associations and three trends for association. In what concerns genotypic frequencies, four noteworthy results were found in *GABRE* and *GABRA3* genes. After multiple testing correction, two allelic associations remained significant (*GABRA3* and *GABRE*) and one genotypic association resisted to Bonferroni correction (*GABRE*), all in the females group.
No significant results were found in the haplotypic analyses but an additive effect was observed between two SNPs of *GABRA3* and two of *GABRE*.
With this study we show, for the first time, a possible involvement of polymorphisms in GABA receptors in migraine susceptibility and in gender-specific liability.

P09.081
The role of genes involved in neurogenic inflammation as susceptibility factors for migraine

S. Vaz-Osório[1], *J. L. Neto*[1], *J. Pereira-Monteiro*[1,2,3], *J. Barros*[2,3], *J. Sequeiros*[1,2], *A. Sousa*[1,2], *I. Alonso*[1,2], *C. Lemos*[1,2];
[1]UnIGENe - IBMC, Porto, Portugal, [2]ICBAS, Universidade do Porto, Porto, Portugal, [3]Serviço de Neurologia, Centro Hospitalar do Porto- Hospital de Santo António, Porto, Portugal.

Migraine is one of the commonest neurological and complex disorders, affecting 11% of the world's adult population. In the pathogenesis of migraine several mechanisms are involved such as neurogenic inflammation, with the release of neuropetides (like substance P, neurokinin A or CGRP).
Our aim was to unravel the role of three candidate genes related to neurogenic inflammation processes - F2RL1, TAC1 and CALCRL- in migraine susceptibility. CALCRL encodes the CALCRL receptor of CGRP and F2RL1 gene encodes PAR2; PAR2 agonists increase SP and CGRP release. Additionally we have also selected TAC1 which encodes protachykinin-1 that can normally undergo alternative splicing to generate both SP and NKA.
A case-control association study was designed and performed, using a sample of 188 unrelated migraineurs and 287 healthy controls, age- and gender-matched with cases.
SNPs on candidate genes were selected based on a data dump from The International HapMap Project. From the three candidate genes 14 tagging SNPs were obtained and genotyped by the SNaPshot technique.
Allelic, genotypic, and haplotypic frequencies were compared between cases and controls and multiple testing corrections were applied. Also, gene-gene interactions were assessed using multifactor dimensionality reduction (MDR) method.
Four SNPs in the CALCRL gene showed nominal significant genotypic associations and one significant haplotype association. Importantly, a significant interaction was found between three SNPs of TAC1 gene.
The results obtained reinforce the importance of neurogenic inflammation in migraine susceptibility. Deepening these genetic susceptibilities will be crucial, contributing to public health research and to develop more effective therapeutic strategies.

P09.082
Mitochondrial Uncoupling protein 2 gene variations (exon 8 insertion/deletion and -866 A/G) are associated with childhood obesity

S. Oguzkan Balci[1], *N. Col-Araz*[2], *M. Nacak*[3], *M. Araz*[4], *A. Balat*[5], *S. Pehlivan*[1];
[1]University of Gaziantep, School of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey, [2]University of Gaziantep, School of Medicine, Department of Pediatrics, Gaziantep, Turkey, [3]University of Gaziantep, School of Medicine, Department of Pharmacology, Gaziantep, Turkey, [4]University of Gaziantep, School of Medicine, Department of Endocrinology and Metabolism, Gaziantep, Turkey, [5]University of Gaziantep, School of Medicine, Department of Pediatric Nephrology, Gaziantep, Turkey.

Objectives: Uncoupling protein 2 (UCP2) belong to a family of mitochondrial carrier proteins which plays important role in thermogenesis and energy metabolism. UCP2 is releated to pathogenesis of several disease including human cancers, neurodegeneration, cardiovascular disease, metabolic disorders and obesity. Our aim was to investigate whether childhood obesity may be associated with variations of UCP2 gene
Methods: In this study, 80 obese children and 100 age-and sex-matched healthy controls were tested for two variations which were exon 8 (45 bp insertion/deletion) and promoter (-866 A/G) variations in UCP2 gene. Genotyping were performed by PCR and/or RFLP.
Results: Exon 8 variation in UCP2 gene was showed an association with obese patients. The distribution of DD, DI and II genotypes for the gene was 47.5 %, 25 % and 27.5 % in obese compared with 65 %, 30 % and 5 % in the controls. II genotype was found lower in patients ($p < 0.0001$), while DD genotype was higher in controls (p=0.0092). The distribution of UCP2 gene promoter variation GG, GA and AA genotypes was 17.5 %, 46.2 %, 36.3 % in obese compared with 16 %, 63 %, 21 % in the controls. Statistically, AA genotype was found to be increased in patients (p=0.0116).
Conclusion: The present study showed that UCP2 gene variations were associated with childhood obesity. Insertion genotype (II) of exon 8 and AA

genotype of promoter variations may influence the susceptibility to obesity. Identification of genetic backround in obesity may provide clues about etiology and therapeutic targets.

The MTHFR gene C677T polymorphism is associated with athlete status and muscle fiber hypertrophy

I. I. Ahmetov[1,2,3]*, N. V. Makarova*[2]*, E. A. Khismatullina*[4]*, E. V. Lyubaeva*[3]*, A. A. Arkhipova*[1]*, A. S. Glotov*[5]*, E. V. Vorobyeva*[4]*, V. Y. Gorbunova*[4]*, N. D. Golberg*[2]*, O. L. Vinogradova*[3]*;*
[1]*Kazan State Medical University, Kazan, Russian Federation,* [2]*St Petersburg Research Institute of Physical Culture, St Petersburg, Russian Federation,* [3]*Institute for Biomedical Problems of the Russian Academy of Sciences, Moscow, Russian Federation,* [4]*Bashkir State Pedagogy University, Ufa, Russian Federation,* [5]*St Petersburg State University, St Petersburg, Russian Federation.*

Recent findings by Terruzzi et al. (2011) suggest that DNA hypomethylation induces the activation of factors determining proliferation and differentiation of myoblasts promoting muscle growth and increase of muscle mass. The C677T polymorphism of the MTHFR gene (involved in DNA methylation) was shown to be associated with reduced 5,10-Methylenetetrahydrofolate reductase activity. We therefore hypothesized that carriers of the MTHFR T allele may have DNA methylation deficiency, and as a consequence, increased skeletal muscle mass and predisposition for high level athletic performance. To test this hypothesis, we examined the MTHFR gene C677T polymorphism in 1,819 Russian athletes and 1,041 controls. We also investigated the association between the MTHFR polymorphism and muscle fiber characteristics in 47 physically active healthy men. Genotyping for the C677T variant was performed by PCR-RFLP. Muscle fiber characteristics of m. vastus lateralis was determined by immunohistochemistry. The MTHFR TT genotype (9.5 vs. 6.6%; P=0.0088) and T allele (30.3 vs. 26.3%; P=0.0015) frequencies were significantly higher in athletes compared with control subjects. Furthermore, the highest frequencies of the MTHFR TT genotype (13.9%: P=0.0003) and T allele (34.1%; P=0.0009) were found in a group of highly elite athletes (n=223). The carriers of the MTHFR T allele (n=25) had significantly higher cross-sectional area of slow-twitch fibers (5545+/-242 vs. 4900+/-169 square microns; P=0.0175) than CC homozygotes (n=22). Thus, the MTHFR gene C677T polymorphism is associated with athlete status and muscle fiber hypertrophy. Collectively, our data support the hypothesis that the presence of MTHFR T allele has a beneficial effect on athletic performance.

Circadian rhythm genes and multiple sclerosis (MS)

P. Lavtar[1]*, G. Rudolf*[1]*, A. Maver*[1]*, L. Lovrecic*[1]*, S. Ristic*[2]*, N. Starcevic Cizmarevic*[2]*, M. Kapovic*[2]*, J. Sepcic*[3]*, A. Stankovic*[4]*, M. Zivkovic*[4]*, E. Dincic*[5]*, R. Raicevic*[5]*, S. Sega Jazbec*[6]*, Z. Klemenc Ketis*[7,8]*, B. Peterlin*[1]*;*
[1]*Clinical Institute of Medical Genetics, Ljubljana, Slovenia,* [2]*Department of Biology and Medical Genetics, School of Medicine, University of Rijeka, Rijeka, Croatia,* [3]*Postgraduate Study, School of Medicine, University of Rijeka, Rijeka, Croatia,* [4]*Laboratory of Radiobiology and Molecular Genetics, Institute of Nuclear Sciences "Vinca", Belgrade, Serbia,* [5]*Department of Neurology, Military Medical Academy, Belgrade, Serbia,* [6]*Department of Neurology, University Medical Center Ljubljana, Ljubljana, Slovenia,* [7]*Department of Family Medicine, Medical School, University of Ljubljana, Ljubljana, Slovenia,* [8]*Department of Family Medicine, Medical School, University of Maribor, Maribor, Slovenia.*

Background : Evidence from epidemiological studies indicates, that, prevalence of MS varies with geographic latitude, increasing with distance from the equator on both hemispheres. We hypothesized that explanation for the latitude effect might be related to sun exposure which has been shown to impact internal circadian rhythm. This rhytm is controlled by circadian rhythm genes and that could therefore affect MS susceptibility.

Methods: A total of 826 Caucasian patients and 888 healthy unrelated ethnically matched controls without family history of MS, were included in the study. In patients, the diagnosis of MS was established according to McDonald's criteria. Altogether, 8 SNP were included in our study, 4 in CLOCK gene: rs6811520, rs6850524, rs11932595 and rs13124436; and 4 in ARNTL gene: 3789327, rs1481892, rs4757144 and rs12363415. The significance of association for individual SNPs was analyzed using the Chi-Square test (χ2). Odds ratios (OR) and their respective 95% confidence intervals (CI) was also calculated to compare the allelic frequency and genotype distribution in patients and control subjects.

Results: Significant difference in distribution of ARNTL rs3789327 polymorphism genotypes was found in patients with MS in comparison to controls, with P-value of 4.6e-07 and odds ratio equal to 0.56 (95% CI: 0.45-0.71). Other SNPs in ARNTL and CLOCK genes did not display significant association with MS susceptibility.

Conclusion: We provide evidence for association between genetic variation in ARNTL gene and multiple sclerosis. Further studies will be required to substantiate the significance of these genetic variations.

Multiple Sclerosis Risk Variant HLA-DRB1*1501 Associates with High Expression of DRB1 Gene in Different Human Populations

M. Fedetz[1]*, A. Alcina*[1]*, M. Abad-Grau*[2]*, G. Izquierdo*[3]*, M. Lucas*[4]*, O. Fernández*[5]*, D. Ndagire*[1]*, A. Catalá-Rabasa*[1]*, C. Delgado*[6]*, C. Arnal*[7]*, F. Matesanz*[1]*;*
[1]*Instituto de Parasitología y Biomedicina 'López Neyra', Granada, Spain,* [2]*Universidad de Granada, Granada, Spain,* [3]*Unidad de Esclerosis Múltiple, Hospital Virgen Macarena, Sevilla, Spain,* [4]*Servicio de Biología Molecular, Hospital Virgen Macarena, Sevilla, Spain,* [5]*Instituto de Neurociencias Clínicas Hospital Carlos Haya, Málaga, Spain,* [6]*Centro Regional de Transfusión Sanguínea Granada-Almería, Granada, Spain,* [7]*Servicio de Neurología, Hospital Virgen de las Nieves, Granada, Spain.*

The human leukocyte antigen (HLA) exerts the largest genetic contribution to MS susceptibility) and HLA DRB1*1501 has been consistently associated with multiple sclerosis (MS) in nearly all populations tested, but exactly how it alters the risk of developing MS is not fully understood. The identification of expression quantitative trait loci (eQTL) for genes in the HLA locus raises the question of the role of gene expression in MS susceptibility. We analyzed the eQTLs in the HLA region with respect to MS-associated HLA-variants obtained from genome-wide association studies (GWAS). We found that the Tag of DRB1*1501, rs3135388 A allele, correlated with high expression of DRB1, DRB5 and DQB1 genes in a Caucasian population. In quantitative terms, the MS-risk AA genotype carriers of rs3135388 were associated with 15.7-, 5.2- and 8.3-fold higher expression of DQB1, DRB5 and DRB1, respectively, than the non-risk GG carriers. The haplotype analysis of expression-associated variants in a Spanish MS cohort revealed that high expression of DRB1 and DQB1 alone did not contribute to the disease. However, in Caucasian, Asian and African American populations, the DRB1*1501 allele was always highly expressed. In other immune related diseases such as type 1 diabetes, inflammatory bowel disease, ulcerative colitis, asthma and IgA deficiency, the best GWAS-associated HLA SNPs were also eQTLs for different HLA Class II genes. Our data suggest that the DR/DQ expression levels, together with specific structural properties of alleles, seem to be the causal effect in MS and in other immunopathologies rather than specific antigen presentation alone.

Multiple sclerosis (MS) is a complex autoimmune disease of the central nervous system. Recent GWAS have discovered over 50 common variants associated with MS. An isolated population in Southern Ostrobothnia in western Finland has two-fold prevalence and familial clustering of MS. Our aim was to study whether the accumulation of common predisposing variants in the isolate and multiplex families contributes to the increased prevalence. We used a weighted log-additive model to calculate a genetic burden score in all samples based on previously identified 51 SNPs. We evaluated the differences in the genetic score distribution between the sample groups by using a non-parametric Kolmogorov-Smirnov test. As in previous reports, the genetic burden score was increased in MS patients: mean 6.73 in the sporadic (n=522) and 6.78 in the familial cases (n=64) compared to IBS-matched population controls (n=1198) mean 6.23 (p <0.0001). When we divided the MS cases according to region of origin, both the isolate (n=111, mean 6.64) and the general Finnish cases (n=497, mean 6.77) had significantly higher score compared to the population controls (p<0.0001). However, we could not detect significant differences in the genetic score distribution between familial and sporadic cases (p=0.16) or between isolate cases and cases from elsewhere in Finland (p=0.26). Since the common variants do not seem to explain the increased familial prevalence in these multiplex families or in the isolate, we hypothesize that there are specific variants that contribute to MS predisposition in familial cases and in the Southern Ostrobothnian region.

P09.087

Investigation of relationship Between ATP5β gene expression and multiple sclerosis disease

***J. Motaei**, M. Sanati, a. mirmiran;*
1. Department of Medical Genetics, National Institute of Genetic Engineering and Biotechnology (NIGE, Tehran, Islamic Republic of Iran.

Multiple sclerosis (MS) is an inflammatory, demyelinating, neurodegenerative disorder of the central nervous system (CNS) with unclear exact cause; However studies confirmed the role of environmental and genetic factors in MS etiology. Disease onset usually occurs in young adults and it is more common in women. A number of studies have reported mitochondrial defects in MS and implied a pathogenic role for mitochondria in axonal degeneration. Mitochondria respiratory chain are the most efficient produces of ATP and defects in ATP synthesis may be an important factor in neurodegenerative disease such as Parkinon, Alzhimers and MS. Analysis of the mitochondrial proteomin experimental autoimmune encephalomyelitis (EAE) mous model of MS reveal decrease expression in 5 protein mitochondrial respiratory chain (COX5b, COX5a, ATP5b, NDUFS8, NDUFV2) . One of these proteins was β subunit of complex V with ATP synthase activity. ATP5β encodes a subunit of mitochondrial ATP synthase. In this study, we tested the altered expression of ATP5β in LCLs derived from 30 patients with MS and 31 controls. A significant reduction of ATP5β mRNA expression was seen in MS patients (P> 0.05). According to our results, we suggest that ATP5β can be used as a biomarker for early diagnosis of MS. However, more researches are necessary to reach this goal.

Does miR-634 play a role in multiple sclerosis predisposition?

***E. M. Paraboschi**, V. Rimoldi, T. Tabaglio, G. Soldà, S. Duga, R. Asselta;*
Dipartimento di Biologia e Genetica per le Scienze Mediche, Università degli Studi di Milano, Milano, Italy.

Multiple sclerosis (MS) is a neurological disorder characterized by chronic inflammation, demyelination, and axonal damage, probably caused by an altered immune response.

The protein kinase C alpha gene (PRKCA, encoding a protein critical for T-lymphocyte activation) was the first non-HLA gene demonstrated to be involved in MS both by linkage and association studies, and subsequently replicated in 4 populations. This gene produces at least 2 alternative transcripts with different 3'UTRs, and hosts a microRNA, miR-634, in its intron 15. Since several miRNAs have recently been implicated in MS pathogenesis, and our preliminary results suggested that both PRKCA and miR-634 are differentially expressed in MS patients vs healthy controls, we decided to better characterize miR-634 expression and function.

The PRKCA and miR-634 discordant expression profiles in different human tissues suggested the presence of an independent miRNA promoter and/or the possible miR-634-mediated silencing of PRKCA. Transfection experiments followed by both luciferase-based and RT-PCR assays demonstrated the existence of a miRNA-specific promoter. Co-transfection of a vector expressing the wild-type pre-miR-634 hairpin into HeLa cells, together with a construct containing the luciferase cDNA coupled to each of the two PRKCA 3'UTRs, showed that miR-634 does target the PRKCA shorter 3'UTR. The specificity of this interaction was confirmed by site-directed mutagenesis of the miR-634 target site.

In conclusion, we demonstrated that miR-634 expression is driven by an independent promoter and we suggest that this miRNA, by modulating PRKCA expression, may be involved in MS pathogenesis.

P09.089

Modulatory influence of vitamin D receptor genotype on OPG/RANKL System and Pathogenesis and Clinical Manifestations in Multiple Sclerosis

*S. Ahmadi[1], K. Mirzaei[1,2], **A. Hossein-nezhad**[1], F. Mokhtari[1], A. Tootee[1], A. Najmafshar[1];*
[1]Endocrinology and Metabolism Research Institute, Tehran University of Medical Sciences, Tehran, Iran, Tehran, Islamic Republic of Iran, [2]Department of Nutrition and Biochemistry, school of Public Health and institute of public health research, Tehran University of Medical Sciences, Tehran, Iran, Tehran, Islamic Republic of Iran.

The OPG/RANKL has identified role in immune system via T-cell-activating cytokines. Considering that immune mechanisms play a key role in the pathogenesis of MS, OPG/RANKL might be importance in the underlying mechanism of the disease. The aim of this study is to measure plasma levels of OPG and RANKL as well as to analyze VDR *FokI* polymorphism (rs2228570) in MS patients and healthy individuals to detect any potential correlation. We included a total of 397 participants, 105 of them suffering from two different types of MS, namely relapsing and remitting and secondary progressive multiple sclerosis.

The results showed differences in the plasma levels of OPG and RANKL between patients and the healthy control group that were statistically significant. We found higher plasma levels of OPG and lower RANKL concentrations in RRMS patients in comparison with PPMS and SPMS types of the disease. We detected higher plasma levels of OPG and lower levels of RANKL in subjects with F allele compared to those with f allele in healthy subjects. However, contradicting results were observed when patients with MS were analyzed. We detected lower plasma levels of OPG and higher RANKL concentrations in patients with F allele in comparison with those with f allele.

This might define a role for *FokI* polymorphism and OPG/RANKL system in the pathogenesis and progression of multiple sclerosis with further practical applications.

P09.090

Association of *MMP-8* promoter gene polymorphisms with myocardial infarction: A hospital based study

***S. Dayakar**[1,2], T. Parvathi Kumara Reddy[3], B. Shyamala Sesikeran[2], M. Sadhnani[1];*
[1]Department of Clinical Biochemistry, Institute of Genetics & Hospital for Genetic Diseases,Osmania University, Hyderabad-500016, India, [2]Apollo Hospitals Educational And Research Foundation, Hyderabad-500033, India, [3]Instituto de Genetica,Dpto.de Biología Molecular Y Genomica, Centro Universitario de, Guadalajara, Jalisco, Mexico.

Matrix mettalloproteinases (MMPs) are the family of peptidase enzymes responsible for the degradation of extracellular matrix (ECM) proteins. MMP-8 cleaves collagenotype I three times more potently than two other interstitial collagenases, MMP-1 and -13. Therefore, MMP-8 plays a important role in atherosclerosis. The aim of the study was to investigate the association of two MMP-8 polymorphisms, rs11225395 (-799C/T) and rs1320632 (-381A/G). 319 patients were studied out of whom 152 individuals were documented angiographically for coronary atherosclerosis without any evidence of previous MI. 167 patients with normal coronary arteriograms were included as healthy controls. PCR- based restriction fragment length polymorphism (RFLP-PCR) method was applied. MMP-8-799C/T gene polymorphism was observed with CC 93/152 (61.1%), CT among 34/152 (22.3%) and TT in 25/152 (16.4%) among the patients with MI; while in control group, 151/167(90.4%) had CC genotype, 13//167 (7.7%) CT and 3/167 (1.7%) carried TT. The prevalence of TT was 9.0 times higher among the case patients than the controls (16.4% vs. 1.7%, p = < 0.0001). MMP-8-381 A/G gene polymorphism was observed with AA 89/152 (58.5%), AG among 36/152 (23.6%) and GG in 27/152 (17.7%) patients with MI; while in control group, 144/167 (86.2%) had AA genotype, 21//167 (12.5%) AG and 2/167 (1.1%) carried GG. The prevalence of GG was 15.0 times higher among the case patients than controls (17% vs. 1.1%, p = < 0.0001).Our preliminary data indicate that MMP-8-381A/G ,-799C/T gene polymorphisms could be a risk factor for MI.Further studies may explore more to confirm the role of these polymorphisms

P09.091

Long-term outcome of anti-VEGF treatment in patients with neovascular age-related macular degeneration is influenced by the initial response and the genotype of complement factor H (CFH)

***B. Kloeckener-Gruissem**[1,2], M. Menghini[3], J. Fleischhauer[3], M. Kurz-Levin[3], F. Sutter[3], D. Barthelmes[3,4], W. Berger[1,5];*
[1]University of Zurich, Institute of Medical Molecular Genetics, Schwerzenbach, Switzerland, [2]ETH Zurich, Zurich, Switzerland, [3]University Hospital of Zurich, Zurich, Switzerland, [4]University of Sydney, Save Sight Institute, Sydney, Australia, [5]Center for Integrative Human Physiology (ZIHP), Zurich, Switzerland.

The outcome of anti-VEGF treatment in patients with neovascular age-related macular degeneration (AMD) is influenced by several factors. The aim of this study was to assess the impact of three parameters: (i) loading phase, (ii) initial response for the long-term outcome and (iii) the effect of the complement factor H (CFH) polymorphism (p.His402Tyr). Patients treated with ranibizumab for neovascular AMD were analyzed over a period of 24 months. Visual acuity (VA) was recorded at each visit, effects of loading phase and initial response were analyzed, and the genotype of CFH rs1061170 (c.1204C>T, p.His402Tyr) was determined. The study included 204 eyes. A change of +5.0 [-1;+11] and +1.5 [-5.5;+9.5] letters was observed with a median of 4 [3;7] and 10 [7;14] ranibizumab injections during 12 and 24 months, respectively. Loading phase was no significant predictor for treatment as VA outcome in eyes with and without loading phase was similar (p=0.846 and p=0.729) at 12 and 24 months. In contrast, initial response was a significant predictor for improving vision of 5 or more letters at 12 (p=0.001; OR=6.75) and 24 months (p=0.01; OR=4.66). Furthermore, the CT genotype at CFH rs1061170 was identified as a significant predictor for a favorable VA outcome at 12 and 24 months (OR= 6.75, p=0.001 and OR=4.66, p=0.01). Our data suggest that an initial response as well as the genotype of SNP rs1061170 at CFH present critical criteria that influence treatment outcome. Clinicians may include these when designing a treatment regimen using ranibizumab injections.

P09.092

Nuclearcytoplasmic Shuttling of Disease Protein in Autosomal Dominant Machado-Joseph Disease

***A. S. Sowa**, M. Opitz, M. Mutter, Z. Wang, J. Weber, A. Kaiser, P. Antony, O. Rieß, T. Schmidt;*
University of Tübingen, Tübingen, Germany.

Neurodegenerative disorders are a large category of conditions all caused by a loss of structure or function of neurons, often resulting in progressive neuronal death. Of these conditions, Machado-Joseph Disease, or Spinocerebellar Ataxia Type 3 (SCA3) is an autosomal dominant, late onset neuromuscular disease associated with a coding expansion of a CAG repeat in the *Ataxin-3* gene. The expanded unstable CAG repeat encodes for an abnormally expanded polyglutamine (polyQ) track which in turn causes protein misfolding and aggregation. The most recent research in polyQ disorders has focused on protein transport mechanisms responsible for the traffikking of disease proteins. The ability of proteins to be shuttled between the cytoplasm and the nucleus confers on them the capability to affect cellular transcription in the nucleus and avoid the cellular clearance machinery of the cytoplasm. For disease proteins such as expanded Ataxin-3, localization of protein aggregates to the nucleus has been shown to worsen disease phenotype and increase symptoms in SCA3 animals. In this work we use microscopy, cell viability studies and the filter trap assay to analyze the possible partners of Ataxin-3 which affect the localization, aggregation, pathogenicity, and protein trafficking of this protein. With further understanding of the pathways involved in the progress of SCA3, it will be possible to determine potential targets of therapy to mitigate the course of the disease in patients.

P09.093

The relationship of the COMT gene polymorphism rs4680 with the components of nicotine dependence in a central Romanian population

***K. Csep**, C. Banescu, N. Argyo, A. Todoran Butila, G. Dudutz;*
University of Medicine and Pharmacy Tg Mures, Tg Mures, Romania.

Through dopamine release nicotine activates the mesocorticolimbic reward pathway which mediates reinforcement of continued use. Thus, in the multifactorially determined addiction, enzymes responsible for dopamine metabolism and polymorphisms of their genes may be involved. The rs4680 functional polymorphism of COMT (catechol-O-methyl-transferase) due to a Val→Met substitution results a high (H, G1497) and a low activity allele (L, A1497). It has been suggested that carriers of the H allele might present an increased risk to develop dependence, however, results have been contradictory, and no study in this respect has been carried out in our population. In a case-control study of 113 smokers and 84 non-smokers, we assessed nicotine dependence by NDSS, HSI and FNDS adapted for the local population, and genotyped for rs4680 by PCR-RFLP using NlaIII.

Allele frequency in the smoker and non-smoker study group was 53.1 and 46.9 versus 44.4 and 55.6, respectively. Though genotype associated risk for smoking was not statistically significant (GG vs AA: OR = 1.96, CI95%: 0.5-8.2, p = 0.16; GG vs GA+AA:1.54, CI95%: 0.57-4.34, p = 0.2), the overall scores of dependence and its certain components, namely drive and priority, showed significant differences across the genotypes (p<0.05).

In conclusion, COMT might be a risk modifier involved in nicotine dependence rather than a susceptibility gene. Studying the various traits of dependence on a higher number of subjects would be meaningful and could have direct practical implications in cessation management.

P09.095

Association between a promoter SNP in MUC5B and idiopathic pulmonary fibrosis in the Newfoundland population

***A. Pirzada**, M. Woods, B. Fernandez, K. Mahoney, G. Zhai;*
Memorial University, St. John's, NL, Canada.

Idiopathic pulmonary fibrosis (IPF) is a late-onset, complex genetic disease characterized by inflammation/scarring of the lung parenchyma. To date, heterozygous causal variations in *TERT*, *hTR*, *SFTPC*, *SFTPA2* that account for 2-20% of IPF in various populations have been documented. Recently, Seibold et al identified a promoter variant (rs35705950) upstream of *MUC5B* that is associated with IPF in US populations.

A TaqMan SNP Genotyping assay and a 7900HT Real-time PCR analyzer were used to genotype rs35705950 in our cohort. A case-control analysis was carried out using 110 affected individuals and 277 healthy controls from the Newfoundland population. Our results showed that there was significant association between rs35705950 genotypes and IPF. The odds ratio for individuals affected with IPF who were heterozygous for the variant allele of this promoter polymorphism was 5.4 (95% confidence interval, 3.3 to 9.6, P < .001). The odds ratio for individuals affected with IPF who were homozygous for the variant allele was 12.2 (95% confidence interval, 3.3 to 44.7, P < .001). Furthermore, some of our cases displayed familial segregation of the variant allele with the phenotype.

This study supports the suggestion that the minor T allele of rs35705950 is a contributor to the pathogenesis of IPF. The *MUC5B* gene encodes for a major gel-forming mucin macromolecule in respiratory secretions and is upregulated in some other lung diseases. Further evidence of association is provided by tissue expression studies done through previous research.

P09.096

Common variants in *HFE* and *TMPRSS6* are strongly associated with iron parameters but not with serum hepcidin, regulator of systemic iron homeostasis

***T. E. Galesloot**, S. H. Vermeulen, D. W. Swinkels;*
Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.

Introduction: Genome-wide association studies have convincingly shown that single nucleotide polymorphisms (SNPs) in *HFE* and *TMPRSS6* are associated with iron traits. However, the role of hepcidin, central regulatory molecule of systemic iron homeostasis, in these associations is not clear. Here, we investigated the associations between common variants in *HFE* and *TMPRSS6* with hepcidin and iron traits, including interaction and haplotype analysis.

Methods: A total of 103 SNPs in *HFE* and *TMPRSS6* were extracted from genome-wide SNP data of 1832 individuals from the general population (Nijmegen Biomedical Study). Associations with serum iron parameters and hepcidin (sHep) were studied using linear regression analyses, adjusted for age, gender and time of blood sampling.

Results: The associations between rs1800562 in *HFE* and rs855791 in *TMPRSS6* with iron and transferrin saturation (TS) were confirmed (p<1E-10) and were independent of sHep. sHep was not statistically significantly associated with any of the SNPs, but sHep/ferritin and sHep/TS ratio were (p between 1E-7 and 1E-3). Our data suggested the presence of an interaction between rs1800562 and rs855791 in relation to sHep and a haplotype effect of rs1799945, rs198853 and rs1800562 in *HFE*, independent of rs1800562.

Conclusion: SNPs in *HFE* and *TMPRSS6* influence iron parameters independent of sHep and affect sHep/iron parameter ratios. This unexpected finding suggests that there might be other, yet unknown, hepcidin-independent mechanisms which play a role in these associations. Larger sample sizes are needed to draw definite conclusions about the additional effect of combinations of *HFE* and *TMPRSS6* SNPs on sHep and iron traits.

P09.097

Association of the FTO variant with obesity in two ethnic groups in Slovakia

***S. Macekova**, J. Bernasovska, J. Carnogurska, I. Boronova, A. Bozikova, D. Gabrikova;*
Department of Biology, Faculty of Humanities and Natural Sciences, University of Presov, Presov, Slovakia.

Obesity is a global epidemic, arising from the interaction between environmental factors and genetic variants. Recently, common genetic variants in the FTO gene have been found to be associated with obesity phenotype in multiple ethnic groups. The aim of this study was to test the association of the rs9939609 polymorphism with obesity indices in two ethnic groups in Slovakia. Genotyping was performed in 294 Roma and 560 Slovak ethnic subjects, using the TaqMan assay. The minor allele A frequency at rs9939609 polymorphism in the FTO gene was 0.46 in Roma and 0.44 in Slovak ethnic group. The genotypes distributions in Roma (AA 21.1%; AT 50.7%; TT 28.2%) and Slovak (AA 18.9%; AT 50.4%; TT 30.7%) ethnic groups were compatible with the Hardy-Weinberg equilibrium. We observed that the mean values of obesity indices in Roma subjects with AA genotype were significantly higher than in ethnic Slovaks with the same genotype (BMI=28.7±6.6 kg/m^2

vs. BMI=24.5±4.1 kg/m^2, $P^{BMI}<0.001$; WC=99.8±17.8 cm vs. WC=86.2±13.9 cm, $P^{WC}<0.001$; WHR=0.94±0.1 vs. WHR=0.85±0.1, $P^{WHR}<0.001$). On ANOVA analysis, we found significant differences in mean values of BMI, waist circumference (WC) and waist to hip ratio (WHR) between different genotypes in Roma (P=0.001, P=0.004 and P=0.008, respectively) as well as in ethnic Slovak group (P=0.042, P=0.007 and P=0.017, respectively). In conclusion, our genotype-phenotype analysis showed significant association of genetic variation in the FTO gene with obesity in Roma and Slovak ethnic population.

Supported by research project APVV-0716-10 and **project ITMS** 26220120041 (ERDF).

Analysis of the MC4R in relation to obesity in population of Latvia

V. Ignatovica[1]*, R. Petrovska*[1]*, I. Kalnina*[1]*, I. Vaivade*[1]*, D. Fridmanis*[1]*, L. Tarasova*[1]*, R. Peculis*[1]*, H. B. Schioth*[2]*, J. Klovins*[1]*;*
[1]*Latvian Biomedical Reseach and Study centre, Riga, Latvia,* [2]*Uppsala University, Uppsala, Sweden.*

Melanocortin 4 receptor (MC4R) regulates feeding behaviour, therefore, genetic studies are trying to associate genetic variation in MC4R locus with obesity related phenotypes. In this study we preformed evaluation in both non-coding and coding part of MC4R in cohort of extremely obese subjects (n=380) of the population of Latvia. We found no association of common polymorphism rs17782313 in promoter region of MC4R in severely obese individuals and matched normal weight controls with obesity or related phenotypes. Additionally, we explored three SNPs in another obesity related fat mass and obesity-associated protein (FTO) gene locus for association with any available phenotype, two of the studied polymorphisms being in complete linkage disequilibrium, were associated with obesity in our study group, but the third demonstrated p-value close to the border of significance. The sequencing of the MC4R coding region revealed four heterozygous nonsynonymous substitutions - V103I, S127L, V166I and I251L. Two subjects had double V103I and S127L mutations. Noticeably, V166I is a novel substitution that has not been reported before. S127L, V166I and double V103I/S127L mutant receptors had significantly decreased quantity in cell surface compared to wt MC4R. Intriguingly, despite the low abundance in plasma membrane newly discovered V166I variant demonstrated higher cAMP response upon αMSH activation than wt receptor. The results of this study incorporate an influence of the common polymorphisms and rare genetic variants in relation to obesity and suggest that in the study group of morbidly obese cases both SNPs and rare mutations could affect the outcome phenotype of the individual.

Whole transcript expression microarray profiling in oesophageal tissue of neonates with oesophageal atresia - preliminary results.

R. Smigiel[1]*, A. Lebioda*[2]*, D. Patkowski*[3]*, M. Blaszczyński*[4]*, K. Korecka*[5]*, P. Czauderna*[6]*, A. Jakubiak*[1]*, D. Bednarczyk*[1]*, H. Maciejewski*[7]*, P. Wizinska*[8]*, M. M. Sasiadek*[1]*;*
[1]*Genetic Department Wroclaw Medical University, Poland, Wroclaw, Poland,* [2]*Institute of Molecular Techniques, Wroclaw Medical University, Poland, Wroclaw, Poland,* [3]*Department of Pediatric Surgery and Urology, Wroclaw Medical University, Poland nd, Wroclaw, Poland,* [4]*Department of Pediatric Surgery, and Urology, Poznan Medical University, Poland, Poznan, Poland,* [5]*Department of Surgery of Congenital Defects in Children and Traumatology, Silesian Medical University, Zabrze, Poland, Zabrze, Poland,* [6]*Department of Pediatric Surgery and Urology, Gdansk Medical University, Poland, Gdansk, Poland,* [7]*Institute of Computer Engineering, Control and Robotics, Wroclaw University of Technology, Wroclaw, Poland,* [8]*Department of Histology and Embryology, Wroclaw Medical University, Wroclaw, Poland, Wroclaw, Poland.*

Etiology of oesophageal atresia and tracheoesophageal fistula (OA/TOF) is not clearly understood and no single, specific genetic factor for its etiology was confirmed. OA/TOF may occur as isolated (IOA) or syndromic anomaly (SOA). Combination of multigenic factors and epigenetic modification of genes can play a role in its pathogenesis.

Methods: Total RNA was extracted from 26 esophageal tissue collected during thoracoscopic esophageal atresia repair in neonates with isolated and syndromic form. Control tissues were taken during autopsy from aborted fetuses and stillborn neonates without OA/TOF. The study was accepted by the University Ethical Committee. We used Agilent One-Color Microarray standard protocol to determined gene expression profiling in IOA and SOA vs control. Multiplicative detrending background subtraction method (Agilent software) was performed to quantify the signal. Quality analysis and scale normalization for results were performed. Analysis of differential expression (DE) was done with the R limma package (multiple testing correction and 0.05 threshold for the adjusted p-value). We also performed pathway analysis using the globaltest method (Hochberg multiple testing p-value adjustment).

Results: We identified about 2300 down- and 2700 up-regulated probes between SOA and controls, and about 2600 down- and 2100 up-regulated probes between IOA and controls. None of the probes showed DE between IOA and SOA. We also identified (0.02 threshold) 74 pathways DE between the SOA and controls and 42 IOA vs controls. No DE pathways were found between the IOA and SOA.

We hope that these observations could suggest an excellent candidates genes and pathways for OA/TOF etiology.

Identification of genes involved in the initiation of osteoarthritis

M. Lee[1]*, C. Chou*[1]*, C. Wu*[2]*, Y. Chen*[1]*;*
[1]*Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan,* [2]*Department of Orthopaedic Surgery Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan.*

Objective: The aim of this study is to select small areas from osteoarthritic cartilages and subchondral bone of different severities to represent different stages of disease to provide a more complete picture of the molecular alternations in OA pathogenesis as well as to identify genes involved in the initiation of OA.

Methods: Joint tissues were collected from the knee tibia plateau from primary OA and non-OA patients undergoing total knee arthroplasty. Severity of destruction was estimated based on histopathology assessment (OARSI grading system). Each tibia plateau was divided into three parts: outer lateral tibia (oLT) regions defined as undamaged stage (OARSI score: OA=5.23±1.95, n=67), inner lateral tibia (iLT) regions defined as intermediate stage (OARSI score: OA=5.23±1.95, n=71), and medial tibia (MT) regions defined as damage stage (OARSI score: OA=16.8±2.56, n=52). Expression profiling analysis was performed using Agilent microarray on these regions and real-time quantitative PCR using a second cohort of patients were performed for replication.

Results:Our results revealed that 958 transcripts were significantly up or down regulated at least 2-fold between these three stages. These genes were related to the cell matrix interaction, extracellular matrix remodeling, bone development, inflammation, cytokine, cell proliferation, WNT signaling.

Conclusion: This study revealed some novel genes which have not been reported in cartilage to play a role in the pathology of OA. These results identify molecular targets that can be further investigated in the search for therapy or as biomarker for OA.

The study of polymorphisms P447L of calcitonin receptor gene (CALCR) and A986S of calcium response receptor gene (CASR) in women with postmenopausal osteoporosis from Volga-Ural region of Russia

A. Maltsev[1]*, R. Khusainova*[2]*, I. Yanberdin*[1]*, E. Khusnutdinova*[2]*;*
[1]*Bashkir State University, Ufa, Russian Federation,* [2]*Bashkir State University, Institute of Biochemistry and Genetics USC RAS, Ufa, Russian Federation.*

Osteoporosis characterized by reduced bone mass, and disruption of bone architecture, resulting in increased risk of fractures. The aim of this study was to examine any associations of polymorphisms c.1377C>T (P447, rs1801197) in calcitonin receptor gene (CALCR) and c.2956G>T (rs1801725; A986S) in the Ca+ receptor gene (CASR) with fractures and BMD level in Russian postmenopausal women. As the object of the research were 828 DNA samples (366 with fractures and 462 without fractures). According to the literary data *T allele of polymorphism P447L gene CALCR in homozygotic state is associated with fractures. As a result of our research in women with fractures *T allele frequency was lower (0,669) compared with the control group (0,687) the difference doesn't measure up the statistic significancy. With the arrangement according to BMD level in women with osteoporosis *T allele frequency was lower compared with the control group (0.66 and 0,68, respectively). The study of polymorphism A986S of Ca+ receptor gene (CASR) revealed no certain difference arrangement allele frequency and genotypes between women with fractures and women without factures. In our research the tendency of rising frequency *T*T genotype in women with low level of BMD (0,034) was found compared with the control group (0,005) the difference doesn't measure up the statistic significancy. Our results show no associations of polymorphisms A986S Ca+ receptor gene (CASR) and polymorphism P447L in calcitonin receptor gene (CALCR) with the fractures and BMD level in postmenopausal women from the Volga-Ural region of Russia.

P09.102

Associations of polymorphic variants of OPG gene with male osteoporosis in the Volga-Ural region of Russia

R. Shakirova, R. Khusainova, E. Khusnutdinova;
Institute of Biochemistry and Genetics USC RAS, Ufa, Russian Federation.

Osteoprotegerin (OPG), a secreted member of the tumor necrosis factor receptor family, is a potent inhibitor of osteoclast activation and differentiation.

We examined the effect of polymorphisms c.1217-15 C>T (rs3102734), c.6890-8 A>T (rs7844539), c.950 T>C (rs2073617), 163 A>G (rs3102735), 245 T>G (rs3134069), 1181 G>C (rs2073618) in the OPG gene with fractures and level of BMD in 131 Russian men with osteoporosis, 149 with osteopenia and matched control (n=152).

The study of polymorphic locus c.1217-15 C>T localized in 1 intron of the OPG gene revealed that frequency *T allele was 0.14 in male patients with osteoporosis, in control group - 0.16, the differences were not significant.

Frequency of allele *C of locus c.6890-8 A>C in men was higher (0.32), compared with the control group (0.11), the differences did not reach statistical significance.

The study of polymorphic loci c.950 T>C (rs2073617) and 163 A>G (rs3102735) located in the promoter of the osteoprotegerin gene, also revealed no associations with fractures and BMD level in men from Russia.

The analysis of polymorphism 1181 G>C (rs2073618) in the first exon revealed highly significantly differences among patients with osteoporosis and controls. It was found heterozygous genotype *GC associated with increased risk of osteoporosis ($\chi2=7,11$; $p<0,007$; OR=1,95(1,19-3,19)), homozygous genotype *CC was protective for the development of osteoporosis ($\chi2=6,65$; $p<0,009$; OR=0,49 (0,28-0,84)). This locus was not associated with fractures.

Thus, we found association of 1181 G>C (rs2073618) locus of OPG gene with decreased BMD level in male from Volga-Ural region of Russia.

P09.103

Morphogenetic gene Meis1 and bone characteristics in 1975 patients

N. Schweighofer[1], E. Lerchbaum[1], A. Fahrleitner-Pammer[1], H. Dobnig[1], T. R. Pieber[1], W. Renner[2], B. Obermayer-Pietsch[1];
[1]Department of Internal Medicine, Division of Endocrinology and Metabolism, Medical University, Graz, Austria, [2]Clinical Institute of Medical and Chemical Laboratory Diagnostics, Medical University, Graz, Austria.

Bone mineral density, an important parameter in the diagnosis of osteoporosis, is determined by heredity in about 50 to 80 percent, dependent on its measuring site. Many candidate genes are known to be involved in the inheritance of bone characteristics. We investigated a polymorphic morphogenetic gene called Meis1 which belongs to the HOX (homeobox-containing genes) family and is an evolutionarily highly conserved gene. It is involved in the regulation of the development of segmental vertebral structures and a variety of other tissues.

We investigated the effect of two SNPs in the MEIS1 gene in 1975 patients either routinely referred to our outpatient clinic or investigated in nursing homes. Life style factors, fracture incidence, routine laboratory and parameters of bone turnover and bone mineral density at 3 sites (DXA Hologic 4000 plus) or bone heel ultrasound were compared between genotypes.

Genotype frequencies of MEIS1 SNP rs2049019 were 45,5% (wildtype, WT), 44,7% (heterozygotes, HE) and 9,9% (homozygotes, HO) and 31,2% (WT), 50,6% (HE) and 18,3% (HO) of rs6716792. We detected a significant association of SNP rs2049019 with bone mineral density, body size and testosterone levels in young males. Old males homozygous for one of the two SNPs, showed a significantly higher bone ultrasound values at all sites measured compared to WT or HE persons.

The morphogenetic gene Meis1 is known to influence a variety of bone characteristics during development. We show associations with bone parameters in adults, this gene might therefore be of importance for diagnostic and therapeutic aspects in osteoporosis.

P09.104

Identification of novel genetic markers that predict disease severity and complications in Paget's Disease of Bone

N. Alonso, O. M. E. Albagha, M. Rios-Visconti, S. H. Ralston;
Rheumatic Disease Unit-IGMM-Molecular Medicine Centre, Edinburgh, United Kingdom.

Paget's disease of bone (PDB) is a skeletal disorder affecting 2% of the UK population over 55. Some patients show deafness, bone deformity, fractures and osteoarthritis. Mutations of SQSTM1, found in 10% of patients, are significantly associated with disease severity (Rios-Visconti et al;JBMR, 2010). We analysed seven SNPs (rs10494112, rs4294134, rs2458413, rs1561570, rs10498635, rs5742915, rs3018362) associated with PDB in a recent GWAS in 771 patients without SQSTM1 mutations from the PRISM study (Albagha et al;Nat Gen, 2011). The study population was divided by the number of risk alleles carried (<14, n=254;14-16, n=254;>16, n=259). Total disease severity score was significantly increased in patients carrying >16 risk alleles (6.24±0.10vs5.57±0.16, $p<0.0001$). They had a greater number of affected bones (1.45±0.04vs1.23±0.07, $p<0.009$); and received previously a greater number of treatments for PDB (2.01±0.04vs1.74±0.07 $p<0.001$). Deafness due to skull involvement was also increased (10% vs. 5.8%, $p=0.037$). There was no difference between the groups in quality of life scores. We found that the novel risk alleles interacted with SQSTM1 mutations to affect disease severity. Patients with SQSTM1 mutations carrying >16 risk alleles had a 44% increase in disease severity score, compared with SQSTM1 negative patients carrying <16 alleles (7.82 ± 0.50 vs. 5.40 ±0.11, $p<0.001$). We conclude that the novel risk alleles identified recently not only predispose to the development of PDB but also significantly influence disease severity both alone and in combination with SQSTM1 mutations. They could identify patients at high risk of complications and this, in turn, could target therapy more effectively.

P09.105

Genetic pathways for ADHD show association to hyperactive/impulsive behavior

J. Bralten[1], I. Waldman[2], S. Faraone[3], J. Buitelaar[4], B. Franke[5], **A. Arias-Vásquez**[5];
[1]Radboud University Nijmegen Medical Center, Departments of Human Genetics and Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behavior, Nijmegen, Netherlands, [2]Department of Psychology, Emory University, Atlanta, GA, United States, [3]Department of Psychiatry and Neuroscience and Physiology, SUNY Upstate Medical University, Syracuse, NY, United States, [4]Radboud University Nijmegen Medical Center, Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behavior & Karakter Child and Adolescent Psychiatry University Center, Nijmegen, The Netherlands, Nijmegen, Netherlands, [5]Radboud University Nijmegen Medical Center, Departments of Psychiatry & Human Genetics, Nijmegen, Netherlands.

Finding genetic risk factors for Attention-Deficit Hyperactivity Disorder (ADHD) has been challenging. As multiple genes with small effect size are assumed to play a role, considering multiple SNPs within the same analysis might increase the explained phenotypic variance, thereby boosting the power of genetic studies. We investigated whether a pathway-based analysis, considering SNPs within the same biological pathway simultaneously, could bring us closer to unraveling the underlying genetic component of ADHD.

Biological pathways involved in dopamine, serotonin and noradrenalin neurotransmission as well as genes involved in neurite outgrowth, were investigated for pathway-based association to ADHD using data from the International Multicentre ADHD Genetics (IMAGE) study. The DSM-IV inattention and hyperactivity/impulsivity scales of the Conners' Parent Rating Scale were used to assess ADHD symptom severity in the 931 probands. From the imputed and pruned genome-wide data 6501 SNPs were selected and used for the association analysis.

Combined analysis of the four pathways showed significant association with the hyperactive/impulsive score ($p=0.0049$), but no association for inattentive or combined scores ($p>0.05$). Post-hoc analyses showed contribution of three pathways ($p<0.05$) to the hyperactive/impulsive score, only the dopamine pathway showed less nominal significance ($p=0.07$).

The current analysis specifically finds association to the hyperactive/impulsive component of ADHD, suggesting similar underlying mechanisms for the studied pathways. Other mechanisms may be involved in the inattentive component of the disorder. These findings show that pathway-based association analyses may overcome power problems in association testing by taking into account allelic heterogeneity.

P09.106

Genetic variants of interferon-g and periodontitis in patients with coronary heart disease

S. Schulz[1], A. Schlitt[2], T. Seifert[1], A. Lutze[1], K. Werdan[2], B. Hofmann[3], C. Gläser[4], H. Schaller[1], S. Reichert[1];
[1]Department of Operative Dentistry and Periodontology, Halle, Germany, [2]Department of Medicine III, Halle, Germany, [3]Department of Cardiothoracic Surgery, Halle, Germany, [4]Institute of Human Genetics and Medical Biology, Halle, Germany.

Background: Periodontitis and coronary heart disease are inflammatory diseases. Both are influenced by genetic predisposition. The c.-874T>A polymorphism of the gene encoding for interferon-γ (IFN-γ) has been associated with altered cytokine production.

Patients and methods: A total of 960 consecutive patients with angiographic proven coronary heart disease (no or mild periodontitis: n=493, severe periodontitis: n=447) were prospectively included in the study entitled "Periodontitis and Its Microbiological Agents as Prognostic Factors in Patients with Coronary Heart Disease" (ClinicalTrials.gov identifier:NCT01045070).

In this subanalysis, the c.-874T>A polymorphism of the gene encoding for IFN-γ was analyzed by CTS-PCR-SSP Tray kit (Heidelberg, Germany). Subgingival bacterial colonization (11 bacteria) was assessed using a polymerase chain reaction (PCR)/DNA probe test (micro-Ident®).
Results: The genotype (p=0.987) and allele frequencies (p=0.860) of the c.-874T>A polymorphism were not risk indicators for the severity of periodontitis in patients with coronary heart disease. However, AA-genotype and A-allele carriers had a decreased risk for subgingival occurrence of *P. intermedia* (genotype: p=0.006, allele: p=0.01) and *E. corrodens* (genotype: p=0.034, allele: p=0.013). These associations remained also significant after forward stepwise binary logistic regression analyses considering age, gender, smoking, diabetes, plaque index as well as other potential confounders.
Conclusions: Despite the c.-874T>A polymorphism of the gene encoding for IFN-γ could be shown to be associated with subgingival colonization of *P. intermedia* and *E. corrodens* there was no evidence that it is a risk indicator for severity of periodontitis in coronary patients.

P09.107

Genetic polymorphism and mRNA levels of *TNFα* and *TGFβ* genes in patients with chronic leg ulcers

M. Zagozda[1], *M. Fic*[1], *A. Sarnecka*[1], *W. Olszewski*[1,2], *M. Durlik*[1,2];
[1]*Mossakowski Medical Research Centre Polish Academy of Sciences, Warsaw, Poland,*
[2]*Central Clinical Hospital, Ministry of Internal Affairs, Warsaw, Poland.*

TNFα and TGFβ mediates a number of biological processes, including lipid metabolism, coagulation, endothelial functions and also have an essential function in healing of pathological wounds such as venous leg ulcers. The purpose of this study was to investigate frequencies of single nucleotide polymorphisms in *TNFα* and *TGFβ* genes and evaluate expression of mRNA levels in chronic leg ulcers. The study population consisted of 65 patients with chronic leg ulcers and 95 healthy control subjects. Polymorphisms were investigated by PCR-RFLP method. The level of *TNFα* and *TGFβ* genes expression was performed by Real-Time PCR with GAPDH as internal control. There were differences in frequency of genotypes TNFα G-308A in both groups. Patients showed higher frequency of AA (43%) and lower of GG (15%), GA (42%) genotypes than controls (2%, 22% and 76% respectively). TGFβ 29T>C heterozygotic genotype was similar in both groups (53% in patients, and 46% in controls). TT genotype was lower (19%), however polymorphic CC genotype was more often (28%) represented in patients than in controls (44% and 10%, respectively). TGFβ 74G>C GG genotype reached 80% whereas GC 20%. The polymorphic CC genotype was not detected both in study and control groups. The level of *TNFα* gene expression was higher than in control group whereas in case of TGFβ the level of expression was similar in both groups. Analyzed polymorphism of *TNFα* gene could be a probable risk factor in patients with leg ulcers and should be taken into account during medical treatment.

P09.108

Association of PON1 and APOA1 genes polymorphism with men's life expectancy in Russian population

V. Miroshnikova[1,2], *A. Zaharchuk*[3], *O. Sirotkina*[1,2], *A. Taraskina*[1,2], *S. Pchelina*[1,2];
[1]*Saint-Petersburg Pavlov State Medical University, Saint-Petersburg, Russian Federation,*
[2]*Petersburg Nuclear Physics Institute, Saint-Petersburg, Russian Federation,* [3]*Saint-Petersburg State University, Saint-Petersburg, Russian Federation.*

Paraoxonase 1 (PON1) is a high-density lipoprotein (HDL)-associated enzyme that prevents oxidation of low-density lipoproteins. Apoprotein A1 (APOA1) is the key protein of HDL. PON1 and APOA1 play important role in the prevention of atherosclerosis. So PON1 and APOA1 are plausible candidate genes for human longevity due to its modulation of cardiovascular risk. In our previous studies we demonstrated that PON1 192Q/R polymorphism is associated with higher risk of premature atherosclerosis and myocardial infarction and APOA1 83C/T polymorphism is associated with reduced risk of atherosclerosis in Russian population. We conjectured that polymorphism of PON1 and APOA1 genes can be associated with longevity in Russian population. In this study we investigated 192Q/R and (-108)C/T PON1 and 83C/T and (-75)G/A APOA1 gene variants in the group of elderly men which we observed during 8 years (75-104 years old, mean age 84.1±5.7 in the moment of the beginning of investigation, N=144). There was no association of (-108)C/T PON1 and 83C/T and (-75)G/A APOA1 gene variants with life expectancy for men. Unexpectedly, the 192R allele was overrepresented in the group of elderly men when compared with population (df=1, p<0.01). Also we analyzed distribution of 192Q/R PON1 genotypes in group of men that lived 85 years or longer (age of death 85-105, mean age of death 91.0±4.1, N=114) and found significant differences when compared with population (df=2, p<0.05). Men heterozygous for 192Q/R PON1 have 2 times higher chances to live till 85 (p<0.01).

P09.109

Allelic imbalance in retinal expressed disease genes: a common phenomenon?

S. Balendran, *B. Wissinger, S. Schimpf-Linzenbold;*
Institute of Ophthalmic Research, Tuebingen, Germany.

In retinal dystrophies, reduced penetrance and variability in disease expression with respect to onset, course, and severity is a well-documented feature. This makes reliable genotype/phenotype correlations as well as individual disease prognosis difficult. Although the basis of this variability is largely unknown, it is commonly accepted that secondary genetic factors (modifier-genes) are key factors for this phenomenon.
We hypothesize that *cis*-acting variants governing gene expression levels play a crucial role in phenotypic variation and disease penetrance in hereditary retinal disorders.
The aim of this project is the identification of such *cis*-acting gene variants and the determination of their impact on disease expression.
To demonstrate if and how common allelic imbalance (AI) in retinal expressed genes are, experiments were done in crossbreeds of five different inbred mouse strains as a proof-of-principle experiment.
Up to now more than **25** different retinal genes were screened for heterozygous cSNPs applying PCR and sequencing. We applied Pyrosequencing assays on RT-PCR amplified cDNAs generated from retinal RNA to determine allelic expression differences based on the identified cSNPs.
Using the Pyrosequencing technology, we identified an AI in **7** retinal disease genes. In two of those genes we can see the AI already on genomic level suggesting a copy number variation. Screening of the *Pde6c* gene revealed a 116-bp insertion on cDNA level that results in a premature termination codon leading, due to the nonsense mediated mRNA decay, to a downregulation of the mutant transcript. For the remaining genes the cause of the AI has to be verified.

Psoriasis (Ps, OMIM 177900) is a chronic hyperproliferative inflammatory disease of the skin, scalp, nails, and joints. About 30% of affected develop psoriatic arthritis (PsA, OMIM 607507). Psoriasis and psoriatic arthritis have a multifactorial etiology, involving environmental (infections, drugs, stress, smoking and climate) and genetic factors. It's well known that inflammation plays a central role in the development of many multifactorial diseases, as in age-related macular degeneration (AMD, OMIM 603075). As psoriasis and psoriatic arthritis share with AMD a multifactorial etiology and the inflammation as central process, we analyzed the some replicated genetic variations associated with AMD in our cohorts of Ps and PsA. A number of 400 Ps cases, 510 PsA cases and 400 healthy controls were tested for rs1061170 (Y402H) in the CFH gene and rs10490924 (A69S) in the ARMS2 gene. Our results suggest that variations in these genes are not associated with the development of Ps and PsA.
The work was supported by ADIPSO, (Italian Association of psoriatic subjects)

P09.111

Genome-wide analysis of copy number variants suggests common and rare copy number variants contributing to psoriatic arthritis

Not only single nucleotide polymorphisms (SNP) but also copy number variants (CNV) contribute to variability of the human genome and can therefore be involved in genetic disease. In order to identify CNVs for psoriatic arthritis (PsA), we investigated our previously described SNP-based GWAS dataset (*Hüffmeier et al. Nat Genet 2010*) for CNVs using the *Birdsuite* algorithm optimized for the array system used and performed a CNV GWAS. Primarily, we detected significant differences at 33 gene loci at the 5% level, while a first *in silico* analysis revealed "batch effects" at 16 loci - false-positive findings due to erroneous CNV-determination of single batches. Of the remaining 17 loci, *in silico* association analysis showed association at 15 loci (n=9: MAF>5%, n=6: MAF<5%), 11 loci with $p<1x10^{-4}$. Validation of those 15 CNVs with an alternative quantitative method (MLPA) confirmed CN-variability at 11 loci. For four common CNVs, perfect concordance between array system and MLPA was observed in 136-157 individuals. Genes located in or nearby CNVs are reported to be involved in immune regulatory pathways, maintenance of extracellular matrix or signal transduction and are therefore plausible candidates. These four validated common variants fit a dosage-additive model with a p-value of $1.11x10^{-4}$, suggesting the presence of simple additive effects towards disease susceptibility. Ongoing studies aim to replicate associations in independent case-control studies, if replicated to identify the break points and to functionally analyze the CNVs.

P09.112
Too much, but also too little of calreticulin in major psychiatric disorders

S. Farashi[1], *A. Mirab Zadeh*[2], *M. Ohadi*[1];
[1]*Genetic Research Center, Tehran, Islamic Republic of Iran,* [2]*Welfare and Rehabilitation University, Tehran, Islamic Republic of Iran.*

Evidence on population association studies support the hypothesis that the high heritability of major psychiatric disorders is a combination of relatively common alleles of modest effect, and rare alleles some with relatively larger effects. We have recently reported three mutations in the proximal promoter of the human calreticulin (CALR) gene at positions

-48C, -205T and -220A that co-occur with the spectrum of psychosis, including schizophrenia, schizoaffective disorder, and bipolar disorder type I. The frequency of those mutations was estimated at <0.0007, and none of those mutations have been detected in the control population (p<0.005). Mutations -48C and -220A were found to increase the expression of the CALR gene. The third mutation at -205C>T was detected in an isolate case of schizoaffective disorder.

In this paper, the functional implication of mutation -205T was studied in the human neuroblastoma cell lines BE(2)-C and LAN-5, and HEK-293 cell lines. In contrast with other mutations in the promoter region, which increase expression of the gene, the -205T mutation significantly decreased gene expression in those cell lines in comparison with the wild-type -205C-nucleotide (p<0.0005, p<0.001, and p<0.017, respectively). Treatment of the cells lines with the anti-psychotic drug, valproic acid, showed synergistic increase in gene expression in the cell lines with the mutant -205T allele vs. wild type -205C constructs (p<0.001). We propose that a deviation from normalcy in the level of CALR in either direction is associated with major psychiatric disorders.

Giovanni di Dio-Fatebenefratelli, Brescia, Italy,* [5]*Department of Biomedical Sciences and Biotechnologies, University of Brescia, Brescia, Italy,* [6]*Department of Health Sciences, University of Genova, Genova, Italy.*

Though the basic pathophysiology of psychosis is largely unknown, the role of synaptic dysfunction and altered neural connectivity that origin early in neurodevelopment is currently recognised. There is reliable evidence that genes contribute to the aetiology of psychosis and recent findings provided consistent clues for an overlap in genetic susceptibility across the traditional psychosis categories.

Genetic variations can influence disease risk through the interaction with environmental factors (gene-environment interaction). Epidemiologic studies suggested that chronic use of cannabis is a risk factor for the development of psychosis. Recent researches have focused on the identification of genetic variants that moderate the effect of cannabis on psychosis risk under the gene-environment interaction paradigm.

We performed a systematic literature search to identify genetic studies that explored the association between cannabis and psychosis. We included genetic studies that reported the direct measures of genetic risk in the association between cannabis and psychosis.

Out of 184 articles identified in the screening phase, 14 articles met the inclusion criteria. We report a structured summary of populations studied, methodology, genetic variations used as predictors, evaluations of cannabis use, outcome measures and main results.

The current state and limitations of genetic researches on interplay cannabis and psychosis is discussed. We address how the application of new genetics technologies and the harmonization of the data between the studies could allow to consistently identify genetic risk variants that in conjunction with exposure to cannabis may explain the occurrence of psychotic symptoms.

P09.114
Matrix metalloproteinase genes on chromosome 11q22 and range of motion assessments in physically active individuals.

M. C. Burger[1], *K. O'Connell*[1], *S. M. Raleigh*[2], *M. Posthumus*[1], *M. Collins*[1,3];
[1]*MRC/UCT Research Unit for Exercise Science & Sports Medicine, University of Cape Town, South Africa,* [2]*Division of Health & Life Sciences, University of Northampton, United Kingdom,* [3]*South African Medical Research Council, Cape Town, South Africa.*

INTRODUCTION: A recent heritability study demonstrated that human range of motion (ROM) has a substantial genetic component. The objective of this study was to investigate if variants within the *MMP10*, *MMP1*, *MMP3* and *MMP12* genes associate with ROM measurements, including sit-and-reach (SR), straight leg raise (SLR) and total shoulder rotation (ShTR), in physically active individuals.

METHODS: Three hundred and thirty-four physically active Caucasians were genotyped, using a Taqman assay, for the *MMP10* C/T rs486055, *MMP1* 1G/2G rs1799750, *MMP3* A/G rs679620 and *MMP12* A/G rs2276109 variants. Genotype effects on SR, SLR and ShTR ROM measurements were determined. Significance was accepted p<0.05.

RESULTS: There were no significant differences between the MMP10 (SR, mm: CC 267±114mm, n=222; CT 273±102, n=70; TT 252±125, n=16; p=0.923), MMP1 (SR, mm: 1G1G 267±110, n=79; 1G2G 265±116, n=170; 2G2G 282±110, n=64; p=0.507), MMP3 (SR, mm: AA 265±114, n=81; AG 277±102, n=160; GG 257±120, n=88; p=0.078) or MMP12 (SR, mm: AA 265±110, n=147; AG 270±110, n=61; GG 331±61, n=7; p=0.321) genotypes and the SR ROM measures. Furthermore there were no significant genotype effects on SLR and ShTR. Interestingly, individuals with the minor *MMP12* rs2276109 GG genotype were much more flexible for all measurements (SR, mm: GG 331±61, n=7; AA+AG 266±110, n=308; p=0.135), however, due to sample size, this finding was not significant.

CONCLUSION:

The *MMP10*, *MMP1*, *MMP3* and *MMP12* genes were not associated with ROM in this study. Due to the observed trends and rarity of the *MMP12* GG genotype, further analysis with a larger sample size is required.

P09.115
Genome-wide association study for refractory celiac disease (RCDII) in Europeans

B. Hrdlickova[1,2], *R. L. J. van Wanrooij*[3], *G. Malamut*[4,5,6], *Y. Kamatani*[7], *G. Bouma*[3], *S. Zhernakova*[1,8], *B. Meresse*[4,5], *F. Biagi*[9], *G. R. Corazza*[9], *C. Cellier*[4,5,6], *M. Lathrop*[7], *N. Cerf-Bensussan*[4,5], *C. J. Mulder*[3], *V. Kumar*[1], *C. Wijmenga*[1];
[1]*Department of Genetics, UMCG, Groningen, Netherlands,* [2]*University of Groningen, Groningen, Netherlands,* [3]*Department of Gastroenterology, FUMC, Amsterdam, Netherlands,* [4]*Université Paris Descartes, Paris, France,* [5]*Inserm U989, Faculté de Médecine Paris Descartes, Paris, France,* [6]*Assistance Publique des Hôpitaux de Paris, Gastroenterology, Hôpital Européen Georges Pompidou, Paris, France,* [7]*Fondation Jean Dausset-Centre d'Etude du Polymorphisme Humain (CEPH), Paris, France,* [8]*Department of Rheumatology, LUMC, Leiden, Netherlands,* [9]*Dona alla Fondazione IRCCS Policlinico San Matteo, Pavia, Italy.*

Celiac disease (CeD) is a common autoimmune disorder triggered by dietary gluten in genetically susceptible individuals. The only treatment is a lifelong, gluten-free diet (GFD). However, about 5% of CeD patients do not respond to GFD and some develop refractory celiac disease (RCD), which is characterized by persistent symptoms, severe malabsorption, and intestinal damage despite a strict GFD. RCD patients with clonal T-cells, referred to as 'RCDII', have a high mortality and poor prognosis due to the development of lymphomas.

To discover genetic risk factors associated with RCDII, we performed a genome-wide association study (GWAS) in a Dutch cohort (38 patients, 846 controls), validating the top-associated variants in an independent French cohort (33 patients, 787 controls).

This revealed 21 potential susceptibility variants in 15 independent loci (p < 1x10-5); we genotyped the top-15 variants. Using the Fisher Exact test, we found evidence for association with two variants in our replication cohort: SNP4 in the KLF12 gene at chromosome 13 (p = 0.04, OR = 1.703) and SNP7 in the WWOX gene at chromosome 16 (p = 0.007, OR = 2.139).

None of the known celiac disease susceptibility variants showed association with RCDII, suggesting that the RCDII phenotype is due to different genetic factors. To further validate our findings, we are currently performing replications in other European RCDII cohorts.

P09.116

Investigating the association of rs1800801 and rs1800802 single nucleotide polymorphisms on the promoter of MGP gene with Renal Stone

M. Keramatipour[1], *M. Taghizadeh*[1], *B. Ahadi*[2], *G. Zarrinrad*[1], *A. Tabibi*[2];
[1]Department of Medical Genetics, Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran, [2]Section of Urology, Dr Labbafinejad Hospital, Shahid Beheshti University of Medical Sciences, Tehran, Islamic Republic of Iran.

The Matrix Gla Protein (MGP) is an important inhibitor of calcification. Polymorphisms of MGP have been shown to be associated with stone formation in Kidney. Mainly two single nucleotide polymorphisms (SNPs) G-7A (rs1800801) & T-138C (rs1800802) on MGP gene have been suggested to play a role in susceptibility towards calcification which may affect gene expression due to their location in promoter region of the gene.

This work is investigating the possible association of these two SNPs with the formation of renal stone in Iranian population using a family based (Parents-Affected Child Trios) association study.

So far 100 trios were recruited. After obtaining their written consent, blood samples were taken and DNA was extracted. For genotyping, the target region was amplified by PCR and the products were sequenced. Genotypes of both SNPs were confirmed for 40 trios so far. Analysis of the preliminary data shows over transmission of A allele for rs1800801 and T allele for rs1800802, although the differences statistically were not significant. Transmission Disequilibrium Test (TDT) value was 2.45 (*p-value* $\approx$ *0.1)* for rs1800802, and 0.25 (*p-value* $\approx$ *0.6)* for rs1800801. It is very likely that adding the genotypes of the remaining trios, reveals a significant over transmission of T allele in rs1800802, confirming the association of this allele with the disease.

This work is being continued by genotyping the rest of samples and the full data will be presented at the meeting.

P09.117

Functional study of Peptidylarginine deiminase type 4 as genetic risk factor for RA

A. Suzuki[1], *Y. Kochi*[1], *H. Shoda*[2], *K. Fujio*[2], *E. Kanno*[1], *R. Yamada*[1,3], *K. Yamamoto*[1,2];
[1]RIKEN, Yokohama, Japan, [2]Department of Allergy and Rheumatology, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan, [3]Center for Genomic Medicine, Kyoto University, Kyoto, Japan.

Rheumatoid arthritis (RA) is well-known as an autoimmune disease and is a chronic inflammatory disorder characterized by the destruction of multiple joints. Many genome wide association studies were performed and multiple RA-susceptibility loci and autoimmune-susceptibility loci have been identified. These studies suggested that multiple genes and its functions were related with disease causing and development.

Previouly, peptidylariginine deiminase type 4 **(**PADI4) was identified as a susceptibility gene for RA in a Japanese population by case-control association study. PADI4 is a member of the PADI gene family and converts arginine residue (peptidylarginine) to citrulline residue (peptidylcitrulline). PADI4 is highly expressed in bone marrow, macrophages, neutrophils and monocyte. Peptidylcitrulline is an interesting molecule in RA, because it is an antigen of ACPA and only PADs (translated protein from PADI genes) can provide peptidylcitrullines, via modification of protein substrates. To evaluate the importance of PADI4 gene in the progression of RA, we generated Padi4 -/- C57BL/6 (B6) mice by speed congenic method. We used Padi4-/- mice to show that PAD4 is affected to development and progression of collagen induced arthritis (CIA), well known as an RA model animal. Padi4-/- B6 and WT mice were immunized with Chicken type II collagen (CII) for CIA. Clinical disease score was reduced and the incidence of WT and Padi4-/-mice were 56% and 44%, respectively. Padi4-/- mice also significantly reduced concentrations of serum anti-CII IgM and IgG compared with WT mice. Resulting from these studies, we suggested that Padi4 enhanced collagen-initiated inflammatory responses.

Copy number variants in RB1CC1 and OR4C46 are overrepresented in a German case-control sample of schizophrenia

F. Degenhardt[1,2], *L. Priebe*[1,2], *J. Strohmaier*[3], *S. Herms*[1,2], *P. Hoffmann*[1,2], *R. Mössner*[4], *I. Nenadic*[5], *H. Sauer*[5], *D. Rujescu*[6], *W. Maier*[4], *M. Rietschel*[3], *M. M. Nöthen*[1,2,7], *S. Cichon*[1,2,8];
[1]Institute of Human Genetics, University of Bonn, Bonn, Germany, [2]Department of Genomics, Life and Brain Center, University of Bonn, Bonn, Germany, [3]Department of Genetic Epidemiology in Psychiatry, Central Institute of Mental Health, University of Heidelberg, Mannheim, Germany, [4]Department of Psychiatry, University of Bonn, Bonn, Germany, [5]Department of Psychiatry, University Hospital Jena, Jena, Germany, [6]Molecular and Clinical Neurobiology, Department of Psychiatry, Ludwig-Maximilians-University, Munich, Germany, [7]German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany, [8]Institute of Neuroscience and Medicine (INM-1), Structural and Functional Organisation of the Brain, Genomic Imaging, Research Centre Juelich, Juelich, Germany.

Schizophrenia is a severe and debilitating neuropsychiatric disorder with an estimated heritability of 60-80%. Recent studies have shown that rare, highly penetrant variants account for a fraction of the overall genetic risk.

Some of these disease-associated rare variants have been identified several times in sporadic cases as independent de novo mutations and are obviously subject to negative selection. These findings support the hypothesis that the recurrent de novo occurrence of risk variants may compensate for risk variants that constantly disappear from the gene pool by negative selection.

It is reasonable to assume that schizophrenia susceptibility genes identified by de novo mutations in patients might carry additional risk variants, such as other rare single nucleotide mutations but also rare copy number variants (CNVs). We tested this hypothesis by starting from 34 potential schizophrenia susceptibility genes that were reported to carry de novo mutations by Xu et al. (2011). Using Illumina BeadArray data of 1,637 patients with schizophrenia and 1,627 population-based controls, we investigated whether CNVs at these loci might contribute to the allelic spectrum in schizophrenia. Each individual's SNP-chip information was analyzed with QuantiSNP and PennCNV.

In two genes, RB1CC1 and OR4C46, we found CNVs overrepresented in patients compared to controls providing further support for an involvement of these genes in the development of schizophrenia. We are currently extending our analyses to large, independent case-control datasets. From a functional point of view, it is noteworthy that RB1CC1 insufficiency causes neuronal atrophy. This may provide a link to pathophysiological considerations in schizophrenia.

P09.119

Unraveling the implication of de novo mutations in the genetics of schizophrenia

S. L. Girard[1,2], *P. A. Dion*[1], *J. Gauthier*[1], *S. Geoffroy*[2], *M. Dubé*[2], *G. A. Rouleau*[1,3];
[1]Center of Excellence in Neuromics, Montréal, QC, Canada, [2]Beaulieu-Saucier Pharmacogenomics Centre of the University of Montreal, Montreal, QC, Canada, [3]CHU Ste-Justine Research Center, Montreal, QC, Canada.

Recently, a wave of studies has shown that de novo mutations play a very important role in the genetic mechanism of psychiatric disorders. Our group has shown that there is an enrichment of pathogenic de novo mutations in schizophrenia. Other groups have made the same observation in schizophrenia, but also in autism and mental retardation. We are now trying to characterize this paradigm using two methods. First, we are looking at healthy twins to evaluate the rates of germ line and somatic de novo mutations using exome capture. This is the first report of an exonic de novo mutation rate that can be used as a direct comparison to the previous studies. We are also doing a follow up of the genes identified in the first study using an enrichment solution in order to evaluate the rare variants burden of each gene in a schizophrenia cohort. We are resequencing approximately a hundred genes that were found to harbour a de novo mutation in previous studies, in a cohort of 250 schizophrenia patient and 250 healthy individuals.

Analysis of copy number variants (CNV) and gene expression in monozygotic twins discordant for schizophrenia

F. B. Basmanav[1,2], *S. Herms*[1,2], *A. Sharma*[3], *K. Langbein*[4], *A. Hedman*[5], *M. Bohlken*[5], *S. Edkins*[6], *E. Bramon*[7], *H. Sauer*[4], *M. Rietschel*[8], *N. van Haren*[5], *I. Nenadic*[4], *R. Ophoff*[5,9], *H. Hulshoff Pol*[5], *M. Weisbrod*[3,10], *M. M. Noethen*[1,2,11], *P. Hoffman*[1,2], *S. Cichon*[1,2,12];
[1]Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany, [2]Institute of Human Genetics, University of Bonn, Bonn, Germany, [3]Section for Experimental Psychopathology and Neurophysiology, Department of General Psychiatry, Centre for Psychosocial Medicine, University of Heidelberg, Heidelberg, Germany, [4]Department of Psychiatry and Psychotherapy, Jena University Hospital, Jena, Germany, [5]Department of Psychiatry, Division of Neuroscience, Rudolf Magnus Institute, University Medical Centre Utrecht, Utrecht, Netherlands, [6]Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton Cambridge, United Kingdom, [7]Division of Psychological Medicine, Institute of Psychiatry, King's College London, London, United Kingdom, [8]Department of Genetic Epidemiology in Psychiatry, Central Institute of Mental Health, University of Heidelberg, Mannheim, Germany, [9]UCLA Center for Neurobehavioral Genetics, Los Angeles, CA, United States, [10]Psychiatric Department, SRH Klinikum Karlsbad-Langensteinbach, Karlsbad, Germany, [11]German Center for Neurodegenerative Disorders (DZNE), Bonn, Germany, [12]Institute of Neuroscience and Medicine (INM-1), Research Center Juelich, Juelich, Germany.

Schizophrenia has a lifetime prevalence of 1% and is a severe psychiatric disorder characterized by positive symptoms (e.g. hallucinations, delusions), negative symptoms (e.g. apathy, poor social functioning) and cognitive deficits (e.g. poor working memory). There is strong evidence that a polygenic component and environmental factors contribute to disease development. A powerful strategy to identify etiologically relevant genetic, epigenetic and gene expression patterns is the investigation of phenotypically discordant monozygotic (MZ) twins. Recent studies have identified differences in copy number variation (CNV) between MZ twins with both concordant and discordant phenotype suggesting that somatic mosaicism may not be uncommon. These findings suggest that CNV analysis in phenotypically discordant MZ twins may provide a powerful tool for identifying disease susceptibility loci.

In the present study, we utilized 20 MZ twins discordant for schizophrenia (n=18) or schizoaffective disorder (n=2) collected in 3 medical research centers located in Germany and The Netherlands. All 20 pairs are currently being genome-wide genotyped on Illumina HumanOmni1S beadchips to analyze CNV discrepancies. In addition, for 7 of these discordant MZ twin pairs peripheral mRNA is available and will be subjected to whole genome expression profiling by use of llumina HumanHT-12 Expression BeadChips to determine potentially differentially expressed regions and to enable integration of the genetic and expression data.

P09.121

Genetic association of RGS2 gene variants with schizophrenia and antipsychotic response

A. Gareeva[1], *D. Zakirov*[2], *E. Khusnutdinova*[1,2];
[1]*Institute of Biochemistry and Genetics of Ufa Scientific Center, Russian Academy of Sciences, Ufa, Russian Federation,* [2]*Bashkir State University, Ufa, Russian Federation.*

Schizophrenia is a common and complex psychiatric disorder with a strong genetic component. As regulators of G protein signaling and regulators of G protein signaling-like proteins play a pivotal role in dopamine receptor signaling, genetically based, functional variation could contribute to interindividual variability in therapeutic and adverse effects

The present study is aimed at exploring whether two single nucleotide polymorphisms (SNPs) rs2746073 and rs2746072 within RGS2 gene could be associated with schizophrenia and whether they could predict clinical outcomes in 300 patients of two ethnic groups (158 Russians and 142 Tatars) from the Volga-Ural region of Russia treated with antipsychotics. Baseline and final clinical measures, including PANSS and SAS scales were recorded. No significant association was found with the diagnosis of schizophrenia. However analysis of variance revealed that genotype RGS2*T/*T to be a marker of reduction of Negative symptoms (P=0.04) in the overall sample comprised of Russians and Tatars on the 21 day from the baseline.

Our findings provide no evidence for an association between SNPs within RGS2 gene under investigation and schizophrenia susceptibility. However, taking into account the several limitations of our study, further research is needed to draw more definitive conclusions.

This work was supported by grant of the Russian Foundation for Humanities (11-06-00554a)

P09.122

Influence of GRIN2B gene polymorphic loci on antipsychotic treatment response and susceptibility to schizophrenia

D. Zakirov[1], *E. Suleimanova*[1], *A. Gareeva*[2], *E. Khusnutdinova*[2,1];
[1]*Bashkir State University, Ufa, Russian Federation,* [2]*Institute of Biochemistry and Genetics of Ufa Scientific Center, Russian Academy of Sciences, Ufa, Russian Federation.*

One major problem in the schizophrenia (SZ) treatment is finding the right drug for the right patients.

We aimed to examine the effect of five polymorphic loci (rs1805502, rs7301328, rs1805247, 5806A/C, rs1805482) of GRIN2B gene on treatment response to typical antipsychotics (TA) in schizophrenia patients from Russia.

Study sample comprised of 300 drug naive patients with the first episode of SZ (158 Russians and 142 Tatars) from the Volga-Ural region of Russia. Clinical response and severity of Extrapyramidal symptoms (ES) were determined by administering the PANSS and SAS scales at base line and at days 21 and 45. Differences between groups were tested by using unpaired t-test (two-tailed), analysis of variance (ANOVA), and chi-square test.

Analysis of variance detected genotype GRIN2B *T/*T (rs1805247) to be a marker of reduction of Negative (P=0.03) and General Psychopathology symptoms (P=0.04) in Tatar patients on the 21 assessment day.

ANOVA revealed GRIN2B *T/*T (rs1805502) genotype to be a marker of low risk of ES development (P=0.003) in Russian patients on the 21 assessment day.

Analysis of association educed allele GRIN2B *T (rs1805247) to be a risk marker for schizophrenia in Tatars (OR=2,39). A CTC haplotype encompassing rs180552, rs1805247, rs1805482 of GRIN2B gene was significantly overrepresented among Tatar patients (OR=2,32).

Our results are preliminary and suggest that the SNPs in GRIN2B gene may influence the treatment response to TA and susceptibility to schizophrenia. Further studies are necessary to confirm the reported associations.

This work was supported by the Russian Foundation for Humanities grant 11-06-00554a.

Association study of candidate gene polymorphisms with paranoid schizophrenia susceptibility in Russian population

D. Galaktionova[1], *O. Gra*[1], *A. Gareeva*[2], *E. Khusnutdinova*[2], *T. Nasedkina*[1];
[1]*Engelhardt Institute of Molecular Biology Russian Academy of Sciences, Moscow, Russian Federation,* [2]*Institute of Biochemistry and Genetics Russian Academy of Sciences, Ufa, Russian Federation.*

Schizophrenia is a multifactorial disorder (about 1% in the most populations studied) and is characterized by the contribution of multiple susceptibility genes that could act in conjunction with epigenetic processes and environmental factors. Based on previous molecular genetic studies the following polymorphisms: *HTR2A (rs6311, rs6313, rs6314* and *rs7997012), BDNF (rs6265), SLC6A4 (rs28914832), DISC1 (rs3737597), ZNF804A (rs1344706), RELN (rs7341475), COMT (rs165599), SLC18A1 (rs2270641)* and *PLXNA2* (*rs1327175*) have been chosen and analyzed in 198 patients with schizophrenia and 192 healthy individuals. The genotyping procedure included multiplex PCR with fluorescently labeled nucleotides and allele-specific hybridization of labeled PCR products with a biochip. The statistically significant association between *rs6314* (p = 0.014, OR = 2.26) of *HTR2A* gene and risk of paranoid schizophrenia was found. Also it was shown that genetic variants *rs6311* (p = 0.011, OR = 2.33) and *rs6313* gene *HTR2A* (p = 0.008, OR= 2.40) were associated with suicidal behavior in schizophrenic patients.

The work was supported by Ministry of Science and Education of Russian Federation (State contracts ## 02.740.11.0869 and 02.527.11.0006).

Association study of class II cytokine genes with psoriasis in three ethnic groups from the Russia

E. Galimova[1], *V. Akhmetova*[1], *K. Kingo*[2], *R. Rätsep*[3], *T. Traks*[2], *S. Kõks*[3], *E. Khusnutdinova*[1];
[1]*Institute of Biochemistry ang Genetics, Ufa Scientific Center of Russian Academy of Sciences, Ufa, Russian Federation,* [2]*Department of Dermatology and Venerology, University of Tartu, Tartu, Estonia,* [3]*Department of Physiology, University of Tartu, Tartu, Estonia.*

Background: The molecular basis of pathogenesis of psoriasis remains unclear, but one unifying hypothesis of disease aetiology is the cytokine network model. The class II cytokines (CF2) and their receptors (CRF2) are all involved in the inflammatory processes and single nucleotide polymorphisms (SNPs) in respective genes have been associated with psoriasis in a previous study of the Estonian population.

Objective: We performed a replication study of 47 SNPs in CF2 and CRF2 genes in independent cohorts of psoriasis patients of three ethnic groups (Russians, Tatars, and Bashkirs) from the Volga-Ural region of Russia.

Methods: DNA was obtained from 499 psoriasis patients of three ethnic groups from the Russia and 581 ethnically matched controls. 47 SNPs in the loci of CF2 and CRF2 genes were selected by SNPbrowser version 3.5. Genotyping was performed using the SNPlex™ (Applied Biosystems) platform.

Results: Comparison of allele frequencies between cases and controls using chi square test revealed differences for seven SNPs rs276466, rs30461, rs3795299, rs1342642, rs10784680, rs4896227, and rs2834117. Only the SNP rs30461 in the IL29 gene displayed a statistically significant association with psoriasis in the cohort of Russians when adjusted for multiple comparisons (corrected P-value (Pc)=0.008, OR=0.44).

Conclusion: Our results suggest that polymorphisms rs30461 of the IL29 gene may contribute to a protection to psoriasis in Russian population. In addition, there might be a probability that other variations in CF2 and CRF2 genes influence susceptibility to psoriasis, but further investigations are needed to provide more conclusive evidence theirs exact contribution.

Ferrara, Italy.

Sox9 has an essential role in chondrogenesis. Nonsense mutations and deletion of Sox9 suggested haploinsufficiency to underly campomelic dysplasia (CD), a rare autosomal dominant disease characterized by campomelia, skeletal defects and Pierre Robin sequence (PRS). Translocations in the 350kb region upstream or downstream of SOX9 were reported in less severe CD patients. Some translocations and deletions further upstream have been identified in patients with acampomelic campomelic dysplasia (ACD) and PRS, suggesting that these three syndromes form a continuum of phenotypes. We report the identification of a translocation 600kb upstream of SOX9 in a patient with classical features of ACD. In parallel, we identified a deletion in a PRS family that overlaps a deletion reported in a patient with the same phenotype. These data and the literature lead us to test whether or not there is a genetic association between the SOX9 locus and cleft palate (CP) and/or PRS. We used three SNPs in a cohort of case-parent trios analyzed using TDT. While two SNPs, tagging a conserved region upstream of SOX9, achieved borderline significance (p=0.045 and p=0.052) in the PRS cohort, significant over-transmission of an intragenic SNP was detected in the combined CP+PRS cohort (p=0,026), with a relative risk of 0.43. The association has been replicated in an independent Italian CP-cohort. Our data are in agreement with the hypothesis that removal or disruption of cis-regulatory elements upstream of SOX9 can lead to phenotypes of gradual severity. We show for the first time an association of SOX9 with CP and PRS.

Specific language impairment (SLI) is a developmental language disorder that, in the absence of any comorbid neurological deficits, affects an individual's spoken and/or receptive language despite adequate intelligence and accessibility to learning. SLI is a common childhood disorder with an estimated prevalence in pre-school children of up to 7%. It is a complex genetic disorder that is closely related to autism, dyslexia and ADHD. SLI has a high genetic component with twin studies finding a monozygotic concordance rate of up to 70%. Recent studies of neurodevelopmental disorders have implicated copy number variants (CNVs) in conditions such as autism, intellectual disability and ADHD. Therefore a study of CNVs within families containing individuals with SLI is currently being performed. The SLI consortium has collected a cohort of samples from across the UK that have been phenotypically well characterised for language. 176 of these families containing 186 individuals with SLI have been genotyped using the Illumina HumanOmniExpress beadchip that contains more than 700,000 SNPs. The SNP data is being used to identify CNVs across the genome using the copy number detection algorithms QuantiSNP and PennCNV. Data will be presented, for example, of the relative burden of CNVs in cases compared to their unaffected siblings and of novel variants. CNVs of interest are to be validated using quantitative PCR. To our knowledge this will be the first genome-wide CNV analysis performed within a cohort of samples with SLI.

Association study of the functional polymorphisms in candidate genes with ischemic stroke in residents of central Russia

M. Avdonina[1], *T. Nasedkina*[1], *A. Ikonnikova*[1], *E. Bondarenko*[2], *P. Slominsky*[2], *N. Shamalov*[3], *I. Shetova*[3], *S. Limborskaya*[2], *A. Zasedatelev*[1], *V. Skvortsova*[3];
[1]*Engelhardt Institute of Molecular Biology Russian Academy of Sciences, Moscow, Russian Federation,* [2]*Institute of Molecular Genetics Russian Academy of Sciences, Moscow, Russian Federation,* [3]*Research Institute of Cerebrovascular Pathology and Stroke Russian State Medical University, Moscow, Russian Federation.*

The frequencies of 34 SNP in candidate genes associated with ischemic stroke (*F12, PON1, PON2, NOS2, PDE4D, HIF1a, GPIba, CYP11B2, REN, AGT, AGTR1, AGTR2, BKR2, ADRB2, ACE, FGB, F2, F5, F7, GPIIIa, PAI-1, MTHFR, APOE, NOS2, NOS3, LTA, ALOX5AP, ADRB3*) have been studied in ischemic stroke (IS) patients and healthy controls, the residents of Central Russia*.* Also polymorphism in *TUB* gene (rs4578424) and rs2881013, rs4459584 in non-coding regions revealed in genome-wide association study in Russian population were analyzed. The genotyping procedure included the amplification of selected gene sequences following by hybridization of fluorescently labeled fragments with SNP-specific DNA probes immobilized on a biochip. An analysis of allele and genotype frequencies for each SNP in IS patients (n=300) and controls (n=300) did not reveal any significant difference. The pair-wise comparison of genes demonstrated that the frequency of genotype combination *PON1* A/- *x PON2* GG was higher in the group of IS patients *(*p=0.044, OR=3.4, 95% CI 1.06-10.4) compared to controls and, thus, was associated with higher risk of stroke. Further the analysis using MDR (Multifactor Dimensionality Reduction) algorithm has been performed. The statistically significant association with stroke for several genotype combinations was revealed, for example for *FGB* G/- *x ACE* I/- *x MTHFR* C/- *x PAI-1* 5G/5G (p=0.018, OR =2.6, 95% CI 1.2-5.6).

P09.128

Association analysis of CRH, CRHR1 and CHRM2 genes in suicidal behavior

A. Zainullina[1], *Z. Khalilova*[1], *A. Valiullina*[2], *K. Kinasheva*[2], *D. Gaysina*[3], *S. Cohen-Woods*[4], *I. Craig*[4], *P. McGuffin*[4], *E. Khusnutdinova*[1,2];
[1]*Institute of Biochemistry and Genetics Ufa Scientific Center of RAS, Ufa, Russian Federation,* [2]*Bashkir State University, Ufa, Russian Federation,* [3]*University College London, MRC Unit for Lifelong Health and Ageing, London, United Kingdom,* [4]*Institute of Psychiatry, Medical Research Council Social Genetic and Developmental Psychiatry Centre, London, United Kingdom.*

Dysregulation in the stress response of the HPA axis, involving the corticotrophin-releasing hormone (CRH) and its main receptor (CRHR1), is considered to play a major role in suicidal behavior (SB). Cholinergic mechanisms are also implicated in stress.

The aim of the present study was to investigate three genes involved in stress response, the corticotrophin-releasing hormone gene (CRH), the CRH receptor 1 gene (CRHR1) and the muscarinic cholinergic 2 receptor gene (CHRM2), for association with suicidal behavior (SB) in Russian population.

Cases were 288 suicide attempters hospitalized in the Clinical Republic Hospital (Ufa, Russia). Controls were 348 individuals without a personal or familial (first degree) history of neuropsychiatric disorders and SB.

Two SNPs (rs6159, rs1870393) of the CRH gene, five SNPs (rs242941, rs878886, rs242938, rs1876831, rs1876828) of the CRHR1 gene and four SNPs (rs1824024, rs2061174, rs2350786, rs324650) of the CHRM2 gene were genotyped. For pairwise linkage disequilibrium and haplotype analysis, the Haploview 4.1 program was used. Odds ratios (OR) with 95% confident intervals (CI) were calculated.

The only association we observed was an allele association between CRHR1 rs878886 and SB: C was significantly overrepresented in patients with SB as compared to controls (OR=2.65, 95%CI: 1.12-2.02). Haplotype analysis showed a significant overrepresentation of the CHRM2 (rs1824024, rs2061174, rs2350786, rs324650) C-G-G-T haplotype (OR=12.48, 95%CI: 1.24-2.01) in suicide attempters as compared to controls. These results may help understand better the pathophysiology of suicidal behavior, its prevention and treatment.

This work was supported by grant of the Russian Foundation for Humanities (11-06-00554a).

P09.129

Copy number variations (CNVs) in the androgen receptor gene (AR) in British patients with systemic sclerosis - a pilot study

G. Rittner[1], *C. Fonseca*[2], *D. Abraham*[2], *O. Bartsch*[1], *U. Zechner*[1];
[1]*Institute of Human Genetics, University Medical Center of the Johannes Gutenberg University Mainz, Mainz, Germany,* [2]*Centre for Rheumatology, Royal Free and University College Medical School, London, United Kingdom.*

Systemic sclerosis (SSc) is an autoimmune disorder characterized by excessive fibrosis and vascular abnormalities in various organs. It is the end result of a complex interaction of genetic factors and unknown environmental influences. Three subgroups can be distinguished, morphea, limited and diffuse SSc. SSc is 3 (diffuse SSc) to 9 (limited SSc) times more frequent in females than in males which has been discussed to be due to elevated ratios of skewed X-chromosome inactivation (XCI) in female patients.

Previously, we investigated the XCI patterns in a cohort of 205 patients with limited SSc and 97 patients with diffuse SSc using the human androgen receptor (AR) gene (HUMARA) assay. This analysis identified 34 patients (11%) that were homozygous for the CAG polymorphism in the AR gene, thereof 17 patients belonging to the limited SSc subgroup (17 of 205, 8.3%) and 17 patients belonging to the diffuse SSc subgroup (17 of 97, 17.5%). To verify if homozygosity of the CAG polymorphism in these patients is due to a deletion of the AR gene, we determined the gene dosage at the AR locus in these patients as well as heterozygous female and hemizygous male controls using genomic qPCR. Two of the 34 patients belonging to the limited SSc group displayed copy number changes ; one had a deletion and one a duplication at the AR gene. These data let us speculate that changes at the AR gene itself might contribute to the female predisposition for SSc indicated by elevated ratios of skewed XCI.

Association of leukocyte telomere length and plasma antioxidants :Results of the Austrian Stroke Prevention Study(ASPS)

A. Sen[1], *M. Schallert*[2], *C. Nagl*[1], *K. Petrovic*[2], *P. Freudenberger*[1], *G. Marsche*[3], *R. Schmidt*[2], *H. Schmidt*[1,2];
[1]*Institute of Molecular Biology and Biochemistry, Graz, Austria,* [2]*Department of Neurology, Graz, Austria,* [3]*Institute of Clinical Experimental and Pharmacology, Graz, Austria.*

Background: Telomere length plays an important role in the maintenance of DNA and chromosomal stability. Telomeres undergo progressive shortening in replicating cells that lack active telomerase. Ageing, oxidative stress and inflammation are related to shorter telomere length. The objective of the present study was to explore the association between plasma levels of antioxidants and leukocyte telomere length (LTL).
Methods: Relative LTL was measured by quantitative Real Time PCR in 907 participants of the Austrian Stroke Prevention Study, a community-based cohort study on brain aging. Levels of plasma antioxidants including ascorbate, cryptoxanthin, canthaxanthin, lycopene, α-carotene, β-carotene, retinol, γ- & α- tocopherol and zeaxanthin were measured by HPLC in 614 subjects. Association between plasma antioxidants and LTL was analyzed using multiple linear regression by adjusting for age and sex (*Model 1*) and additionally for hypertension, diabetes, cardiac disease and BMI (*Model 2*).
Results: There was a significant association between LTL and ascorbate (*Model 1*:β=0.003;95%CI:0.002,0.005;p<0.001), lycopene (β=-0.192;95%CI:-0.338,-0.045;p=0.01), retinol (β=-0.045;95%CI:-0.084,-0.005;p=0.029) and β-carotene (β=-0.052; 95%CI:-0.104,0.000;p=0.050). After adjusting for vascular risk factors (*Model 2*) the significance of the associations and the effect sizes remained unchanged.
Conclusion: This is the first study investigating the association between plasma antioxidants and LTL in a healthy elderly population. Our results suggest a protective role for ascorbate and an opposite role for lycopene, retinol and β-carotene in maintaining telomere length. The effect of these antioxidants on LTL is not mediated by vascular risk factors.

GJA5 gene (MIM# 121013), localized at 1q21.1, encodes for the cardiac gap junction protein connexin 40. In humans, copy number variants of chromosome 1q21.1 have been associated with variable phenotypes comprising congenital heart disease (CHD) including isolated tetralogy of Fallot (TOF). In mice, the deletion of *Gja5* can cause a variety of complex CHDs, in particular of the cardiac outflow tract, corresponding to TOF in many cases. In the present study, we screened for mutations in the *GJA5* gene 178 unrelated probands with isolated TOF. A heterozygous nucleotide change in exon 2 of the gene leading to a missense variant at the carboxyl-terminus of the protein was found in two unrelated sporadic patients, one with classic anatomy and one with pulmonary atresia. This *GJA5* missense substitution was not observed in 1,568 ethnically-matched control chromosomes. Immunofluorescent staining and confocal microscopy revealed that cells expressing the mutant protein form sparse or no visible gap-junction plaques in the region of cell-cell contact. Moreover, analysis of the transfer of the gap junction permeant tracer lucifer yellow showed that cells expressing the mutant protein have a reduced rate of dye transfer compared to wild-type cells. Finally, use of a zebrafish model has shown that microinjection of the *GJA5*-mutant disrupts overall morphology of the heart tube in the 37% (22/60) of embryos, compared to the 6% (4/66) of the *GJA5* wild-type-injected embryos. These findings implicate *GJA5* gene as a novel susceptibility gene for TOF.

P09.132

Intron5 +104 A/G polymorphism (IVS+104A> G) of TGF-β gene can be considered as a marker for the onset of non-syndromic cleft lip with/without palate in Turkish patients

K. Ulucan[1], *M. Yetiskin*[1], *T. Cetin*[1], *E. C. Kaspar*[2], *A. I. Guney*[3];
[1]*Marmara University, Faculty of Dentistry, Department of Medıcal Biology and Genetics, Istanbul, Turkey,* [2]*Yeditepe University, Faculty of Medicine, Department of Biostatistics, Istanbul, Turkey,* [3]*Marmara University, Faculty of Medicine, Department of Medıcal Genetics, Istanbul, Turkey.*

Introduction: Non- syndromic cleft lip with or without palate (NS-CL/P) affects about 1/700 births and have diverse causes including environmental factors of either ethnic or socioeconomic origin and genetic factors. The nature of the environmental and genetic factors contributing to this malformation is still unclear. In this study, we aimed to identify the effect of TGF**β** gene IVS+104A> G polymorphism on the onset of NS-CL/P in Turkish patients.
Material- Methods: 68 NS-CL/P patients and 114 healthy controls were enrolled to the study. Study procedure was in accordance with the principles of the Declaration of Helsinki II and all subjects provided written informed consent prior to the enrollment. DNA isolation was carried out from peripheral blood and genotyping was assessed by PCR- RFLP methodology.
Results: The respective frequency of the AA, AG and GG genotypes of the patients were 24%, 29% and 47 %, whereas they were 54%, 36% and 20% for the controls. The frequencies of the patient group showed statistically difference from that of the controls (p<0,05). When AA genotype was used as the reference group, G allele frequency was found to be statistically higher in patients when compared to controls (p<0,05).
Discussion: The risk of NS-CL/P was statistically increased as the number of the G allele of the TGF-β IVS5+104 increased. The results of this study are in agreement with the previous studies. This gene locus suggested to be an informative screening marker for NS-CL/P in Turkish patients.

P09.134

A rare variant on chromosome 11 is associated with total mortality in a European case-cohort study

A. Joensuu[1], *K. Kristiansson*[1], *V. Salomaa*[1], *M. Perola*[1], *.. for the MORGAM Project*[2];
[1]*National Institute for Health and Welfare, Helsinki, Finland,* [2]*MORGAM Consortium, Belfast, United Kingdom.*

Aims
The aim of our study was to find genomic regions which associate with total mortality and to study the molecular mechanisms behind the detected associations.
Methods
6535 individuals from five European countries in the MORGAM prospective study were genotyped with Illumina Cardio-MetaboChip capturing nearly 200,000 common and rare genomic variants. The 2458 individuals who died during the follow-up of 7-18 years were selected as cases.
A Cox proportional hazards model was used to estimate the association of the genotyped variants with total mortality. The genomic region within 1Mb of the top mortality variant was studied further for association to other disease end points and to 22 mortality and cardiovascular risk factors in MORGAM and in two subcohorts of the FINRISK 2007 Study (n=3950+694).
Results
A rare SNP (MAF=0.0022 in MORGAM) on chromosome 11 was associated with total mortality (p=2.93*10-8, HR = 4.6, 95% CI 2.7-7.9). The SNP showed association to mortality also in independently analyzed MORGAM subsamples: men, women, two Finnish cohorts and the combined non-Finnish cohorts. Furthermore, the SNP was associated with CVD, CHD and cancer mortality (p<10-4) and with CVD and CHD events (p<0.05). None of the SNPs studied for association with risk factors survived correction for multiple testing.
Conclusions
The genome-wide significant association of a rare variant on chromosome 11 with mortality is highly interesting as it does not seem to mediate through common risk factors. Replication of the association in multiple subcohorts and disease end points gives strength to the original finding.

P09.135

Screening of first degree relatives of type 1 diabetes patients by using HLA genotyping in combination with regular autoantibodies testing

J. Vcelakova, *L. Petruzelkova*, ***K. Stechova***, *S. Kolouskova*;
University Hospital Motol and 2nd Faculty of Medicine, Charles University in Prague, Prague, Czech Republic.

Introduction: The most important genes which are related to type 1 diabetes (T1D) are supposed to be genes for HLA class II molecules. First degree relatives (FDR) of T1D patients have an increased risk to develop the diseases as well. In the Czech republic we screen FDR (children under 18 years of age) of T1D patients and we provide HLA genotyping and annual screening for T1D associated autoantibodies (Abs).
Methods: In our programme (established in 2001) 724 children were HLA genotyped (by PCR-SSP method), 170/724 children developed at least one autoantibody during their follow-up, in 37/740 tested persons T1D was dia-

gnosed. We check by using RIA method for antiinsulin (IAA), antiGAD65 (gamaglutamyltransferase) and IA2 (antityrosinphosphatase) autoantibodies and we successfully attended the last international Diabetes Autoantibody Standardisation Programme (DASP).

Results: Within carriers of risky DQA1 DQB1 haplotypes (DQA1*03 DQB1*0302 resp. DQA1*05 DQB1*02) autoantibody(ies) positivity was observed more frequently (55,9% resp.45,3%) in comparison with carriers of protective haplotype DQA1*01 DQB1*0602 where only 7,1% of children were Abs+ at least once during their follow-up. The presence of the most risky genotype (DQA1*03/05 DQB1*02/0302) was connected to shorter period from the occurrence of positivity of the first autoantibody to the disease diagnose (p=0,005).

Conclusion: Screening of FDR of T1D patients allows early disease diagnose which has a protective effect to the resting pancreatic beta cell mass and also it is useful for designing of future immunointervention strategies (for the selection of their suitable candidates).

Association of polymorphisms representing obesity-related loci comprising FTO and TMEM18 with type 2 diabetes and age at diagnosis of the disease in the population of Latvia

I. Kalnina[1], *L. Tarasova*[1], *I. Vaivade*[1], *V. Ignatovica*[1], *J. A. Jacobsson*[2], *M. S. Almen*[2], *H. B. Schiöth*[2], *V. Pirags*[3], *J. Klovins*[1];
[1]*Biomedical Research and Study Centre Latvia, Riga, Latvia,* [2]*Departement of Neuroscience, Uppsala University, Uppsala, Sweden,* [3]*University of Latvia and Department of Endocrinology, Pauls Stradins Clinical University Hospital, Riga, Latvia.*

GWA studies have revealed a number of common obesity susceptibility variants with the strongest signals observed in the loci comprising FTO and TMEM18. Variants predisposing to obesity have been demonstrated to contribute to the risk of type 2 diabetes (T2D), although this has been mostly explained by BMI mediated effects. Association between polymorphisms in the FTO and T2D has been asserted across different populations, however impact of the variation downstream TMEM18 on T2D risk remains elusive. Our aim was to investigate relationship between variants in or near FTO and TMEM18 genes and T2D in the population of Latvia.

For this study we selected SNP rs7561317 located near TMEM18 and rs9939609 and rs57103849 along with other two in the FTO. SNPs were genotyped in 1080 controls and 983 cases by performing TaqMan SNP genotyping assays.

Three of the SNPs in the FTO and rs7561317 showed positive association with BMI and T2D. Furthermore association between the FTO variants and T2D remained significant after adjustment for BMI. We found no correlation between rs57103849 genotype and BMI or T2D, however rs57103849 and rs7561317 were strongly associated with younger age at diagnosis of T2D in a BMI independent manner.

In the current study we confirm that genetic variation in the loci comprising FTO and TMEM18 contributes to higher risk of obesity and T2D in the population of Latvia. Our data support the evidence that obesity susceptibility variants may have an impact on T2D risk through the mechanisms unrelated to those involved in the BMI regulation.

P09.137

Genetic determinants of IL-1-receptor antagonist in the circulation

M. Nuotio[1,2], *K. Kristiansson*[2], *M. Perola*[2,1,3], *V. Salomaa*[2];
[1]*Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland,* [2]*National Institute for Health and Welfare (THL), Helsinki, Finland,* [3]*University of Tartu, Tartu, Estonia.*

Introduction: Interleukins play an essential role in human immunity system acting as mediators of inflammation and tissue damage. The interleukin-1 superfamily consists of two agonists, two receptors, and a receptor antagonist, IL-1Ra. *IL1RN* in chr 2 has been carefully studied, since IL-1Ra concentration in circulation shows a clinical significance and association for example with AMI. Systemic elevation in IL-1Ra concentrations has been previously shown to enable the better control of type 2 diabetes. Recombinant form of IL-1Ra is also commonly used drug in a treatment of rheumatoid arthritis and gout. We wanted to perform GWAS for IL-1Ra concentrations in circulation in independent Finnish population- and case-control-cohorts. We also wanted to test the association of resulting top SNPs with leukocyte transcriptome data.

Methods: We performed GWAS in a sample consisting in total of 7169 adults.

Results: As a result, 17 SNPs were associated with IL-1Ra at p < 10-^{12}, while adjusting with age, sex, BMI and WHR. Furthermore, 29 SNPs were associated with IL-1Ra at p < 10$^{-\ 8\text{-}11}$. While testing the association of the top SNPs with leukocyte transcriptome data, one polymorphism in *IL1F10* was shown to act as cis-eQTL to *PAX8* and trans- eQTL to *ALDH2* in chr 12 and *LILRB4* in chr 19.

Conclusion: IL-1Ra has shown a clinical significance and association with a number of medical conditions. Identifying genetic variants associated with IL-1Ra level in circulation provides further information about related pathophysiological pathways and enables the evaluation of its potential effects on cardiovascular disease and diabetes.

Genetic characteristics of Lithuanian and Latvian patients with ulcerative colitis

J. Sventoraityte-Skieceviciene[1], *G. Kiudelis*[2], *L. V. Jonaitis*[2], *A. Zvirbliene*[1], *T. Balschun*[3], *G. Denapiene*[4], *G. Pranculiene*[2], *M. Leja*[5], *S. Schreiber*[3], *A. Franke*[3], *L. Kupcinskas*[1];
[1]*Institute for Digestive Research, Lithuanian University of Health Sciences, Kaunas, Lithuania,* [2]*Department of Gastroenterology, Lithuanian University of Health Sciences, Kaunas, Lithuania,* [3]*Institute for Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany,* [4]*Center of Hepatology, Gastroenterology and Dietetics, Vilnius University, Vilnius, Lithuania,* [5]*University of Latvia, Riga, Latvia.*

Introduction. Genetic susceptibility is known to play a large part in the predisposition to ulcerative colitis (UC). The past years have witnessed remarkable success in the identification of low-penetrance, high-frequency susceptibility variants in inflammatory bowel disease (IBD). However, a large part of the genetic variance in IBD is still unaccounted for. Thus, we aimed to investigate the role of the IBD associated genetic variants in a

Methods. We performed a replication study in 447 Lithuanian and Latvian UC patients and 1,154 controls. In total, 77 SNPs that showed moderate or strong association in five GWAS were studied. Single marker case-control, genotype-phenotype association analysis, and SNP-SNP epistasis analysis were performed.

Results. After correcting for multiple testing, we confirmed associations at 21q21.1 (rs1736135, P = 8.01E-06), 6q21 (rs7746082, P = 6.41E-05), *JAK2* (rs10758669, P = 8.08E-06), *RNF186* (rs3806308, P = 2.40E-06), and *ORMDL3* (rs2872507, P = 1.24E-06). No association with any disease subphenotype was found. SNP-SNP interaction analyses showed significant epistasis between SNPs in the *PTPN22* (rs2476601) and *C13orf31* (rs3764147) genes and increased risk for UC (P = 1.64E-06, OR = 2.44). *In silico* prediction of the interactive network of these genes further validated a possible interaction.

Conclusions. We confirmed the association of five loci (21q21.1, 6q21, *JAK2*, *RNF186*, and *ORMDL3*) with UC in the Lithuanian-Latvian population. SNP-SNP interaction analysis showed that the combination of the SNPs in the T-cell processes involved gene *PTPN22* (rs2476601) and gene participating in *Mycobacterium* infection clearance *C13orf31* (rs3764147) increase the risk for UC.

The aim of this study was to evaluate the relationship between HLA Class II HLA-DQA1, HLA-DRB1 and HLA-DQB1 loci, CIITA gene polymorphisms and susceptibility to multiple sclerosis (MS). Peripheral blood samples were taken from 52 MS patients registered with the outpatient clinic of neurology at Clementino Fraga Filho University Hospital (UFRJ, Brazil), as well as from 116 healthy control subjects, who were matched for ancestry, sex and age with the 52 MS patients. The patients were classified according to the criteria laid out by McDonald et al. (2001). After DNA extraction, the alleles of HLA-DQA1, HLA-DRB1 and HLA-DQB1 loci were identified by sequencing and PCR-SSP. Sequencing of polymorphisms -168A/G and +1614 G/C at gene CIIPA was carried out by PCR, followed by capillary electrophoresis (ABI PRISM® 3500 Genetic Analyzer Applied Biosystems). Our results have indicated that the relative risk (RR) associated with the allele HLA-DRB1*15:01 was 3.11. For allele HLA-DQB1*06:02, RR was equal to 2.54. For the haplotype HLA-DRB1*15:01-DQB1*06:02, the RR was 3.35. The polymorphism -168A/G (rs3087456) at CTIIA gene was not associated with susceptibility to MS, but the polymorphism +1614G/C (Rs4774), together with HLA-DRB1*15:01+, increased the RR to 4.46. These findings reinforced the multifactorial and polygenic trait of the disease, indicating that when both the polymorphism +1614G/C of the CIITA gene and the HLA-DRB1*15:01+ allele were present, susceptibility to MS was increased. In addition, our results suggested that HLA-DRB1*08:01, HLA-DRB1*11:01, HLA-DRB1*11:02 and HLA-DRB1*13:03 contributed to resistance against MS, with RR of 0.5, 0.7, 0.27 and 0.27, respectively.

P09.140

Polymorphism in IL12RB1 Contributes to the Risk for Uterine Leiomyomas

L. Zemljic[1], *U. Potočnik*[1,2];
[1]Center for Human Molecular Genetics and Pharmacogenomics, Faculty of Medicine, University of Maribor, Maribor, Slovenia, [2]Laboratory for Biochemistry, Molecular Biology and Genomics, Faculty for Chemistry and Chemical Engineering, University of Maribor, Maribor, Slovenia.

Uterine leiomyoma (ULM), a common female pelvic benign tumour, occurs in ~40% of women. The mechanism of ULM development is believed to be the result of complex interactions between genes and environment. The aim of this study was to investigate the role of single nucleotide polymorphisms (SNPs) in genes IL12B (rs6887695), IL12RB1 (rs11575934) and IL23R (rs7517847) as the potential risk factors for ULM. The association study was performed in 169 women with clinically and surgically diagnosed ULM and 92 women with verified absence of myomas used as the control group. Women with three or more (multiple) ULM had higher prevalence of positive family history (40,0% vs. 19,5%; p=0,029), higher number of miscarriages (60%; p=0,005), higher percentage of smoking (57,4% vs. 21,1%; p=0,001), higher prevalence of GG genotype with G allele frequency in *IL12RB1* rs11575934 polymorphism (p=0,036; OR=0,13 and p=0,029; OR=0,46 respectively), lower age at menarche (0,8 years; p=0,015), lower age at first sexual intercourse (17,7 vs. 19 years; p=0,003), lower number of pregnancies (48%; p=2x10^{-6}) and lower parity (46%; p=1x10^{-6}) compared to healthy controls. Women with solitary ULM had lower parity (27%; p=0,006) and higher prevalence of AG and GG genotypes in *IL12RB1* rs11575934 polymorphism (p=0,037; OR=2,54) compared to healthy control subjects. Our results clearly show an association of GG genotype and G allele frequency in rs11575934 with prevalence of multiple ULM and AG + GG genotypes with solitary ULM. The rs11575934 polymorphism, together with epidemiological factors can contribute to a higher risk for development of ULM.

P09.141

Allele specific hemizygosity in Velocardiofacial syndrome as a risk determinant of schizophrenia

M. GUIPPONI[1], *X. Bonilla*[2], *F. Santoni*[2], *C. Gehrig*[1], *S. Dahoun*[1], *S. Eliez*[2], *S. Antonarakis*[2];
[1]University Hospitals of Geneva, Geneva, Switzerland, [2]University of Geneva Medical School, Geneva, Switzerland.

Velocardiofacial syndrome is caused by a microdeletion in 22q11.2 ranging between 1.5 and 3 Mb, containing about 60 genes, with an incidence of 1 in 4,000 live births. One third of VCFS patients develop schizophrenia during early adulthood. The incidence of schizophrenia in patients with VCFS is thirty times higher than in the general population; thus making the 22q11.2 deletion an important risk factor for schizophrenia.

Based on the high incidence of schizophrenia in these individuals, we hypothesized that some patients with VCFS develop schizophrenia due to allele-specific hemizygosity of one or more critical regions in the 22q11.2 locus.

Paired-end libraries were prepared from 37 VCFS patients, 21 with schizophrenia, schizoaffective disorder or psychotic symptoms, and 16 without. A custom-made SureSelect target enrichment library was used to capture the 3Mb non deleted allele on chromosome 22q11.2 plus 200kb of upstream and downstream genomic sequences. The enriched region was then sequenced on an Illumina HiSeq2000. Bioinformatics analysis revealed that 98% of the targeted region was covered at least 8x and on average 2500 variants were detected per sample.

The complete haplotype of the non deleted 22q11.2 region was created using approximately 3500 unique variant sites (including on average 16 non-synonymous sites per sample). A candidate region that showed allele-specific enrichment in VCFS patients with schizophrenia was identified. Validation with an independent sample is ongoing.

This study suggests that the remaining hemizygous region in microdeletion syndromes could be a further risk determinant for certain variable phenotypes of such syndromes.

P09.142

Association of single nucleotide polymorphism in TGFB1 and acute radiation-induced mucositis in patients with nasopharyngeal carcinoma

I. Cheuk[1], *S. Yip*[1], *D. Kwong*[2], *V. Wu*[1];
[1]Department of Health Technology and Informatics, The Hong Kong Polytechnic University, Hung Hom, Hong Kong, [2]Department of Clinical Oncology, Li Ka Shing Faculty of Medicine, The University of Hong Kong, Pokfulam, Hong Kong.

Radiation therapy (RT) is the standard primary treatment of nasopharyngeal carcinoma (NPC), which is particularly common in southern China. Radiation-induced side effects may affect treatment outcomes and lead to postponement of RT. Studies have shown that genetic variations in genes that control cellular processes may act as potential markers to detect radiation hypersensitivity in normal tissues.

Blood samples were collected from local Chinese NPC patients treated with RT to extract genomic DNA. Patients in control (n=34) and case groups (n=34) were matched based on age, sex, staging, treatment regimen, and severity of mucositis. Severity of mucositis was graded by oncologists based on radiation morbidity scoring criteria published by Radiation Therapy Oncology Group (RTOG). Eleven tag single nucleotide polymorphisms (SNP) were selected from *TGFB1* and *XRCC1*.

Four out of six tag SNPs (rs12983047, rs11466345, rs4803455, rs2241716) in *TGFB1* were genotyped. The major allele (A) of rs12983047 at the 3' flanking region of *TGFB1* was found to be associated with increased risk of developing radiation induced mucositis with an odd ratio 2.16 (95% confidence interval 1.06-4.41, p=0.0328, chi-square test). No significant difference was found in all tag SNPs of *XRCC1* (rs25487, rs3213344, rs1001581, rs12611088, rs3213282).

XRCC1 did not show association to radiation-induced mucositis while *TGFB1* maybe a potential marker for exploring individual variation of radiation sensitivity in normal tissues. The remaining tagSNPs (rs1800469, rs1800470) of *TGFB1* will be genotyped for haplotype analysis. Complete analysis of all tag SNPs in *TGFB1* may provide support for our hypothesis.

Investigation of the effect of polymorphic variants of genes ACE and BDKRB2 on hemodynamic parameters of power and strength athletes

E. V. Lekontsev, *V. P. Pushkarev*, *V. Y. Vishnev*, *D. A. Dyatlov*, *L. M. Kulikov*;
Ural State University of Physical Culture, Chelybinck, Russian Federation.

In the course of the experiment was to study the functional state of central and peripheral hemodynamics (noninvasive tetrapolar impedancemetry) of power and strenght athletes (n = 119, in the following age groups: 13-16 years - 56 people., 17-21 years - 30 people., 21 and over - 23 people). During a survey of athletes at rest (horizontal position) were recorded 16 indicators of central and peripheral hemodynamics and oxygen transport for 500 kardioitervals.

Statistical analysis using the Statistica 6.1 software package includes: Z-transformation (standardization) and T-test for independent variables.

The study has been shown in a group of athletes with genotype ACE * I / I a statistically significant increase in the rate AfPG (amplitude photoplethysmogram) (p = 0,044709), reduction in vivo (stroke volume) (p = 0,031834) and chdREO (respiratory raterheovasography) (p = 0,021320) compared with ACE * I / D. As well as lowering chdREO index (p = 0,046426) and rising OPS (total pepefericheskoe resistance) (p = 0,039986) compared with ACE*D/D.

The study can make a preliminary conclusion that the athletes with genotypes ACE*I/I and BDKRB2*-9/-9 adaptation of the cardiovascular system more efficient at high loads and moderate power. And in the types of endurance, they will have an advantage and a lower risk of pathological conditions, compared to athletes with genotypes ACE*D/D and BDKRB2*+9/+9, and the speed and power modes do not realize their „genetic potential".

P10.02

Differential selection for the 3.7-type and 4.2-type single alpha-globin gene deletions within the same population

S. S. Chong[1,2,3], *Z. Yap*[4], *K. Sun*[5], *C. R. L. Teo*[1,2], *A. S. C. Tan*[1,2];
[1]National University of Singapore, Singapore, Singapore, [2]National University Health System, Singapore, Singapore, [3]National University Hospital, Singapore, Singapore, [4]University College London, London, United Kingdom, [5]Nanyang Technological University, Singapore, Singapore.

Since the 1950s, the relationship between high carrier rates for α- and β-thalassemia mutations and selective survival advantage in tropical and sub-tropical "malarial belt" regions has been well established. Mechanistically, the -$\alpha^{3.7}$ and -$\alpha^{4.2}$ α-globin single gene deletions arise from non-allelic recombination between the homologous α1- and α2-globin genes during meiosis, with concomitant production of reciprocal $\alpha\alpha\alpha^{anti3.7}$ and $\alpha\alpha\alpha^{anti4.2}$ triplicated alleles, respectively. A characteristic signature of positive selection for the -$\alpha^{3.7}$ deletion has been its significantly higher frequency compared to its reciprocal $\alpha\alpha\alpha^{anti3.7}$ allele frequency within the same population. Much less is known about the relative frequencies of the -$\alpha^{4.2}$ and $\alpha\alpha\alpha^{anti4.2}$ crossover alleles. Using simple, multiplex PCR strategies, we genotyped 1,285 unselected anonymous cord blood DNAs from the 3 major ethnic groups in Singapore for the presence of α-globin deletions and triplications. The frequency of the -$\alpha^{3.7}$ deletion was significantly higher than its reciprocal $\alpha\alpha\alpha^{anti3.7}$ triplication, consistent with the hypothesis of positive selection for -$\alpha^{3.7}$ in malarial endemic regions. In marked contrast, there was no significant difference between the -$\alpha^{4.2}$ and reciprocal $\alpha\alpha\alpha^{anti4.2}$ allele frequencies in the same population groups, suggesting an absence of positive selection for the -$\alpha^{4.2}$ allele. Similar frequencies of the $\alpha\alpha\alpha^{anti4.2}$ and $\alpha\alpha\alpha^{anti3.7}$ triplicated alleles suggest negligible difference in crossover frequencies at the ~1.3kb X-homology and ~1.6kb Z-homology boxes. The factor(s) underlying preferential positive selection for the -$\alpha^{3.7}$ allele but not for the -$\alpha^{4.2}$ allele, within the same population groups, merits further investigation.

P10.03

Ancestry Informative Markers Set in Brazilian Amerindians and Ancestry Estimates in Brazilian Quilombo Remnant Communities

*C. E. V. Wiezel[1], M. R. Luizon[1], S. M. B. Santos[2], K. Abé-Sandes[3], I. R. SOUSA[4], Y. C. N. Muniz[5], C. T. Mendes-Junior[6], **A. L. Simoes**[1];*
[1]Fac.Medicina Ribeirão Preto, Univ. São Paulo, Ribeirão Preto(SP), Brazil, [2]State University of Santa Cruz, Santa Cruz(BA), Brazil, [3]State University of Bahia, Salvador (BA), Brazil, [4]Dept Cell Biology, Embryology and Genetic, Federal University of Santa Catarina, Florianopolis(SC), Brazil, [5]Dept Cell Biology, Embryology and Genetics, Federal University of Santa Catarina, Florianopolis(SC), Brazil, [6]Dept Química, Faculdade de Filosofia Ciências e Letras de Ribeirão Preto, Univ. São Paulo, Ribeirão Preto(SP), Brazil.

Individual and population ancestry can be estimated by AIMs (ancestry informative markers with high allele frequency differentials between founder populations). Ancestry estimates of Brazilian population depend on the knowledge of the frequencies of genetic markers in the three founder populations (Portuguese, Amerindian and African). The main objective of this study is to determine the frequencies for 24 AIMs (FY, RB, LPL, AT3, Sb19.3, APO, PV92, CKMM, DRD2, MID93, MID52, MID575, MID154, MID187, TSC, DRD2-TAQI, OCA, WI-161857, WI-11153, GC*1F, GC*1S, WI-17163, WI-14319, WI-7423) in Amerindias for use in estimates of ancestry in three Brazilian urban population samples (Teresina, Jequié and São Paulo) and in four (Mimbo, Sítio Velho, Gaucinha and São Gonçalo) *quilombo* remnants (african-derived communities founded by fugitive slaves 150-200 years ago). The 24-AIMs were sufficient for an adequate discrimination among the considered ancestral populations. All ancestry estimates were trihybrid. African estimates ranged from 45.1% (Sítio Velho) to 68.7% (Gaucinha). *Quilombo* remnants of Mimbo, Sítio Velho and Gaucinha showed a higher Amerindian contribution in comparison with São Gonçalo (15.5%, 33.8%, 14.3% and 3.5%, respectively). A higher European contribution was observed in urban populations from different Brazilian regions (Northeast or Southeast). This finding was expected and had been previously reported by mtDNA, Y and autosomal AIMs. Population differentiation (F_{ST}) showed significant differences between all quilombo remnants. Our findings could reveal the different founding histories of the quilombo remnants studied, as well as generate reliable ancestry estimates of urban populations from different Brazilian regions.

Analysis of C9orf72 repeat expansion in an Italian cohort with amyotrophic lateral sclerosis

***C. Tiloca**[1], D. Calini[1], N. Ticozzi[1], C. Colombrita[1], C. Morelli[1], E. Onesto[1], F. Verde[1], A. Ratti[1,2], V. Silani[1,2];*
[1]Department of Neurology and Laboratory of Neuroscience, IRCCS Istituto Auxologico Italiano, Milan, Italy, [2]Department of Neurological Sciences, "Dino Ferrari" Center, Università degli Studi di Milano, Milan, Italy.

Amyotrophic Lateral Sclerosis (ALS) is an adult-onset and fatal neurodegenerative disease characterized by the selective loss of upper and lower motor neurons. Although most cases are sporadic (SALS), approximately 10% of patients are classified as familial forms (FALS). ALS is a genetically heterogeneous disorder and 12 genes, including *SOD1, FUS* and *TARDBP,* are associated with the disease, accounting for about 30% of FALS cases. Recently, a hexanucleotide repeat expansion in the non-coding region of *C9orf72* gene has been identified as a major cause of ALS (23-47%) and fronto-temporal dementia (FTD) (12-29%), which can often occur together with ALS in the same individual or familial pedigree.

We assessed the frequency of the *C9orf72* repeat expansion in a large cohort of ALS Italian patients, including 35 FALS and 487 SALS cases. The genetic analysis was performed by a two-step protocol including a standard PCR with primers external to the expanded region and a fluorescent repeat-primed PCR. In our cohort, 20% of FALS (7/35) and 4.1% of SALS (20/487) patients carried a pathogenic repeat expansion (more than 40 repeats). We also observed *C9orf72* repeat expansion in 0.2% (1/382) of controls included in the study.

Survival time was shorter in patients carrying the repeat expansion and a prevalence of bulbar onset was also observed.

Our findings suggest that *C9orf72* hexanucleotide repeat expansion can be considered the most common cause of FALS in Italian population with large impact even on sporadic forms, according to previous studies conducted on cohorts of different origin.

P10.05

Molecular characterization of the ancestral centromere of chromosome 2

***G. Chiatante**;*
University of Bari Aldo Moro, Bari, Italy.

Human chromosome 2 is the product of a head-to-head fusion of two acrocentric ancestral chromosomes, IIp and IIq, which remained separated in chimpanzee and gorilla. The dicentric chromosome originated from the fusion reached stability by inactivating one centromere corresponding to the IIq, through the loss of alphoid DNA, via poorly understood mechanisms. Unlike the fusion point, the ancestral centromere mapping at 2q21.1-2q21.2 has been poorly investigated.

Here we performed comparative in silico and molecular analyses in chimpanzee, gorilla, orangutan and macaque genomes in order to shed light on the genomic organization of the 2.1 Mb region encompassing the ancestral centromere. This approach allowed us to track precisely the evolutionary history of the ancient centromere and the corresponding pericentromeric region, whose assembly is still complicated by segmental duplications. In particular our data invalidated the hypothesis of the neocentromere formation occurred in macaque lineage and confirmed the pericentric inversion occurred in the common ancestor of human, chimpanzee and gorilla. In this study we provide the patterns of segmentally duplicated regions among chromosomes for each analyzed species and propose a two-steps model to explain the rearrangements occurred in the region flanking the ancestral centromere, highlighting species-specific deletions and duplications.

P10.06

Using ancestry-informative markers to identify fine structure across 15 populations of European origin.

***L. M. Huckins**[1], V. Boraska[1,2], C. Franklin[1], J. Floyd[1], Genetics Consortium of Anorexia Nervosa, Wellcome Trust Case Control Consortium, P. Sullivan[3], D. Collier[4], C. Bulik[3], C. Tyler-Smith[1], E. Zeggini[1], I. Tachmazidou[1];*
[1]Wellcome Trust Sanger Institute, Hinxton, United Kingdom, [2]University of Split, Split, Croatia, [3]University of North Carolina, Chapel Hill, NC, United States, [4]King's College, London, United Kingdom.

The Wellcome Trust Case Control Consortium 3 anorexia nervosa genome-wide association scan includes 2,907 cases from 15 different populations of European origin genotyped on the Illumina 670K chip (UK, Dutch, Swedish, Finnish, German, Austrian, Polish, Northern Italian, Southern Italian, Greek, USA, Canadian, Czech, French, Norwegian). This offers a unique opportunity to study genomic variation within and across these populations, and establish genomic relationships with other publicly available populations of European ancestry. We have examined the allele frequency spectrum of common variants, and compared genomic characteristics across these populations and also with populations from the 1000 Genomes Project. It is usual to identify population structure in such studies using only common variants with minor allele frequency (MAF)>5%; we find that this may result in highly informative SNPs being discarded, and suggest that instead all SNPs with MAF>1% should be used. We have established informative axes of variation identified via principal component analysis and highlight important features of the genetic structure of diverse European-descent populations (Novembre et al. 2008), some studied for the first time at this scale. We identified ancestry-informative markers using a method novel to the human genetics field, which may correct for sample size bias in smaller population sizes (following the bias-corrected entropy estimator proposed by Panzeri and Treves, 2007) and which allows for more efficient use of these SNPs.

Finally, we investigated substructure within these 15 populations and identified SNPs that help capture hidden stratification. This work can inform the design and association results interpretation of trans-ethnic studies.

P10.07
Five novel mutations in the GDAP1 associated with Charcot-Marie-Tooth disease in Iranian families

E. Mohammadi Pargoo[1], *O. Aryani*[2], *S. Hassan Tonekaboni*[3], *P. Yaghmaei*[1], *M. Houshmand*[2,4];

Autosomal-recessive forms of Charcot-Marie-Tooth (ARCMT) are more common in the Mediterranean basin and the Middle East because of more widespread consanguinity. CMT disease caused by mutations in the ganglioside-induced differentiation-associated protein 1 (GDAP1) gene is a severe autosomal recessive neuropathy resulting in either demyelinating CMT4A neuropathy or axonal neuropathy with vocal cord paresis. Total genomic DNA was extracted from whole peripheral blood of the patients and their families by using of standard procedures. PCR- sequencing method were used to analysis the whole coding regions of the GDAP1 gene in all samples. Five novel mutations (c.100_101ins T, c.802_803 del TG, c.254C>T (P85L), c.102G>C (S34S) and IVS5+25C>T) was identified in GDAP1 gene. In order to show that these found novel mutations are pathogenetic 50 normal controls were sequenced for all of these genes for whom no such mutations were found. We are going to discuss about clinical and molecular aspects of our patients. We need further investigation to prove these mutations as founder effect in Iranian population.

P10.08
Array painting of Gibbon chromosomes enables access to 44 evolutionary breakpoints compared to the human genome

A. Weise[1], *M. Voigt*[1], *K. Mrasek*[1], *N. Rubtsov*[2], *T. Karamysheva*[2], *V. Trifonov*[2], *N. Kosyakova*[1], *X. Fan*[1], *T. Liehr*[1];
[1]*Jena University Hospital, Jena, Germany,* [2]*Institute of Cytology and Genetics, Novosibirsk, Russian Federation.*

Gibbon species (Hylobatidae) have accumulated an unusually high number of numerical and structural chromosomal changes. Recently we were able to describe 71 evolutionary conserved changes/ breakpoints compared to the human genome in the white handed gibbon (Hylobates lar, HLA, Mrasek et al., 2003). Until now there are no molecular breakpoint data available for this species. The aim of this study was a molecular characterization of 44 of these euchromatic breakpoints compared to the human genome. Therefore we combined glass needle based microdissection with high resolution array CGH; i.e. HLA chromosomes of interest were painted by specific labelled DNA-probes and FISH-microdissection of the chromosomes or chromosomal regions encompassing breakpoints was done. The obtained DNA-libraries were DOP-PCR amplified and used in array CGH. Applying this method we were able to narrow down the breakpoints to a mean resolution of 26 kb; they were analysed in detail and as a result we could show that most of the breakpoints are localized in copy number variant and/or segmental duplcation regions. Additionally, we were able to identify novel submicroscopic chromosomal changes that were not described before. Supported in parts by DLR RUS 09/008 and the China Scholarship Council.

P10.09
Sequence variations in non-human primate orthologs suggests role for ZNF41 and ATRX in evolution of higher cognitive functions in man

B. Moser[1], ***L. R. Jensen***[2], *R. Weissmann*[2], *R. Krause*[1], *C. Roos*[3,4], *L. Walter*[3,4], *R. Reinhardt*[5], *A. W. Kuss*[2];
[1]*Max-Planck-Institut, Berlin, Germany,* [2]*Universitätsmedizin Greifswald, Greifswald, Germany,* [3]*Primate Genetics Laboratory, Göttingen, Germany,* [4]*Leibniz-Institute for Primate Research, Göttingen, Germany,* [5]*Max-Planck-Institut für Pflantzenzüchtungsforschung, Köln, Germany.*

A comparatively larger relative brain size and the cognitive abilities associated with it are among the most pronounced features that distinguish man from non-human primates. To investigate the molecular background for these differences, particularly focusing on cognitive aspects, we have sequenced the coding region and splice sites of 16 X-chromosomal genes (ARX, KDM5C, DLG3, GDI1, PAK3, IL1RAPL1, MECP2, TSPAN7, ACSL4, PQBP1, ZNF41, NLGN4, FTSJ1, ATRX, PHF8 and PHF6) in five female non-human primates (Pan troglodytes, Pan paniscus, Gorilla gorilla, Pongo pygmaeus and Pongo abelii). These genes play a role in human cognition, as loss-of-function mutations were identified in patients with non-syndromic intellectual disability.

For PCR amplification of our gene set from human genomic DNA we used previously generated primers for a total of 149 amplicons. We then applied these primers also for investigating the non-human primates and were able to amplify and sequence between 79,2% (Pongo pygmaeus) and 90,6% (Pan troglodytes) of the amplicons from their genomic DNA. Alignment of the sequences to a human reference sequence showed that all di-nucleotides flanking each exon were conserved and we detected no insertions or deletions. Of the total of 85 missense changes we found, 21 were located in ZNF41 and 23 in ATRX. A PolyPhen2 analysis of all 85 missense changes showed that 11 had a potentially damaging effect on the gene product. Interestingly, 10 of the latter were located in ZNF41 or in ATRX. This suggests that ZNF41 and ATRX were relatively important in the development of higher cognitive functions.

P10.10
Distribution of eleven autosomal markers in middle age population from South Romania

D. Cimponeriu[1], *N. Panduru*[2], *S. Spandole*[1], *P. Apostol*[1], *M. Toma*[1], *M. Stavarachi*[1], *I. Radu*[1], *C. Serafinceanu*[3], *A. Craciun*[3], *A. D. Ion*[4];

The South part of the Romanian population presents minor cultural and linguistic differences but isn't well studied at the genetic level.

The aim of the present study is to asses the distribution of eleven common di-allelic markers associated with some common human diseases in healthy population living in South Romania. Materials and methods. Healthy Caucasian subjects (n=648, 18-66 years old, M/W: 1/1) living in Bucharest and eight districts from South Romania were selected for this study. PCR or PCR-RFLP protocols were used for genotyping rs1801133, rs3767140, rs2229569, rs1805087, rs5186, rs3842752, rs680, rs2228570, rs4646994, rs1800469 and eNOS ID polymorphisms. PowerMarkerv3.25 and Arlequin3.11 software were used to calculate summary statistics and to compare genotypes distribution between districts.

Results. No deviations from Hardy-Weinberg equilibrium were observed. The polymorphisms were similar represented in booth gender. The observed heterozygosity was found to be in the range of 0,31 (rs2229569) and 0,49 (rs2228570). Average PIC was 0,31 and the overall theta was 0,003. The distribution of genotypes, theta, PIC and gene diversity indicated no significant differentiation of analyzed population.

In age grouped subjects the T allele of rs1801133 increases progressively from subjects of 59-66 years to those with 18-26 years (21,7% vs 41%, p=0,003).

Conclusions. On the bases of eleven di allelic markers we found no significant differentiation of Caucasian population from South Romania.

Acknowledgements. This paper is supported by the Sectoral Operational Programme Human Resources Development, financed from the European Social Fund and by the Romanian Government under the contract number POSDRU/89/1.5/S/ 64109.

Extremely high prevalence of splice site mutation IVS1+1G>A in *GJB2* gene, observed in homozygous state in Yakut deaf patients, allowed us to propose that IVS1+1G>A may also be a common pathogenic mutation among other North-East Asians. However, Siberian populations are significantly distinguished by anthropologic and linguistic affiliations, as well as by their population genetic history. We studied the IVS1+1G>A carrier frequency in six indigenous populations of Sakha Republic (Eastern Siberia): Turkic-speaking Yakuts and Dolgans, Tungusic-speaking Evenks and Evens, and Yukaghirs with uncertain (Paleo-Asiatic or Uralic) linguistic affiliation, and also Slavic-speaking Russians inhabiting the Sakha Republic. Among 423 individuals with normal hearing, originated from investigated populations, mutation IVS1+1G>A in heterozygous state was found in 20 subjects: Yakuts (14), Dolgans (2), Evenks (3), and Evens (1), and this mutation was absent in Yukaghirs and Russians. Carrier frequency of IVS1+1G>A is apparently associated with specific linguistic affiliation of studied ethnical groups. Highest carrier frequency of IVS1+1G>A was revealed in Turkic-speaking Yakuts (11.7%) and Dolgans (4.7%). Lower rate of this mutation was found in Tungusic-speaking Evenks (3.8%) and Evens (2.0%), and this mutation was not found at all in Uralic or Paleo-Asiatic-speaking Yukaghirs and Slavic-speaking Russians. Patterns of the IVS1+1G>A mutation prevalence among the studied populations, in general, correspond to the data from mtDNA and Y chromosome lineages studies in Sakha Republic populations that provides an evidence of most reliable distinctions between Yakut's and Yukaghir's gene pools.

The study was supported by grants of RFBR (11-04-01221-à) and FP (02.740.11.0701, 16.740.11.0190, 16.740.11.0346).

25-hydroxyvitamin D [25(OH)D] is associated with body mass index (BMI) but the direction of causality is uncertain. We explored the causal direction of the relationship between obesity and vitamin D using genetic markers as instrumental variables in bidirectional Mendelian Randomization analysis. We tested associations of 12 obesity-related SNPs with BMI (for validation) and with 25(OH)D (for causal association) individually and in combination as an allelic score in 42,024 individuals based on a meta-analysis from 21 studies. Also, we examined associations of four vitamin D-related SNPs with 25(OH)D (validation) and with BMI (association) individually and in combination using separate allele scores for SNPs involved in either synthesis or metabolism of 25(OH)D. Each 1 kg/m^2 higher BMI was associated with 1.15% lower 25(OH)D. The BMI and 25(OH)D scores showed strong associations with BMI (P=6.30x10^{-62}) and 25(OH)D (synthesis, P=8.07x10^{-57}; metabolism, P=1.07x10^{-118}), respectively. The BMI score was associated with a lower 25(OH)D (P=0.004), but no association was seen between 25(OH)D scores and BMI (P≥0.08). A 10% increase in genetically instrumented BMI was associated with a 4.2% lower 25(OH)D (P=0.005). No association was seen for genetically instrumented 25(OH)D with BMI, a finding that was confirmed using data from GIANT consortium (n=123,864, P≥0.57 for 25(OH)D scores). Based on a bidirectional genetic approach that limits confounding, our study suggests that a higher BMI leads to lower 25(OH)D, while there was no evidence that lower 25(OH)D contributes to elevated BMI. Hence, population level interventions to reduce BMI are expected to decrease the prevalence of vitamin D deficiency.

Evolutionary aspects of centriole associated proteins

A. Mikelsaar[1,2], *A. Sünter*[1], *R. Mikelsaar*[1], *P. Toomik*[3], *I. Mikelsaar*[2], *E. Juronen*[1];
[1]*Institute of General and Molecular Pathology, University of Tartu, Tartu, Estonia,* [2]*LabAs Ltd., Tartu, Estonia,* [3]*Department of Food Science and Hygiene, Estonian University of Life Sciences, Tartu, Estonia, Tartu, Estonia.*

Introduction. We have reported earlier the centriole staining with the anti-titin monoclonal antibody, named MAb Titl 5H1.1 (Mikelsaar et al, 2010). This antibody was developed using the synthetic peptide N-AVNKYGIGEP-LESDSVVAK-C corresponding to an amino acid sequence in the A-band of the titin molecule as immunogen. Now we have further studied the binding of the antigen of MAb Tit1 5H1.1 (titin) with centrioles in association with some other relevant proteins and in connection with the evolution of titin molecule.

Results. We have restricted the epitope of MAb Tit1 5H1.1 by subpeptide mapping to a hexapeptide. According to the data in protein databases this amino acid sequence is located in the COOH-terminus of several different Fn3 domains in the A-band of titin molecule both in human and several other organisms. Our immunohisto- and cytochemical studies with MAb Tit1 5H1.1 in human, mice and zebrafish showed a striated staining pattern in muscle cells and also staining of centrioles, cytoplasm and nuclei in non-muscle cells.

Conclusions. The data prove our previous findings that titin has in addition to the known roles in muscle cells also an important role in non-muscle cells as a centriole associated protein, and this phenomenon is highly conserved in the evolution . P10.14

Genetic epidemiology of Charcot-Marie-Tooth disease in the Cypriot population

P. Nicolaou, *E. Zamba-Papanicolaou, P. Koutsou, K. Kleopa, A. Georghiou, T. Kyriakides, K. Christodoulou;*
The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus.

Charcot-Marie-Tooth disease (CMT) or hereditary motor and sensory neuropathy (HMSN) is one of the most common inherited neuromuscular disorders, affecting approximately 1 in 2,500 people. According to electrophysiological criteria, HMSN is classified into two main subgroups: demyelinating type (HMSN I or CMT1), characterized by decreased motor nerve conduction velocities (MNCV), and axonal type (HMSN II or CMT2) that is characterized by normal or slightly reduced MNCV(s). Further subdivisions within those two types are based on the inheritance pattern and the results of molecular genetic investigations. Inheritance in CMT can be autosomal dominant (AD), X-linked, or autosomal recessive (AR). CMT is associated with more than 30 loci and about 25 causative genes are thus far known. We performed clinical, neurophysiological and molecular genetic studies in thirty six Cypriot families with CMT. The molecular genetic investigation revealed thirteen families with the most frequent mutation the *PMP22* duplication, six families with the S22F point mutation in the *PMP22* gene, four families with *CX32* gene mutations, two families with *MPZ* gene mutations, two families with *MFN2* gene mutations and one family with a *GDAP1* gene mutation. Seven families were excluded from the common CMT genes and are still pending molecular genetic diagnosis and one family is under further investigation for a candidate novel *MFN2* mutation. In conclusion, the PMP22 duplication which is the most frequent CMT mutation worldwide is also the most frequent CMT mutation in the Cypriot population. Five out of the eight other mutations are novel, not reported in other populations.

P10.15

Marriage and population genetic structure in southern Morocco

H. Hami, *L. Sbii, A. Mokhtari, A. Soulaymani;*
Laboratory of Genetic and Biometry, Faculty of Sciences, Ibn Tofail University, Kenitra, Morocco.

The choice of spouse has direct consequences on the distribution, structure and heterogeneity of a population's gene heritage.

The aim of this study is to evaluate geographical endogamy rate among the population of Souss-Massa-Drâa region in southern Morocco in order to estimate the degree of reproductive isolation (or openness) of the population studied.

The study was conducted within a randomly selected sample of Souss-Massa-Drâa population. Various types of endogamous marriage were measured, based on the place of birth, place of residence and geographical origin of the spouses and their parents (600 couples).

The results show a strong tendency towards geographical endogamy of nuptiality (78%). This tendency is important among couples within parental generation. The results of intergenerational comparisons show decrease in endogamy rates from parental generation to current generation. However, this decrease is not statistically significant (p>0,05).

The homogamy index method confirms these results and indicates the importance of this marital behavior among the younger generation.

P10.16

Evolutionary dynamism of the primate *LRRC37* gene family

G. Giannuzzi[1], *P. Siswara*[2], *M. Malig*[2], *C. Bekpen*[3,4], *T. Marques-Bonet*[5], *N. NISC Comparative Sequencing Program*[6], *J. C. Mullikin*[6], *M. Ventura*[1,2], *E. E. Eichler*[2,7];

Core duplicons in the human genome represent ancestral duplication modules shared by the majority of intrachromosomal duplication blocks within a given chromosome. These cores are associated with the emergence of novel gene families in the hominoid lineage but their genomic organization and gene characterization among other primates is largely unknown. Here, we investigate the expression and potential function of the core duplicon on chromosome 17 that led to the expansion of *LRRC37* during primate evolution. A comparison of the *LRRC37* gene family organization in human, orangutan, macaque, marmoset, and lemur genomes shows the presence of both orthologous and species-specific genes in all primate lineages. Expression profiling in mouse, macaque, and human tissues reveals that the ancestral expression of *LRRC37* was restricted exclusively to the testis. In the human lineage, the pattern of *LRRC37* became increasingly ubiquitous, with significantly higher levels of expression in the cerebellum and thymus, and showed a remarkable diversity of alternative splice forms. Transfection studies indicate overexpression of the product can induce filipodia formation in HeLa cells. Subcellular localization of FLAG-tagged recombinant LRRC37 protein indicates that the protein product is secreted after cleavage of a transmembrane precursor.

P10.17
Deep analysis of human single nucleotide polymorphisms in the Cytochrome P450 superfamily

R. Polimanti[1], *S. Piacentini*[1], *D. Manfellotto*[2], *M. Fuciarelli*[1];
[1]*Department of Biology, University of Rome, Rome, Italy,* [2]*Center of Clinical Pathophysiology, "San Giovanni Calibita" Fatebenefratelli Hospital – AFaR, Rome, Italy.*

Cytochrome P450 (CYP450) superfamily comprises enzymes involved in the cytochrome electron transfer chains. Several studies highlighted that single nucleotide polymorphisms (SNPs) in human CYP450 genes affect disease risk and drug efficacy. Furthermore, CYP450 genes showed a significant variability in the human populations, suggesting that the investigation of inter-ethnic differences in CYP450 genes may be useful to understand individual gene specific properties and then to provide personalized and optimal clinic therapies. This study deeply analyzes SNPs in the fifty-seven CYP450 genes, investigating the differences in human populations and evaluating the functional aspect of the variants.

Using the HGDP and HapMap databases, we analyzed the genetic differences of 449 SNPs in the fifty-seven CYP450 genes evaluating the data from 62 human populations. The HapMap Linkage Disequilibrium (LD) data were used to examine the LD in CYP450 genes: 1,033 SNPs were in perfect LD ($r2=1$) with the previously investigated SNPs. Bioinformatic analyses were performed to predict the functional impact of the CYP450 SNPs.

The analyses of SNPs among human populations highlighted that ethnicity is an influencing factor of CYP450 variability. Considering the functional impact of the variants, we provided an analysis of the functional inter-ethnic variation of CYP450 superfamily. Furthermore, we also considered some SNPs with a high functional impact in order to explain inter-ethnic differences in various health aspects.

In conclusion, our study supplies a deep investigation of CYP450 superfamily highlighting how the population demographic history affects human variation of CYP450 genes and how this variation influences human health.

P10.18
Population analysis of deafness in Mexico in the last century: effects of the genetic background

F. Loeza-Becerra[1], *M. d. Rivera-Vega*[2], *S. A. Cuevas-Covarrubias*[3];
[1]*Facultad de Medicina UMSNH, Genetica, Hospital General de Mexico, Fac Medicina, UNAM, Mexico, D.F., Mexico,* [2]*Genetica, Hospital General de Mexico, Mexico, D.F., Mexico,* [3]*Genetica, Hospital General de Mexico, Fac Medicina, UNAM, Mexico, D.F., Mexico.*

BACKGROUND: Deafness in Mexico is currently the 2nd leading cause of disability. Internal migration and Mexican revolution caused population and geographical redistribution of this disability. OBJECTIVE: To determine geographical distribution of hearing loss focused to congenital sensorineural hearing impairment. METHODS: Analysis of the Mexican population censuses (1895 to 2010) about deaf people and their geographical distribution. RESULTS: The proportional increasing in general population and people with hearing loss between 1900 and 2010 was 730.87% and 5,450.93% respectively. The Mexican Revolution produced a demographic declination that required nearly three decades to return to the previous level. Nevertheless, deafness showed a few changes with persistence in some areas. DISCUSSION: Genetic composition, founder effects and genetic drifts seem to have decisive influence on the persistence of such problems where the inheritance is recognized. More detailed studies are necessary to clarify these findings.

P10.19
Mitochondrial DNA mutations are not a common cause of non-syndromic hearing loss in Republic of Macedonia

E. Sukarova Stefanovska[1], *M. Davceva Cakar*[2], *I. Filipce*[2], *D. Plaseska-Karanfilska*[1];
[1]*Macedonian Academy of Sciences and Arts, Research Center for Genetic Engineering and Biotechnology, Skopje, The Former Yugoslav Republic of Macedonia,* [2]*University Clinic of Otorhinolaryngology, Skopje, The Former Yugoslav Republic of Macedonia.*

Mutations in mitochondrial DNA (mtDNA) are found to contribute to sensorineural deafness, including both syndromic and non-syndromic forms. Hot spot regions for deafness mutations are the MTRNR1 gene, encoding the 12S rRNA and the MTTS1 gene, encoding the tRNA for Ser(UCN). Nucleotide changes are observed with a variable frequency among different populations of deaf persons. Among the known mtDNA mutations, the A1555G is the most common genetic cause of deafness, with variable frequency of 0.4 up to 5.4%, described both among nonsyndromic sensoryneural hearing loss (SNHL) patients and aminoglycoside induced SNHL. The aim of this study was to determine the presence and frequency of the most common mtDNA mutations among 130 Macedonian patients with nonsyndromic hearing loss. A SNapShot analysis for screening of the five mitochondrial mutations associated with deafness (A827G, 961delT+Cn, T1095C, C1494T and A1555G) was performed. None of analyzed deafness-associated mutations were identified in the studied patients. Additionally MTRNR1 gene of 10 patients with only one *GJB2* mutation was sequenced in order to detect other variants that could influence the pathologic effect of the *GJB2* mutation. Mutational screening revealed the presence of one potentially pathogenic substitution T961G in one patient and a G709A polymorphism in two patients. An unpublished variant G1303A was found in a patient with only *GJB2* mutation 35delG. In conclusion, our result suggests that mitochondrial DNA mutations do not represent a significant risk factor for sensorineural deafness in Macedonian population.

P10.20
APCS and RBP4: possible modifiers of age-at-onset in familial amyloid polyneuropathy (FAP ATTRV30M)

D. Santos[1], *T. Coelho*[2], *J. L. Neto*[1], *J. Pinto-Basto*[1,3], *J. Sequeiros*[1,3], *I. Alonso*[1,3], *C. Lemos*[1,3], *A. Sousa*[1,3];
[1]*UnIGENe, IBMC - Universidade do Porto, Porto, Portugal,* [2]*Unidade Clínica de Paramiloidose, CHP, Porto, Portugal,* [3]*ICBAS - Universidade do Porto, Porto, Portugal.*

Familial amyloid polyneuropathy (FAP ATTRV30M) is an AD inherited disease, due to a point mutation in the TTR gene. Remarkable differences in mean age-at-onset (AO) have been described in different clusters, including within Portuguese population.

Among Portuguese families, FAP shows a wide variation in AO (17-82 yrs) and asymptomatic carriers aged 95 can be found; this variation is also often observed between generations.

A previous study in Portuguese patients (Soares et al., 2005) found a modifier effect in AO for APCS and RBP4, when comparing classic and late-onset patients with controls. However, variation between generations was not taken into account.

Our aim was to investigate if these two candidate-genes have a modifier effect in AO variation from parent to offspring.

We collected a sample of 36 FAP families with at least 2 generations. We selected 5 tagging SNPs and also the 5 SNPs previously described. These SNPs were analysed by SNaPshot and RFLP, respectively. Samples' genotyping is currently underway and results are being analyzed with the Gene-Mapper v.4.0 software.

Preliminary results in 5 FAP families showed that although for RBP4 we found different genotype's frequencies in patients for rs7079946 and rs17484721 from HapMap, no striking differences were found between generations in the families analyzed for the two genes.

In the total sample, we expect to find or exclude the potential role of these candidate-genes as modifiers of FAP ATTRV30M, in order to better understand the mechanisms involved in AO variability between generations.

P10.21
Variability in age-at-onset of familial amyloid polyneuropathy (FAP ATTRV30M): an extended haplotype effect?

C. Lemos[1,2], *T. Coelho*[3], *D. Santos*[1], *J. L. Neto*[1], *M. Alves-Ferreira*[1], *J. Pinto-Basto*[1,2], *J. Sequeiros*[1,2], *I. Alonso*[1,2], *A. Sousa*[1,2];
[1]*UnIGENE, IBMC -Univ.Porto, Porto, Portugal,* [2]*ICBAS, Univ.Porto, Porto, Portugal,* [3]*Unidade Clínica de Paramiloidose, CHP, Porto, Portugal.*

FAP ATTRV30M is an AD systemic amyloidosis, due to a point mutation in the transthyretin (TTR) gene. A wider variability in age-at-onset (AO) has been uncovered, including among Portuguese patients [17-82 yrs]. Early (less than 40) and late-onset(greater than 50) cases are not separate entities, often coexisting in the same family, with offspring showing anticipation - a much earlier AO than their affected parent. The 'protection' seeming to exist in late-onset cases may be lost in just one generation, raising the hypothesis of a closely linked modifier. Therefore, our aim is to identify genetic modifiers closely linked to the TTR locus that may in part explain the observed AO variability.

Haplotype analysis is on-going in 100 families, using intragenic SNPs and flanking STRs for extended haplotypes.

Fifteen tagging SNPs were selected based on a data dump from the HapMap Project and using Haploview v4.1, with a minor allele frequency (MAF) of 0.1% and covering 60 Kb around the TTR locus. SNP genotyping is currently underway by SNaPshot, using a multiplex approach.

Eight microsatellite markers were also selected, encompassing 11.4 Mb. STRs genotyping is being performed by PCR, using fluorescent-labelled primer pairs and genotypes is being determined using GeneMapper v4.0 software.

In a preliminary group of five families analysed so far, no differences were found in the disease extended haplotypes. In the total sample of 100 families, we expect to find some variants or regions that may confer protection to some TTR V30M carriers (late-onset patients or aged asymptomatic carriers).

P10.22

The spectrum of Familial Mediterranean Fever (*MEFV*) Mutations in the North- west of Iran

E. Sakhinia[1], *L. Rostamizadeh*[2], *A. Mohammadi*[3], *A. Ebrahimi*[4], *K. Nejati*[4], *M. Alizadeh Sharafi*[4], *M. Sakhinia*[5];

[1]*Department of Medical Genetic, Faculty of Medicine, Tabriz university of Medical Science,, Tabriz, Islamic Republic of Iran,* [2]*Department of Medical Genetic, Tabriz university of Medical Science,, Tabriz, Islamic Republic of Iran,* [3]*department of agronomy and plant breeding, Tabriz university;, Tabriz, Islamic Republic of Iran,* [4]*Tabriz Genetic Analysis Centre, Tabriz, Islamic Republic of Iran,* [5]*Faculty of Medicine, University of Liverpool, United Kingdom, Liverpool, United Kingdom.*

This is the first comprehensive profile of *MEFV* mutations in the North- west of Iran. FMF is an auto-inflammatory autosomal recessive disorder characterized by recurrent and self-limited attacks of fever, abdominal pain, synovitis and pleuritis which are caused by altered pyrin due to a mutated MEFV gene. The most severe complication is amyloidosis, which can ultimately lead to renal failure. FMF is predominantly found among the Mediterranean population, as well as Armenians, Turks, Arabs and Jews. The MEFV gene majority of mutations found on exons 2, 3, 5 and 10. To date, 180 mutations and polymorphisms have been reported with varying prevalence according to the population studied. Our aim was to identify the distribution and the frequency of the MEFV gene mutations in FMF patients in the North- west of Iran .

Five hundred unrelated patients with clinical manifestation of FMF were screened for MEFV mutations in exons 2, 3, 5 and 10 using direct sequencing. The most frequent mutation, M694V, represented only 26.25% of the alleles examined, followed by E148Q in 24.75%, V726A in 11.25% and M680I in 10.75%, respectively. Two novel missense mutations, P313H in 11.47% and P313S in 5.05% were found in heterozygous state in exon 3.

In conclusion molecular analysis rather than clinical symptoms to diagnosis of FMF patient is very trustful therefore to know variations in mutation frequency according to regions of Iran lead to early and correct diagnosis of patient and prevention of amyloidosis with commence lifelong prophylactic treatment of affected individuals with colchicine.

P10.23

The use of survival analysis to estimate age-at-onset of familial amyloid polyneuropathy (FAPATTRV30M) highlights gender differences in early-onset (o.<40) patients but fails to detect it in late-onset (o.>50) patients

A. Sousa[1,2], *T. Coelho*[3], *C. Lemos*[1,2], *D. Mendonça*[1,4];

[1]*ICBAS - Instituto Ciências Biomédicas Abel Salazar, Univ. Porto, Porto, Portugal,* [2]*IBMC -Instituto de Biologia Molecular e Celular, Porto, Portugal,* [3]*Centro Hospitalar do Porto (CHP), Porto, Portugal,* [4]*ISPUP - Instituto de Saúde Pública, Univ. Porto, Porto, Portugal.*

FAP (ATTRV30M) is an AD systemic amyloidosis due to a point mutation in the transthyretin (TTR) gene. First described in Portugal by Andrade (1952) as a disease of young adults (o.<40yrs), Portuguese patients have been characterized by early onset (35.1), unlike patients from Sweden (56.7) and Balearic Islands (45.7) who bear the same mutation. However, late-onset patients (o.>50) and aged asymptomatic carriers have been increasingly ascertained.

While in Portuguese series women had later onset than men, the same was not found either in Swedish or Balearic samples, what raises interesting questions concerning gender and age-at-onset distribution(s). So far, age-at-onset in Portuguese series has only been analysed using information on patients. For the first time we use survival analysis methods, including in the sample age-at-last-observation of asymptomatic carriers, as censored data. Survival curves of patients and carriers were compared by gender using log-rank test.Our sample consisted of 2424 patients (1283 men) and 433 (144 men) proven asymptomatic carriers regularly followed up by the same group of neurologists.

Conventional t-test for independent samples showed significant differences in mean age-at-onset between men (33.1) and women (37.5) patients ($p<0.001$), whereas in the asymptomatic group no significant age differences were found (37.9 vs. 37.1).

The use of survival analysis showed overall different gender distributions and also when considering individuals with onset/age<40yrs. However, for late-onset cases (onset/age>49 yrs), no differences were found.

Further studies are necessary to correct for possible confounding factors and better understand if we are in presence of different underlying gender distributions.

P10.24

How contemporary human reproductive behaviours influence the role of fertility-related genes: the example of the P53 gene

R. M. Corbo[1], *G. Gambina*[2], *E. Broggio*[2], *R. Scacchi*[3];

[1]*La Sapienza University, Rome, Italy,* [2]*Hospital of Verona, Verona, Italy,* [3]*CNR Institute of Molecular Biology and Pathology, Rome, Italy.*

Recently numerous polymorphic fertility genes have been associated with reproductive system diseases causing infertility/subfertility. Investigations carried out in populations at natural fertility suggest that some fertility genes have acquired clinical relevance only in the last decades due to the interaction with contemporary reproductive behaviours (birth control, delayed childbearing, and spacing birth order among others). In recent years, a new physiological role in human fertility regulation has emerged for the tumor suppressor p53 gene (P53), and the P53 Arg72Pro polymorphism has been associated with recurrent implantation failure in humans. In order to detect a possible interaction between fertility gene P53 and reproductive patterns, in present investigation we examined the impact of Arg72Pro polymorphism on fertility in two samples of Italian women collected from populations with different (premodern and modern) reproductive behaviours, not selected for impaired fertility. Among the women at near-natural fertility (n=98), the P53 genotypes were not associated with different reproductive efficiency, whereas among those with modern reproductive behaviours (n=68), the P53 genotypes were associated with different mean numbers of children (Pro/Pro <Pro/Arg <Arg/Arg, $p=0.056$) and a significant negative relationship between the number of children and P53 Pro allele frequencies ($p=0.028$) was observed. These results are consistent with those of clinical studies reporting an association between the P53 Pro allele and recurrent implantation failure. These findings seem to support the hypothesis that some common variants of fertility genes may have become "detrimental" following exposure to modern reproductive patterns and might therefore be associated with reduced reproductive success.

P10.25

Functional SHMT1, MTR and MTRR gene variants of folate metabolism in Roma and average Hungarian population samples

B. I. Melegh, *L. Magyari, L. Járomi, B. Duga, I. Janicsek, P. Kisfali, C. Sipeky, B. Melegh;*

University of Pécs, Clinical Center, Department of Medical Genetics, Pécs, Hungary.

The serine hydroxymethyltransferase 1 (*SHMT1*), 5-methyltetrahydrofolate-homocysteine methyltransferase (*MTR*) and 5-methyltetrahydrofolate-homocysteine methyltransferase reductase (*MTRR*) genes play essential role in the folate metabolism. The aim of the study was to analyze three single nucleotide polymorphisms (rs1979277 in *SHMT1*, rs1805087 in *MTR* and rs1801394 in *MTRR* gene) in the Roma population and to compare the results to the average Hungarian Caucasian population samples. We genotyped 293 (113 males, 180 females, mean age 41.7 ± 16.2 years) randomly selected, unrelated Roma subjects from different locations. Pooled DNA of a group of 276 carefully selected, clinically healthy subjects (153 males, 123 females, mean age 37.1 ± 12.7 years) were also studied. The genotypes were analyzed using real-time PCR method. The prevalence of the minor allele A of *SHMT1* rs1979277 was 25.9% in the Roma group, and it was 33.5% in the controls ($p<0.05$), the frequency of the homozygous AA genotype was 6.10%, while it was 10.5% in the controls. The prevalence of the G allele of *MTR* rs1805087 was 32.1% in the Roma group and 20.5 % in the controls ($p<0.05$). The frequency of the homozygous GG genotype was 8.20%, while it was 2.50% in the controls ($p<0.05$). The prevalence of the G allele of *MTRR* rs1801394 was 64.2% in the Roma group and 43.5% in the controls ($p<0.05$). The frequency of the homozygous GG genotype was 38.2%, while it was 19.6% in the controls (p<0.05). All three variants between the Roma and the Hungarian Caucasian population significant difference was found.

P10.26
Gene x Environment interactions and their impact on the stress response system as studied in space-flight analogs

P. De Boever[1,2], *N. Goswami*[3], *P. Roma*[4], *H. Hinghofer-Szalkay*[3], *S. Schneider*[5], *G. Schoeters*[1,6];
[1]Flemish Institute for Technological Research, Mol, Belgium, [2]Hasselt University, Diepenbeek, Belgium, [3]Medical University of Gräz, Gräz, Austria, [4]Johns Hopkins University, Baltimore, MD, United States, [5]German Sport University Cologne, Cologne, Germany, [6]University of Antwerp, Antwerp, Belgium.

Environmental and social cues activate the stress response system and stimulate a series of adaptation processes along the hypothalamus-pituitary-adrenal axis (HPA). An overload of the HPA can lead to decreased well-being and is associated to functional illnesses. We are studying under well-controlled conditions how gene x environment interactions impinge on the stress response system. For this purpose, we are using space flight analogs (SFA) to investigate the effect of gravitational unloading, isolation and confinement on healthy individuals. The conditions of SFA are known to induce stress, which can lead to cardiovascular, muscular, immunological, and behavioral problems. SFA are important to identify the health effects astronauts can experience during stay in low Earth orbit or during space exploration, and results obtained from this research has also direct relevance for a better understanding of the impact of social isolation, sedentary lifestyle, aging, and osteoporosis.

We present an overview of the use of these unique SFA for studying gene x environment interactions. More specifically, we will focus on our ongoing studies in the Antarctic station Concordia. Using an approach of integrated physiology we are studying the impact of isolation and confinement on health. We apply behavioral assays and questionnaires, physiological analyses (blood pressure, and heart rate variability), stress physiology (salivary cortisol and alpha-amylase), neurohormonal markers of social affiliation and stability (oxytocin and testosterone), and gene expression changes in blood and saliva. Genotypes associated with HPA reactivity (e.g. brain derived neurotrophic factor, corticotropin-releasing hormone) and human social behavior (e.g. oxytocin) are determined in saliva.

P10.27
The prevalence rates of hereditary disorders in European part of Russia

R. A. Zinchenko, *E. K. Ginter*;
Research Center for Medical Genetics, Moscow, Russian Federation.

Based on a genetic epidemiological study, the prevalence rates of autosomal dominant (AD), autosomal recessive (AR) and X-linked hereditary disorders (HDs) in 13 regions of European part of Russia (7 ethnic groups) were established: Russian from seven populations, Adygean, Maris, Chuvashes, Udmurt, Bashkirs, Tatars. The size of the investigated populations was more than 3 million inhabitants (about 3000 HDs of OMIM could be identified by this research). Genetic differentiation between populations of different hierarchical levels by estimated load of HDs was established. On the contrary, the differences between the populations by the load of AD and AR diseases appear statistically significant. First, the load of both AD and AR diseases is always 2 times higher in rural populations as compared with that in urban populations. Secondly, the differences are also seen while comparing the load of the autosomal HDs in various ethnic groups. For example, the load of AD and AR pathology among the Maris, Chuvashs, Bashkirs, Tatars and Udmurts is higher than that among the Russians. The load of AD diseases varied between populations from 1.01 to 15.66 per 1000 persons. The load of AR diseases varied from 0.85 to 6.33. The differences between the populations in their load of X-linked diseases are no significant. Analysing the load of HDs in the examined populations of Russia demonstrated that there exists a clear-cut differentiation between various populations both within each of the 13 regions examined and between them by the index concerned.

P10.28
Genetic risk score of NOS genes variation to understand trends in coronary-event rates across European populations.

R. Carreras, *M. Via*, *E. Esteban*, *P. Moral*;
Faculty of Biology - University of Barcelona, Barcelona, Spain.

Reported population distributions of traditional risk factors, such as obesity, have been applied to understand variation of the incidence/prevalence of complex diseases. In this work we evaluate the ability of a Genetic Risk Score (GRS) to explain the variation in coronary-event rates across European populations. Methodologically, we generated a GRS from 68 SNPs in the nitric oxide synthase (NOS1, NOS2A and NOS3) gene regions that contributed to the discrimination between affected and non-affected from the Mycardial Infarction Genetics Consortium (MIGen) samples and a Spanish case-control study. We also tested the correlation of mean GRS values in 8 populations across Europe (North Spain, South France, North France, Central Italy, North Bosnia-Herzegovina, East Germany, Poland and Scotland) with variation in coronary-event rates in these 8 European populations reported by the WHO MONICA Project. As a result, 8 SNPs in NOS1, 3 SNPs in NOS2A and 2 SNPs in NOS3 contributed to discriminate affected and non-affected people. The AUCs of discrimination in the different case-control samples ranged from 0.538 to 0.584. Mean GRS values of the 8 European populations samples ranged from 3.8 to 4.2, being North Spain and East Germany the samples with the lowest and the highest score, respectively. Mean GRS values correlated with mean CHD mortality rate, non-fatal rate and total coronary events rate with correlation coefficients from 0.3 to 0.6 without reaching statistical significance. These results point towards the ability of GRS to estimate risks to suffer from complex diseases at a population level.

P10.29
Haplotype diversity and reconstruction of ancestral haplotype associated with the c.35delG mutation in the GJB2 (Cx26) gene among the Volgo-Ural populations of Russia

L. U. Dzhemileva[1], *O. L. Posukh*[2], *N. A. Barashkov*[3], *S. Lobov*[1], *E. K. Khusnutdinova*[1];
[1]Institute of Biochemistry and Genetics, Ufa Research Center, Russian Academy of Sciences, Ufa, Russian Federation, [2]Institute of Cytology and Genetics, Siberian Branch, Russian Academy of Sciences, Novosibirsk, Russian Federation, [3]Yakut Research Center of Complex Medical Problems, Siberian Branch, Russian Academy of Medical Sciences, Yakutsk, Russian Federation.

The spectrum and prevalence of the *GJB2* gene mutations are specific to populations of different ethnic origins. For several *GJB2* mutations, their origin from appropriate ancestral founder chromosome was shown, approximate estimations of "age" obtained, and presumable regions of their origin outlined. This work presents the results of the carrier frequencies' analysis of the major (for European countries) mutation c.35delG (*GJB2* gene) among 2308 healthy individuals from 18 Eurasian populations of different ethnic origins: Bashkirs, Tatars, Chuvashes, Udmurts, Komi-Permyaks, Mordvins, and Russians (the Volga-Ural region of Russia); Byelorussians, Ukrainians (Eastern Europe); Abkhazians, Avars, Cherkessians, and Ingushes (Caucasus); Kazakhs, Uzbeks, Uighurs (Central Asia); and Yakuts, and Altaians (Siberia). The prevalence of the c.35delG mutation in the studied ethnic groups may act as additional evidence for a prospective role of the founder effect in the origin and distribution of this mutation in various populations worldwide. For the analysis of the haplotypes and the estimation age of the mutation c.35delG in the *GJB2* gene, three high-polymorphic microsatellite -markers were used: D13S175, D13S141, and D13S143, flanking the DFNB1 locus, which contains the *GJB2* gene. The haplotype analysis of chromosomes with the c.35delG mutation in patients with nonsyndromic sensorineural hearing loss (N=112) and in population samples (N =358) permitted the reconstruction of an ancestral haplotype with this mutation, established the common origin of the majority of the studied mutant chromosomes, and provided the estimated time of the c.35delG mutation carriers expansion (11,800 years) on the territory of the Volga-Ural region.

P10.30
Genotype distribution of GLCCI1 rs37972 in Roma and Hungarian Caucasian samples

B. Duga, *L. Magyari*, *L. Jaromi*, *I. Janicsek*, *P. Kisfali*, *B. I. Melegh*, *C. Sipeky*, *B. Melegh*;
Department of Medical Genetics, Pecs, Hungary.

Asthma is a specific respiratory disease which is widespread in most ethnics. The rate of the asthma incidence is 3.3%, which means 235 million people suffer from this disease in worldwide (WHO data from 2012). Often the first choice of treatment is glucocorticoid derived, however in numerous cases therapy resistance can be observed. We investigated the rs37972 SNP, allele distribution in Roma samples of the glucocorticoid induced transcript 1 (GLCCI1) gene. Kelan et al. reported that certain naturally occurring functional variants as rs37972 cause a decrement response to glucocorticoids in asthma patients[1]. In our study we investigated the distribution of allele and genotype frequencies of rs37972 in average Roma and the Hungarian population. We genotyped 295 Roma (113 males, 182 females, mean age: 41.6±16.1) and 278 control patients (157 males, 121 females, mean age: 37.9±12.7, with real time PCR method. We found that the frequency of the TT genotype is nearly two times higher in the Hungarian Caucasian population than in the Romas (31.7% vs. 16.6%; p<0.001). Regarding the T allele frequencies a similar association can be found (55.15% vs. 41.86%;

$p<0.002$). The data presented here strongly suggest marked difference between the corticosteroid response on Roma in average Hungarians, that can have therapeutic implications.
[1]*Kelan G. et al.; N Engl J Med. 2011; 365:1173-1183.*

P10.31
The role of ethnicity in prevalence of glutathione S-transferases (GSTs) polymorphisms in a healthy Tunisian population: The example of GSTM1 *0/*0, GSTT1 *0/*0, GSTP1 Ile105Val, and GSTA1 *A/*B

H. Kamoun[1], *G. Ben Salah*[1], *F. Kallabi*[1], *S. Maatoug*[1], *E. R. Mkaour*[1], *A. Fourati*[2], *F. Fakhfakh*[1], *H. Ayadi*[3];
[1]*Laboratory of Human Molecular Genetics, Faculty of Medicine, Sfax, Tunisia,* [2]*Research Unit, Chemical Tunisian Group, Sfax, Tunisia,* [3]*Centre of Biotechnology, Sfax, Tunisia.*

Genetic polymorphisms in glutathione S-transferases (GSTs) genes might influence the detoxification activities of the enzymes predisposing individuals to cancer risk. Owing to the presence of these genetic variants, inter-individual and ethnic differences in GSTs detoxification capacity have been observed in various populations. Therefore, the present study was performed to determine the prevalence GSTM1*0/*0, GSTT1*0/*0, GSTP1 Ile105Val, and GSTA1*A/*B polymorphisms in 154 healthy individuals from South Tunisia, and to compare them with those observed in North and Centre Tunisian populations and other ethnic groups. GSTM1 and GSTT1 polymorphisms were analyzed by a Multiplex-PCR approach, whereas GSTP1 and GSTA1 polymorphisms were examined by PCR-RFLP. The frequencies of GSTM1*0/*0 and GSTT1*0/*0 genotypes were 53.9% and 27.9%, respectively. The genotype distribution of GSTP1 was 47.4% (Ile/Ile), 40.9% (Ile/Val), and 11.7% (Val/Val). For GSTA1, the genotype distribution was 24.7% (*A/*A), 53.9% (*A/*B), and 21.4% (*B/*B). The combined genotypes distribution of GSTM1, GSTT1, GSTP1 and GSTA1 polymorphisms showed that thirty one of the 36 possible genotypes were present in our population; eight of them have a frequency greater than 5%. To the best of our knowledge, this is the first report of GSTs polymorphisms in South Tunisian population. Our findings demonstrate the impact of ethnicity and reveal a characteristic pattern for Tunisian population. The molecular studies in these enzymes provide basis for further epidemiological investigations in the population where these functional polymorphisms alter therapeutic response and act as susceptibility markers for various clinical conditions.

P10.32
Whole-genome genotyping of saliva-extracted DNA from participants of an Internet based survey: reliability and success rate

K. V. Allebrandt[1], *M. Zaharieva*[1], *S. Stoyanov*[1], *M. RadivojkovBlagojevic*[2], *P. Lichtner*[2], *T. Meitinger*[2], *T. Roenneberg*[1];
[1]*Institute of Medical Psychology, Ludwig-Maximilians-University, Munich, Germany,*
[2]*Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg, Germany.*

Whole-genome genotyping (WGGT) demands high quality DNA, usually obtained with whole blood-extracted DNA. Self-administered collection protocols can make it feasible to obtain biological material without meeting survey participants. Additionally, noninvasive, painless sources of biological samples, such as saliva samples are indicated to improve participation rate. With the intent to conduct a genome-wide association study with subjects phenotyped within an Internet-based epidemiological survey, we mailed participants self-collecting saliva sample-kits. To test the reliability of the method, we evaluated the concordance rates between a few (N = 10) saliva- versus the respective individual blood-extracted DNA samples with a high-density genotyping array (Illumina Human OmniExpress 700K). Genotypes were consistent across sources of biological material; concordance rates between genotype calls of saliva- versus blood-extracted DNA samples from the same individuals were > 99.9 ± 3%. Regarding genotyping efficiency, average genotype call rates were also similar for saliva- (97.3 ± 5%) and blood-extracted (99.5 ± 0.2%) DNA. Among the returned self-collected saliva-kits, 378 high-quality DNA samples were genotyped with an average call rate of 99.0 ± 3%. However, approximately 14% of the saliva-extracted DNA did not meet quality control criteria (inspection of absorbance scans and gel electrophoresis) - even after using a re-purification protocol - and could not be used for WGGT. Although blood-extracted DNA provides higher quality DNA, saliva-extracted DNA has proven to be a reliable method to obtain biological material for high-density genotyping arrays.

P10.33
Genetic determinants of IgG synthesis in the cerebrospinal fluid of patients with multiple sclerosis

E. Albrecht[1], *D. Buck*[2], *M. Aslam*[2], *A. Goris*[3], *N. Hauenstein*[2], *A. Jochim*[2], *S. Cepok*[2], *V. Grummel*[2], *B. Dubois*[3], *A. Berthele*[2], *P. Lichtner*[4,5], *C. Gieger*[1], *J. Winkelmann*[2,4,5], *B. Hemmer*[2];
[1]*Institute of Genetic Epidemiology, Helmholtz Zentrum München, German Research Center for Environmental Healt, Neuherberg, Germany,* [2]*Department of Neurology, Technische Universität München, Munich, Germany,* [3]*Laboratory for Neuroimmunology, Section of Experimental Neurology, KU Leuven, Leuven, Belgium,* [4]*Institute of Human Genetics, Technische Universität München, Munich, Germany,* [5]*Institute of Human Genetics, Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Germany.*

Multiple Sclerosis (MS) is considered a chronic inflammatory disease of the central nervous system of autoimmune origin involving T and B cells. Intrathecal IgG synthesis is observed in the majority of patients with MS. Whereas the amount of intrathecal IgG synthesis varies largely between patients, intrathecal IgG remains rather constant in the individual patient. Based on this observation it seems reasonable to assume that genetic factors may impact on the extent of intrathecal IgG synthesis.

To investigate the genetic determinants of intrathecal IgG synthesis in MS patients, we performed a genome-wide association study (GWAS) based on 526,014 SNPs of the Human660-Quad chip in 233 MS patients. For replication, we genotyped 18 SNPs, showing an association with intrathecal IgG synthesis ($p<1x10-5$), in an independent validation cohort of 279 MS patients using Sequenom. Five of the 18 SNPs, which could be replicated in the first validation cohort, were additionally analyzed in a second validation cohort containing 152 MS patients genotyped on the Illumina Human660-Quad chip. Patients of all three cohorts are of European descent.

All five SNPs showing a significant association with intractheal IgG synthesis in the discovery and replication cohorts ($p=2.61x10-7$; $p=3.38x10-8$; $p=1.2x10-2$) are clustered in one locus on chromosome 14 and are in linkage disequilibrium.

The results of this study suggest that intrathecal IgG synthesis in MS patients is genetically determined by a region located on chromosome 14. Further investigation of this region will identify the responsible gene and its role in the regulation of IgG levels in MS patients.

P10.34
Genetic history of "Yakut" diseases

V. A. Stepanov[1], *N. Maximova*[2], *V. Kharkov*[1], *K. Kurtanov*[2], *A. Marussin*[1];
[1]*Institute for Medical Genetics, Tomsk, Russian Federation,* [2]*Yakut Scientific Centre, Yakutsk, Russian Federation.*

The phenomenon of accumulation of rare genetic diseases in isolated populations with founder effect is well known. French Canadians, Ashkenazi Jews, Finns, Afrikaners are among the examples. In Siberian Russia the Yakut population is characterized by the accumulation of several monogenic disorders with the prevalence in Yakuts more than ten times higher that anywhere in the World. Such diseases as spinocerebellar ataxia 1, myotonic dystrophy, inherited methemoglobinemia, oculopharyngeal muscular dystrophy (OPMD), Yakut short stature syndrome (3M syndrome) and recently described SCOP syndrome belong to the list of "Yakut" diseases.

We have investigated the genetic variability in Yakuts using Y-chromosomal, mtDNA, X-chromosomal markers and genome-wide SNPs, and found reduced genetic diversity associated with the bottleneck effect. This effect, according to phylogeny of specific Yakut Y-chromosomal lineages, is dated back to 11th - 12th centuries.

Haplotype analysis of CUL7 gene in 3M syndrome, NAG gene in SCOP syndrome and PABPN1 gene in OPMD suggested that the accumulation of the disorders in Yakuts was driven by two major events: a bottleneck about 1000 years ago, associated with the initial migration of ancestors of modern Yakuts from south to north; and population expansion approximately 350 years ago when Yakuts extended from the central part into the territory of their modern settlement.

We suggest that research of Mendelian and common diseases in isolated Siberian populations may provide a new source of understanding of disease genetics, as well as improving the quality of health care to indigenous peoples.

P10.35
Criminality in Klinefelter syndrome and 47,XYY, a Danish registry study

A. B. Bojesen[1], *K. Stochholm*[2], *A. S. Jensen*[2], *S. Juul*[3], *C. H. Gravholt*[2];
[1]*Department of Clinical Genetics, Vejle Hospital, Sygehus Lillebaelt, Vejle, Denmark,*
[2]*Department of Endocrinology and Internal Medicine, Aarhus University Hospital NBG, Aarhus, Denmark,* [3]*3Department of Epidemiology, School of Public Health, Aarhus University, Aarhus, Denmark.*

Background: Four to five decades ago several reports showed an increased frequency of criminality among men with Klinefelter syndrome (KS) and 47,XYY, but these studies were hampered by an excessive risk of selection bias. We therefore wanted to study criminality in KS and 47,XYY using linkage of Danish nationwide registries, trying to avoid the selection bias and thereby to give a more realistic picture of the criminality.

Design: Register-based cohort study comparing the incidence of convictions among men diagnosed with KS (N=934) and 47,XYY (N=161) with an age and calendar time matched sample (1:100) from the general population (N=88,979 and 15,356, respectively), in Denmark, from 1978 to 2006. Crime was classified in eight types (sexual abuse, homicide, burglary, violence, traffic, drug-related, arson, and "others").

Results: In KS, The incidence of convictions was significantly increased of sexual abuse, burglary, arson and "others", but significantly reduced of traffic. Adjusting for socio-economic factors reduced the HR's, but convictions of sexual abuse and arson remained significantly increased.

In 47,XYY, the incidence of convictions was significantly increased of all types, except of traffic and drug-related. After adjustment for socio-economic factors, convictions of sexual abuse remained significantly increased.

Conclusion: This large study, covering all diagnosed individuals with KS and 47,XYY in Denmark, demonstrates that KS and 47,XYY are convicted of a number of specific offences more frequently than the background population. The study also demonstrates that unfavorable socio-economic conditions are part of the explanation, since adjustment for socio-economic factors reduced the hazard ratios in both cohorts.

P10.36

Further Development of the Malta Biobank

J. Vella, *A. Fiott, C. Scerri, A. Felice;*
University of Malta, Msida, Malta.

The Malta Biobank forms part of the Laboratory of Molecular Genetics at the University of Malta and is a founding member of EuroBioBank (EBB) and Biobanking and Biomolecular Resources Research Infrastructure (BBMRI). It is designated as the BBMRI-Malta node by the Government of Malta.

"Further Development of the Malta Biobank" is a new biobank project which is being setup with the aim of developing a research resource to discover the genetic causes of disease states in the Maltese population thus increasing medical knowledge of diseases locally. Based on Hb quantitative epidemiology it is assumed that 2-3 alleles at 2-3 loci could generate a braod range of quantitative complexity in phenotypes and account for trans-selective pressures on the regional shaping of genomes.

A new "identifiable" collection of biological samples and associated health and lifestyle information from approximately 1% of the population, i.e. 4200 individuals, will be collected. The collection will be representative of the Maltese population in both age and gender and will be based on Maltese family structures. One newborn cord blood sample will be collected together with its family of approximately 30 to 40 members. Informed parental consent will be obtained from ante-natal classes. Immediate family members will be asked to take part in the study and other family members interested to participate in the study will also be sampled with informed consent. Clinical analysis will include: anthropometric measurements; a complete blood count (CBC); a haemoglobin profile; a lipid profile; urinary metabolites and SNPlotyping.

P10.37

Genetic variants associated with lipid metabolism and cognitive ability at 8 years of age: a Mendelian randomization analysis from the Avon Longitudinal Study of Parents and Children (ALSPAC)

C. Bonilla, *D. A. Lawlor, D. Gunnell, A. R. Ness, Y. Ben-Shlomo, S. M. Ring, G. Davey Smith, S. J. Lewis;*
University of Bristol, Bristol, United Kingdom.

Brain development occurs most rapidly in utero and in young children. Consequently, it places a high demand on the supply of nutrients from the diet, since adequate nutrient concentrations are required for cell growth, synapse formation and myelination. Nutrient deficiency during this time could influence a child's cognitive ability later in life. Because lipids are vital for membrane biogenesis during cellular growth, a relationship between lipids and cognitive ability has been suggested. It is not possible to infer causality from conventional observational studies as associations between nutrition and cognitive ability are confounded by lifestyle and environmental factors. To overcome this problem we used Mendelian randomization, a method that exploits genetic variation associated with a modifiable exposure to examine the causal effects of that exposure on the outcome of interest.

We examined six SNPs, that have been previously associated with plasma lipids, in mothers and children from the Avon Longitudinal Study of Parents and Children (ALSPAC). We detected an association of an APOE-linked SNP in the mothers with offspring IQ (mean difference in IQ, GG vs AG/AA: -5.6; 95%CI -9.8, -1.4). Among children we identified effects of SNPs located in APOA5 (mean difference in IQ per minor allele: -1.1; 95%CI -2.3, -0.01) and LIPC (mean difference in IQ per minor allele: -0.9; 95%CI -1.5, -0.3), where alleles associated with higher total cholesterol were risk factors for a lower IQ. Lipid levels might be important for brain development in children, thus the role of this pathway on cognitive function deserves further investigation.

P10.38

Quick, „Imputation-free“ Meta-Analysis with Proxy-SNPs

M. Leber[1], *C. Meesters*[2,1,3], *C. Herold*[3], *M. Angisch*[1], *M. Mattheisen*[4,5], *D. Drichel*[3], *A. Lacour*[3], *T. Becker*[3,1];
[1]*Institute of Medical Biometry, Informatics and Epidemiology, Bonn, Germany,* [2]*AESKU. KIPP-Institute, Wendelsheim, Germany,* [3]*German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany,* [4]*Department of Biostatistics, Harvard School of Public Health, Boston, MA, United States,* [5]*IMBIE, Bonn, Germany.*

Imputation is the conventional approach for avoiding loss of SNPs in meta-analysis (MA) of genome-wide association studies (GWASes) with differing SNP panels. Here we present an alternative, fast method to avoid forfeiting SNPs present in only a subset of studies, without relying on time-consuming imputation. This is accomplished by using reference linkage disequilibrium (LD) data from 1,000 Genomes/HapMap projects to find proxy-SNPs together with in-phase alleles for SNPs missing in at least one study. MA is conducted by combining association effect estimates of a SNP and those of its proxy-SNPs. Our algorithm is implemented in the MA tool YAMAS (Yet Another Meta Analysis Software).

Association results from GWAS analysis applications can be used as input files for MA, tremendously speeding up MA compared to the conventional imputation approach. Furthermore, analysis of sex-chromosomal markers with YAMAS is readily available, while it can otherwise pose difficulties because of lack of universal implementation in imputing tools.

We show that our proxy algorithm is well-powered and yields valuable ad hoc results, possibly providing an incentive for follow-up. In addition, it is more robust if the data contains cohort-specific LD patterns. We propose our method as a standard approach for studies without available reference data matching the ethnicities of study participants. As a proof of principle, we analyzed six dbGaP Type II Diabetes GWAS and found that the proxy algorithm clearly outperforms naïve MA on the *P*-value level.

P10.39

Analysis of mitochondrial DNA haplotypes of old human populations from the Bronze and Iron Age from Romania

A. Rodewald[1], *G. Cardos*[2], *C. Tesio*[3];
[1]*University of Hamburg, Hamburg, Germany,* [2]*"Personal Genetics" Medical Genetics Center, Bucharest, Romania,* [3]*University of Bucharest, Bucharest, Romania.*

Our genetic study was focused on old human populations from the Bronze and Iron Ages from Romania in order to analysed their genetic variation and their genetic kinship al mitochondrial DNA(mtDNA)level with today´s Romanian populations and other modern European populations.

The ancient DNA(aDNA)was extracted from skeletal remains of 50 individuals from the Bronze and Iron Age by a phenol-chloroform DNA extraction method.MtDNA HVR I and HVR II regions were amplified by PCR and sequenced by the dideoxy chain terminator method.The aDNA data were analysed in comparison with corresponding mtDNA data of modern Romanian people and other 11 European populations.The ancient mtDNA haplotypes were framed into 12 haplogroups. The most frequent mtDNA haplotype identified in the old individual sample from Romania was the CRS-like, and the most frequent haplogroup was H. Significant differences in haplogroup frequencies between the old people and modern Romanians were found. Low values of internal standard genetic diversity indices suggested reduced genetic variability within old human populations from the Bronze and Iron Age from Romania, in contrast to all modern European populations and also modern Romanians, which showed higher mitochondrial haplogroup diversity values. This fact might be the result of social and cultural local organization in small tribes, partially reproductively isolated. Concerning the genetic relationships at mitochondrial level, old human populations from Romania have shown closer genetic relationship to Turks of Thracian origin,while modern Romanians were closer to modern Bulgarian, Italian, Greek and Spanish populations.

P10.40

Complete mitochondrial DNA diversity in Iranians

A. Bahmanimehr[1], *M. Derenko*[2], *B. Malyarchuk*[2], *G. Denisova*[2], *M. Perkova*[2], *S. Farjadian*[3], *L. Yepiskoposyan*[1];
[1]*Institute of Molecular Biology, National Academy of Sciences of Armenia, Yerevan, Armenia,* [2]*Institute of Biological Problems of the North, Russian Academy of Sciences, Magadan, Russian Federation,* [3]*Immunology Department, Shiraz University of Medical Sciences, Shiraz, Islamic Republic of Iran.*

The complete sequencing of mitochondrial DNA has contributed a great deal to the understanding of the timing and direction of human dispersals around the world. To elucidate the early stages of human colonization process outside of Africa and to investigate the demographic history of human populations from the Middle East we have completely sequenced the mtDNAs of 275 Iranians represented by Persians (N=105), Mazandaranians (N=4), Azerbaijanians (N=22), Kurds (N=5), Lurs (N=5), Armenians (N=10), Bakhtiarians (N=2), Gilakis (N=2), Indians (N=1), Turkmens (N=10), and Qashqais (N=109). Overall diversity is very high, with 252 different sequences falling into 75 major haplogroups within macrohaplogroups L, N and M. The majority of Iranian mtDNAs (90.9%) belongs to Western Eurasian component composed of haplogroups N1, N2, X, R2'JT, U, and R0, though the impact of African (L2a, L3d, L3f), Southern Asian (R8, M4, M5, M18, M42), and Eastern Eurasian (A4, B4, C4, C5, D4, F1, G2a) lineages is also perceptible being found at frequencies of 1.5%, 2.5%, and 5.1%, respectively. Results of molecular dating of Iranian mtDNA lineages show that macrohaplogroup N and its haplogroups N1, R, U, R2'JT coalesce to the time of 45-60 kya, marking the first stages of modern humans movement out of Africa. The ancient ancestry of Iranian gene pool is also confirmed by revealing of the unique N23 lineage survived both in Persians and Qashqais, albeit at low frequencies. This study was supported by Russian Foundation for Basic Research (11-04-00620) and by Far-East Branch of the Russian Academy of Sciences (12-III-A-06-101).

P10.41

mtDNA haplogroups in the population of Lithuania

I. Uktverytė[1], *M. Li*[2], *M. Stoneking*[2], *V. Kučinskas*[1];
[1]*Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Vilnius, Lithuania,* [2]*Department of Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany.*

Two major ethno-linguistic groups exist in Lithuania, Aukštaiciai and Žemaiciai, that consist of six dialectal subgroups. Individuals from both groups speak Baltic languages belonging to the Indo-European family. Neighbouring Finno-Ugric (Northern and Eastern Europe), Slavonic (Eastern Europe) and Germanic (Northern Europe) populations which are situated in the Baltic Sea region may have influenced the historical formation of Lithuanian ethno-linguistic groups, which we investigate here by mtDNA analysis.

We used multiplex sequencing on the *Illumina GAII* platform after in-solution capture enrichment to obtain complete mtDNA genome sequences from 276 samples with an average of 352-fold coverage. Haplogroups were determined with *Haplogrep* and in total 116 different haplogroups were identified. The most frequent haplogroups are H1 (19.6%), U5 (12.7%), J1 and V (5.8% each); less frequent haplogroups are T2, U4, H6, H, W (<5% each). AMOVA based on haplogroups frequency distribution showed no statistically significant differences between the two major ethno-linguistic groups (Aukštaiciai and Žemaiciai). The percentage of variation among groups was -0.34 (p-value=0.897), among populations within groups 0.36 (p-value=0.188), and within populations 99.98 (p-value=0.313) based on 10100 permutations. A multidimensional scaling plot based on Fst calculated from haplogroups frequencies depicted ethno-linguistic groups in the first dimension according to their East to West geographical position within Lithuania (stress=0.06).

This study is a part of LITGEN Project (VP1-3.1-ŠMM-07-K-01-013).

Human NADPH-cytochrome P450 oxidoreductase (POR) is a membrane-bound flavoprotein that catalyzes the transfer of electrons to a wide variety of enzymes. It is a member of a small group of proteins containing two flavins, FAD (flavin adenine dinucleotide) and FMN (flavin mononucleotide). As indicated by its name, the main protein partners of POR are the microsomal cytochrome P450 enzymes (CYPs). By interactions with CYPs, POR participates in xenobiotic and drug metabolism, as well as steroidogenesis.

In order to estimate the differences in POR allele frequencies between two ethnic groups, we have analyzed coding sequences and flanking intronic regions of the *POR* gene in 301 healthy unrelated individuals from Ashkenazi and Moroccan Jewish populations (92 males and 209 females) and in 322 healthy persons from the Czech population (137 males and 185 females).

A total of 11 *POR* missense single nucleotide polymorphisms (SNPs) were identified in the Israeli group. Beyond the known *POR* variants, we have reported also 6 previously undescribed missense SNPs (p.Ser102Pro, p.Val164Met, p.Val191Met, p.Asp344Asn, p.Glu398Ala, p.Asp648Asn). In the Czech population, we have identified 6 missense genetic variations, four of which are newly described (p.Thr29Ser, p.Arg371His, p.Pro384Leu, p.Thr572Met). Globally, a comparison of the two groups revealed a higher heterogeneity of the *POR* genetic variations in the Jewish population.

The data collected in this study on missense POR SNPs are interpreted in light of the recently published crystallographic structure of human POR.

Supported by GACR P301/10/1426 and NIH Grant GM081568.

P10.43

Distribution of PON1 and P2RY12 polymorphisms in Roma and Hungarian population samples

I. Janicsek, *C. Sipeky, B. Duga, L. Jaromi, L. Magyari, B. I. Melegh, B. Melegh;*
University of Pécs, Department of Medical Genetics, Pécs, Hungary.

Clopidogrel is a widely used thrombocyte aggregation inhibitor, which has recently been in the focus of a debate because of its serious side effects. There are many factors that affect its efficacy, like SNPs in genes of specific receptors and enzymes. The pharmacogenomic investigation of these factors might also leave clinical benefit. In our study we investigated variants of paraoxonase 1 (PON1) and purinergic receptor P2Y, G-protein coupled, 12 (P2RY12) genes and their distribution in average Hungarian and Roma samples. For the PON1 gene we chose rs662 (Q192R) and rs854560 (L55M), for the P2RY12 gene we analysed 3 SNPs, rs2046934, rs6798347 and rs6801273 as the most frequently investigated naturally occuring variants. We genotyped 491 Roma and 477 Hungarian samples with PCR-RFLP method. For the Q192R variant the frequency of the GG genotype is more than 2.5 times higher in the Hungarian group compared to the Romas (11.3% vs 4.3%, p<0.001). In the G allele frequencies similar significant difference could be detected (24,8% vs 31.7%, p<0.001). For the L55M variant the frequency of the TT genotype was more than 2.5 times higher in the Roma group than in the Hungarian (10.0% vs 3.8%, p<0.001). For the 3 P2RY12 variants we could find significant differencies only in rs2046934: the frequency of the CC genotype is 7 times higher in Hungarians than in Romas (1.4% vs 0.2%, p<0.05). The data presented here confirm major differencies between the distribution of PON1 and P2RY12 variants in Hungarian and Roma patients that might have clinical implications.

P10.44

Analysis of polymorphism at eight nuclear genome DNA loci in Tatars

N. V. Petrova, *E. E. Timkovskaya, T. A. Vasilyeva, R. A. Zinchenko;*
Research Center of Medical Genetics, Moscow, Russian Federation.

Population genetic survey of the indigenious populations of the Tatarstan Republic (Russian Federarion) belonged to the two Tatar ethnographic groups: Kazan (Arskiy, Atninskiy districts) and Mishari (Buinskiy, Drojjanovskiy districts), was carried out. DNA samples of 450 individuals from four districts were examined at eight polymorphic DNA loci of nuclear genome, diallelic: *CCR5 (del32)*, *ACE (del/ins)*, *D7S23 (KM19)*, *NOS3 (VNTR)*, and polyallelic: *THOI (STR)*, *FABP2 (STR)*, *CFTR (IVS6aGATT)*, *PAH (VNTR)*. Allele and genotype frequency distributions were obtained for individual samples and districts as well as for the ethnic group overall. Analysis of allele's frequency of autosomal DNA markers in Tatar subpopulations shows considerable genetic differentiation between them. The highest level of genetic diversity in diallelic system was established at locus *ACE (del/ins)*, H_{obs}=0,4687, in multiallelic system - at locus *THOI (STR)*, H_{obs}=0,8089. The index of mean heterozygosity is 0,4784. The analysis of dendrograms, based on correlations between the matrix of genetic distances, and multidimentional scaling analysis prompted us to conclude that Arskiy and Atninskiy subpopulations of Tatar are genetically closer to each other than to Buinskiy and Drojjanovskiy subpopulations. Our findings are consistent with evidences on Tatar ethnogenesis and historical facts. Analysis of genetic distances between populations of the Volga-Ural region shows that the population of Tatars joined the cluster of Chuvash, Udmurt and Mari populations before the population of Bashkirs.

Population isolates from Greece offer potential for powerful disease gene mapping: the HELIC-Pomak and MANOLIS studies

I. Tachmazidou[1], *A. Farmaki*[2], *L. Southam*[1], *K. Palin*[1], *N. W. Rayner*[1,3], *E. Daoutidou*[2], *I. Ntalla*[2], *K. Panoutsopoulou*[1], *G. Dedousis*[2], *E. Zeggini*[1];

[1]*Wellcome Trust Sanger Institute, Hinxton, United Kingdom,* [2]*Harokopio University, Athens, Greece,* [3]*University of Oxford, Oxford, United Kingdom.*

The study of low-frequency and rare variants can be empowered by focusing on isolated populations, in which rare variants may have increased in frequency and linkage disequilibrium tends to be extended. Sequencing is efficient in isolates, because variants are shared in extended haplotype contexts, supporting accurate imputation. Here we assess sample sets collected from two Greek populations: the Pomak villages are a set of religiously-isolated mountainous villages in the North (population size 11,000); Anogia is a mountainous village on Crete, with high levels of longevity (population size 4,000). 747 and 1118 individuals respectively were typed on the Illumina OmniExpress platform. We calculated genome-wide IBS statistics to assess the degree of relatedness and compared it with the general Greek population (707 samples with OmniExpress data, TEENAGE study). We additionally calculated the proportion of individuals with at least one "surrogate parent" as a means for accurate long-range haplotype phasing and imputation, as proposed by Kong et al, Nature Genetics 2008. We find 1-1.4% of individual pairs with pi-hat>0.05, and ~0.4% with pi-hat>0.1 in the isolates compared to 0% in the general Greek population. We also find that ~80%-82% of subjects have at least one surrogate parent in the isolates, compared to ~1% in the outbred Greek population. We have established the HELIC-Pomak and MANOLIS cohorts as genetic isolates and are currently whole-genome sequencing 250 individuals to enable imputation and subsequent association testing. This approach has the potential to identify novel robust associations with disease-related complex traits.

P10.46

Population stratification assessment and genomic control in Brazilian Head and Neck Squamous Cell Carcinoma (HNSCC) patients

L. F. Araujo[1,2]*, M. R. Luizon*[1]*, G. A. Molfetta*[1,2]*, C. A. Ferreira*[3]*, A. A. Marques*[3]*, A. K. Ribeiro-Santos*[4]*, S. E. Santos*[4]*, W. A. Silva Jr*[1,2]*;*
[1]*Medical School of Ribeirao Preto- USP, Ribeirão Preto/SP, Brazil,* [2]*National Institute of Science and Technology in Stem Cell and Cell Therapy. Regional Blood Center of Ribeirao Preto., Ribeirao Preto/SP, Brazil,* [3]*National Institute of Science and Technology in Stem Cell and Cell Therapy. Regional Blood Center of Ribeirao Preto., Ribeirão Preto/SP, Brazil,* [4]*Federal University of Para, Belem/PA, Brazil.*

HNSCC is the sixth leading cancer by incidence in the world. In Europe, about 87.5 thousand people died from HNSCC in 2008. In Brazil, the mortality rate is estimated in 12 thousand deaths per year. While the genetic basis of susceptibility to HNSCC has not been defined, an increasing number of studies report its association to genetic risk factors. However, the polymorphism frequencies often vary between ethnic groups. Population stratification can cause spurious relations in population-based association studies. For minimizing spurious association, studies recommend adjusting for population stratification. Ethnic categories are usually based on self-reports or complex phenotypic evaluation, but those are pointed as poor predictors of genomic ancestry. This study intends to evaluate the presence of stratification in a population of 28 patients diagnosed with HNSCC and 74 paired healthy controls from Brazil. A twenty Ancestry Informative Markers (AIMs) set based on InDel's markers were selected based on high allele frequency divergence between different ancestral. The samples were genotyped by High Resolution Melting analysis followed by DNA sequencing. Population structure was inferred using STRUCTURE software. The 20-AIMs set was able to distinguish individuals from different parental populations. The population sample of cases exhibited a proportion of 0.349, 0.226 and 0.425, for Ameridian, European and African contribution, respectively. As for the control population, it was found the proportions of 0.041, 0.822 and 0.137, respectively. The ancestral proportions in cases and control population diverged, confirming the importance of population stratification inference in case-control paired association studies. P10.47

Very high frequency of hereditary prosopagnosia among individuals with high intellectual ability

C. Stemper[1]*, T. G. Baudson*[2]*, I. Kennerknecht*[1]*;*
[1]*Institut für Humangenetik Westfäliche Wilhelms-Universität, Münster, Germany,*
[2]*Fachbereich I - Psychologie Universität Trier, Trier, Germany.*

Prosopagnosia or face-blindness is an impairment in human face recognition. Besides a very rare acquired form which can be triggered by e. g. a stroke or a brain injury, there is a much more common congenital form of prosopagnosia, affecting 2.5 % of the human population. The congenital prosopagnosia is almost always heritable. We therefore coined the term hereditary prosopagnosia (OMIM 610382). When establishing the prevalence data, we came across a high number of prosopagnosic subjects with a high IQ. In an unpublished pilot study 11 % of gifted individuals showed signs of congenital prosopagnosia.

Thereupon we tested the prevalence of congenital prosopagnosia among members of a high-IQ society comprising individuals with IQ ≥ 130. Our methodology consisted of an initial questionnaire-based screening process followed by a semi-structured diagnostic interview.

Among 194 highly gifted participants we diagnosed congenital prosopagnosia with varying levels of severity in 29 cases (15 %). This prevalence is six times higher than that observed in the general population. Among participants and those affected by prosopagnosia, both sexes were equally represented.

P10.48

Towards a central registry for rare disease patients in Belgium

E. Swinnen*, V. Van Casteren;*
Scientific Institute of Public Health (WIV-ISP), Brussels, Belgium.

In 2009 the European Commission asked the Member States to develop a strategy to improve the care of rare disease patients by 2013 (2009/C 151/02). In Belgium, recommendations for measures to fill unmet needs of rare disease patients were formulated by the Fund of Rare Diseases and Orphan Drugs at the King Baudouin Foundation. As a result, for 2012-2013, the government provides a budget to work out the implementation of a central rare disease registry collecting a minimum common dataset. Indeed, registration of rare diseases would be highly beneficial to patients, caregivers, authorities, researchers and the general public. Registries can be used e.g. for epidemiological research; incidence, prevalence and survival calculations; quality of patient care, health-care planning and monitoring.

Belgian data on rare disease patients are scarce and fragmented. The primary goal is to bring together already existing data (e.g. by extraction from established registries), to harmonize the different initiatives and to start up registration of core data for additional rare diseases. The Orphanet nomenclature of rare diseases will be used as this will allow mapping to the ICD11 in the future.

The core dataset will serve epidemiological purposes, including some quality indicators. In the future, also data on orphan drug use will be collected and other administrative or dossier functionalities might be implemented. Finally, and importantly, data from the Belgian registry can be shared at European level, to obtain good statistical power.

The methodology behind the central registry and its progress will be documented.

Rett syndrome (RTT) is a neurodevelopmental disorder with one principal phenotype and several distinct, atypical variants (Zappella, early seizure onset and congenital variants). Mutations in MECP2 are found in most cases of classic RTT but at least two additional genes, CDKL5 and FOXG1, can underlie some (usually variant) cases. There is only limited correlation between genotype and phenotype. The Rett Networked Database (http://www.rettdatabasenetwork.org/) has been established to share clinical an genetic information. Through an 'adaptor' process of data harmonization, a set of 293 clinical items and 16 genetic items was generated; 62 clinical and 7 genetic items constitute the core dataset; 23 clinical items contain longitudinal information. The database contains information on 1832 patients from eleven countries (February 2012), with or without mutations in known genes. These numbers can expand indefinitely. Data are entered by a clinician in each center who supervises accuracy. This network was constructed to make available pooled international data for the study of RTT natural history and genotype-phenotype correlation and to indicate the proportion of patients with specific clinical features and mutations. We expect that the network will serve for the recruitment of patients into clinical trials and for developing quality measures to drive up standards of medical management.

P10.50

Genetic variation of six X chromosomal STR loci in Bayash Roma samples from Croatia

***A. Barešić**, M. Peričić Salihović;*
Institute for Anthropological Research, Zagreb, Croatia.

X chromosome STRs are another tool for exploring different populations and their genetic characteristics and have been more and more used in recent years to accompany autosomal and uniparental markers data in population genetics. In the present study, six X chromosomal microsatellite loci (DXS983, DXS1225, DXS8092, DXS986, DXS1066 and DXS8082) were used to analyze 79 samples of unrelated male individuals from two Bayash Roma populations living in Croatia. The number of alleles for the studied loci ranged from 5-8 in Međimurje and 4-9 in Baranja, while the overall gene diversity values varied from 0.9673 to 0.9926, respectively. The most informative marker was DXS8092 (0.80628), whereas DXS1066 (0.18103) was the less informative one. Our results show that there is a statistically significant difference between Baranja and Međimurje samples based on haplotype frequencies, which conforms to our previously obtained data from uniparental markers. The coefficient of genetic differentiation (F_{ST}) is 1.6%, which is lower than in mitochondrial DNA (6%) or Y chromosome (2%). All of these results indicate that although Baranja and Međimurje Bayash Roma populations are part of the bigger Vlax Roma group and thus share similar background and origin, they clearly differ among themselves; however, future investigations should be undertaken to determine whether this difference is a reflection of separation prior to arriving in Croatia or a result of the past two centuries of strong genetic isolation on their current living location.

P10.51

Gorilla genome structural variation reveals evolutionary parallelisms with chimpanzee

***M. Ventura**[1], C. Catacchio[1], C. Alkan[2], T. Marques-Bonet[3], T. A. Graves[4], A. Navarro[5], J. Shendure[2], R. K. Wilson[4], E. E. Eichler[3];*
[1]University of Bari, Bari, Italy, [2]University of Washington, seattle, WA, United States, [3]University of Washington, Seattle, WA, United States, [4]Washington University Genome Sequencing Center, St. Louis, MO, United States, [5]University of Pompeu Fabra, Barcelona, Spain.

Structural variation has played an important role in the evolutionary restructuring of human and great ape genomes. We generated approximately 10-fold genomic sequence coverage from a western lowland gorilla and integrated these data into a physical and cytogenetic framework to develop a comprehensive view of structural variation. We discovered and validated over 7,665 structural changes within the gorilla lineage including sequence resolution of inversions, deletions, duplications and mobile element insertions. A comparison with human and other ape genomes shows that the gorilla genome has been subjected to the highest rate of segmental duplication. We show that both the gorilla and chimpanzee genomes have experienced independent yet parallel patterns of structural mutation that have not occurred in humans, including the formation of subtelomeric heterochromatic caps, the hyperexpansion of segmental duplications, and bursts of retroviral integrations. We present here a comprehensive overview of inversions, deletions, segmental duplications and retrotranspositions within the gorilla genome. Comparisons with humans and other apes reveal that parallel and independent mutational processes have more dramatically restructured chimpanzee and gorilla genomes.

P10.52

Pharmacogenetic variations of the SLCO1B1 gene in Roma and Hungarian population samples

***C. Sipeky**, B. I. Melegh, I. Janicsek, B. Duga, G. Tarlos, I. Szabo, L. Jaromi, L. Magyari, K. Komlosi, K. Hadzsiev, B. Melegh;*
Department of Medical Genetics, University of Pécs, Pécs, Hungary.

SLCO1B1 gene encodes for hepatic transporter protein OATP1B1 that is involved in active cellular influx of statins and many other drugs. The A388G and T521C polymorphisms of the SLCO1B1 gene affect the activity of OATP1B1, which result in muscle myopathy, derangements in hepatic function and psychiatric adverse drug reactions. To improve the predictability of inter-ethnic and inter-individual differences we studied the genetic variability of *SLCO1B1* polymorphisms in Roma and Hungarian populations. Genotypes of 470 Roma and 442 Hungarian healthy subjects for the rs2306283 (A388G) and rs4149056 (T521C) polymorphisms were determined by PCR-RFLP assay. Comparing the genotype and allele frequencies of Roma and Hungarian populations differences were found in the *SLCO1B1* 388 AA (24.5 vs. 45.5%), AG (42.1 vs. 36.6%), GG (33.4 vs. 17.9%) genotypes and in G allele frequency (0.545 vs. 0.362) between the studied groups ($p<0.02$). Futhermore, the frequency of *SLCO1B1* 521 TT (67.0 vs. 65.2%) was higher in Roma than in Hungarian samples ($p=0.05$). Similarly to other Caucasian populations, the 388G allele is the minor allele in Hungarians, while in Roma the 388A was found to be the minor allele. The 388G allele frequency of Roma is similar to that found in populations of Indian origin, however, the minor allele frequency of T521C SNP is almost three times higher in Roma than in Indians. Furthermore, the Roma population differs from Hungarians and Caucasians in common *SLCO1B1* polymorphisms. The results of *SLCO1B1* polymorphisms found in the Hungarian population were similar to that observed in other Caucasian populations.

P10.53

Age-related phenomena in telomere length

***L. Broer**[1], V. Codd[2], P. Henneman[3], N. Amin[1], A. Isaacs[1], B. A. Oostra[1], K. W. van Dijk[3], N. J. Samani[2], C. M. van Duijn[1];*
[1]Erasmus MC, Rotterdam, Netherlands, [2]University of Leicester, Leicester, United Kingdom, [3]Leiden University Mecial Center, Leiden, Netherlands.

Telomere length (TL) is considered a proxy for biological aging. Studies conducted in the 'oldest-old' often find no significant association with longevity, possibly due to reduced variability in TL with age, leaving these studies underpowered. The most important age-related association for TL is with cardiovascular disease (CVD).

We measured TL in the Erasmus Rucphen Family (ERF) study (n = 2,769) to study several characteristics of TL: first, we estimated the heritability of TL using POLY, second, we tested for the equality of variances to compare TL variability in different age categories, and third, we investigated the relationship of TL with known metabolic risk factors for CVD including adipokines.

TL was highly heritable ($h^2 = 0.65$, *p-value* = $1.45*10^{-61}$). Over the entire age distribution (18 to 88 years), we observed a significant reduction in TL variance with age, ranging from 0.150 in younger individuals to only 0.053 in older individuals (*p-value* = $4.23*10^{-6}$). Descendants of the 'oldest-old' had above average TL, suggesting that the 'oldest-old' themselves had above average TL when they were young. Of the 18 metabolic traits tested, only adiponectin was associated with TL after correction for multiple testing (*p-value* = $5.94*10^{-5}$).

In conclusion, we found that TL has a significant and large heritability and that the variability of TL decreases with age, pointing to a survivor effect. Of all the CVD related traits we tested, only adiponectin was significantly associated with TL suggesting a relationship between adiponectin and TL in the development of CVD.

P10.54

Association of IRGM polymorphisms and susceptibility to tuberculosis in zahedan, southeast of Iran

***M. Taheri**, G. Bahari, M. Hashemi, M. Naderi, A. Moazeni Roodi, E. Eskandari Nasab;*
Zahedan University of Medical Sciences, Zahedan, Islamic Republic of Iran.

Tuberculosis (TB) is a major cause of morbidity and mortality throughout the world. IRGM1 is an important protein in the innate immune system against TB. Indeed by regulating autophagy in response to intracellular pathogens it has a critical role in the innate immune system. Polymorphisms in the IRGM genes are known to influence expression levels and may be associated with outcome of infections. The objective of this study was to determine whether the presence of IRGM polymorphisms −1208 A /G, −1161 C/T and −947 C/T was associated with tuberculosis disease.

We investigated the functional polymorphisms of IRGM −1208 A /G (rs4958842), −1161 C/T (rs4958843) and −947 C/T (rs4958846) in 150 patients with pulmonary tuberculosis (PTB) with an average age of 47.5 years (59 male, 91female; minimum 12 years, maximum78 years) and 150 healthy subjects with a mean age of 44.13 years (53 male, 97 female; minimum 20, maximum 82). Genotype analysis was done using tetra amplification refractory mutation system-PCR (T-ARMS-PCR).

In the present study there was a significant difference in −1161 C/T and −947 C/T IRGM between control and PTB groups, whereas no significant difference in IRGM −1208 A /G was observed between control and PTB groups.

In conclusion significant association was found between the IRGM −1161 C/T (rs4958843) and −947 C/T (rs4958846) polymorphisms and susceptibility to PTB in a sample of Iranian population. Our finding suggests that IRGM −1208 A /G (rs4958842) polymorphism may not be a risk factor for susceptibility to tuberculosis in our sample.

P10.55

Vistafin: Association with Genetic Variability in Vistafin (PBEF) Gene, Anthropometric Parameters and Dietary Composition in Obese and Non-Obese Central-European Population

J. A. Bienertova Vasku[1]*, J. Stastny*[1]*, J. Tomandl*[2]*, M. Tomandlova*[2]*, M. Forejt*[3]*, Z. Splichal*[1]*, P. Bienert*[1]*, D. Stafova*[1]*, A. Vasku*[1]*;*
[1]*Department of Pathological Physiology, Faculty of Medicine, Masaryk University, Brno, Czech Republic,* [2]*Department of Biochemistry, Faculty of Medicine, Masaryk University, Brno, Czech Republic,* [3]*Department of Preventive Medicine, Faculty of Medicine, Masaryk University, Brno, Czech Republic.*

Visfatin (PBEF/Nampt) is a recently identified adipocytokine which harbors strong insulin-mimetic activity. However, nothing is known about whether visfatin is related to specific nutritional behavior which may result in obesity development. This is the first study focusing on genetic variability of the visfatin gene and its association with circulating visfatin, anthropometric parameters and dietary composition.

We analyzed a total of 6 exons and adjacent non-coding regions of the PBEF gene in 20 extremely obese Czech individuals (mean BMI 52.2 kg/m2 ± 5.0 SD) using direct sequencing and a frequency of rs2302559 was established in the validation cohort of another 605 individuals with completed 7-day food records and complex anthropometric measurements. Plasma levels of visfatin, leptin and leptin-receptor were measured in all sequenced individuals and in part of the validation cohort.

Three common polymorphisms were identified, two in non-coding regions (rs78411774 A/C, rs71564769 A/C) and one synonymous SNP in exon 7 (rs2302559 A/G). The rs2302559 showed significant correlation with visfatin plasma level throughout the entire study cohort ($p < 0.001$); there was a significant tendency towards higher visfatin levels in G allele carriers with GG homozygotes having the highest visfatin plasma levels. Furthermore, a negative correlation was observed between visfatin and leptin plasma level ($p = 0.01$). No association between investigated SNPs and anthropometric parameters or native dietary composition was observed.

This is the first study to demonstrate that the rs2302559 polymorphism in the PBEF gene is related to circulating levels of visfatin.

P10.56

Allelic and genotypic frequencies of CYP3A5, CYP2C19 and VKORC1 in Bulgarian population

R. Tzveova[1,2]*, S. Bichev*[3]*, P. Atanasov*[4]*, A. Mitkova*[1,2]*, S. Andonov*[4]*, R. Kaneva*[1,2]*, G. Nachev*[5]*, V. Mitev*[1,2]*;*
[1]*Medical university, Sofia, Department of Medical Chemistry and Biochemistry, Sofia, Bulgaria,* [2]*Molecular Medicine Center, Sofia, Bulgaria,* [3]*National Genetic Laboratory, University Hospital of Obstetrics, Sofia, Bulgaria,* [4]*National Sports Academy „ Vasil Levski“, Sofia, Bulgaria,* [5]*St. Ekaterina University National Multi-profile Active Treatment Hospital, Sofia, Bulgaria.*

VKORC1, CYP2C19 and CYP3A5 polymorphisms are frequently studied in pharmacogenetics. VKORC1 is the key enzyme of the vitamin K cycle and a molecular target of coumarins, which represent the most commonly prescribed drug for therapy and prevention of thromboembolic conditions. CYP2C19 and CYP3A5 are members of the cytochrome P450 mixed-function oxidase system and they are involved in the metabolism of xenobiotics.

The goal of this study was to determine the allelic and genotypic frequencies of important variants in CYP3A5, CYP2C19 and VKORC1 in Bulgarian population and compare them with the frequencies in other populations.

We examined 134 unrelated healthy subjects for polymorphisms in CYP3A5, CYP2C19 and VKORC1 by High Resolution Melting on Rotor-Gene Q.

The allelic frequencies for CYP3A5*3 and CYP2C19*2 were 88.43% and 13.81%, respectively, while VKORC1 1173C>T and VKORC1 -1639G>A were found in 51.87% and 45.52% of the subjects tested, respectively. Genotypic frequencies were as follows: 10.45%AA, 2.24%AG, 87.31%GG (CYP3A5); 74.63%GG, 23.13%GA, 2.24%AA (CYP2C19); 26.87%GG, 55.22%GA, 17.91%AA (VKORC1 -1639G>A) and 25.37%CC, 45.52%CT, 20.11%TT (VKORC1 1173C>T). Overall our results showed that the frequencies of allelic and genotypic variants of CYP3A5 and CYP2C19 in Bulgarians were similar to those reported for several other Caucasian populations. Also, a high prevalence of VKORC1 1173C>T and VKORC1 1639G>A polymorphisms among Bulgarians was found.

High-resolution melting analysis provides a simple and accurate method for genotyping of VKORC1, CYP2C19 and CYP3A5. The results of the current study will be useful for clinical pharmacogenetics investigations and for drug dosage recommendations in Bulgarian population.

P10.57

The Homozygosity Index (HI) approach reveals high allele frequency for Wilson Disease in the Sardinian population

A. Gialluisi[1,2]*, S. Incollu*[3]*, T. Pippucci*[1]*, M. B. Lepori*[3]*, A. Zappu*[3]*, G. Loudianos*[4]*, G. Romeo*[1]*;*
[1]*Unità Operativa di Genetica Medica, Dipartimento di Scienze Ginecologiche, Ostetriche e Pediatriche, Bologna, Italy,* [2]*Language and Genetics Department, Max Planck Institute for Psycholinguistics, Nijmegen, Netherlands,* [3]*Dipartimento delle Scienze Biomediche e Biotecnologie, Università di Cagliari, Cagliari, Italy,* [4]*Ospedale Regionale per le Microcitemie, Cagliari, Italy.*

Mutational records make it possible to estimate the allelic frequency (q) of autosomal recessive disorders using a novel approach based on the proportion of homozygotes versus compound heterozygotes born of consanguineous parents or even of apparently unrelated parents (the rarer the disorder, the higher the proportion of homozygotes for the same mutation).

The HI approach, successfully tested for Phenylketonuria and Familial Mediterranean Fever (Gialluisi et al. 2011), has obvious advantages over traditional epidemiological studies. However, the calculation of the coefficient of inbreeding (F) becomes problematic when offspring of apparently unrelated parents is considered. Using inbreeding data from the general Sardinian population (Moroni et al. 1972), we applied the HI approach to a sample of 183 Sardinians (only 3 of whom born of consanguineous parents) affected with Wilson Disease (WD, OMIM #277900) and well characterized for ATP7B mutations.

The estimate of F in this sample, keeping into account the individuals born to consanguineous parents, was equal to 8.9 x 10^{-4} while the HI value was equal to 0.486, which yielded a q of 0.0158 corresponding to a prevalence of 1:3991.

These results confirm that WD prevalence in Sardinia is much higher than previously reported (P=1:10000, Ghiagheddu et al. 1985) and are in line with a recent neonatal screening based on ATP7B mutation analysis (q=0.0192, P=1:2707, Zappu et al. 2008). In conclusion the prevalence of WD, largely underdiagnosed in Sardinia, can be estimated correctly by the HI approach, which is applicable to other autosomal recessive disorders especially in highly inbred populations.

P10.58

A Y -chromosome portrait of modern Bulgarians as viewed from different spatiotemporal aspects

S. Karachanak[1,2]*, V. Grugni*[2]*, D. Nesheva*[1]*, N. Al-Zahery*[2]*, V. Battaglia*[2]*, C. Nici*[2]*, V. Carossa*[2]*, Y. Yordanov*[3]*, A. Torroni*[2]*, A. S. Galabov*[4]*, O. Semino*[2,5]*, D. Toncheva*[1,5]*;*
[1]*Department of Medical Genetics, Medical Faculty, Medical University, Sofia, Bulgaria,* [2]*Dipartimento di Genetica e Microbiologia, Università di Pavia, Pavia, Italy,* [3]*Institute of Experimental Morphology and Anthropology with Museum, Bulgarian Academy of Sciences, Sofia, Bulgaria,* [4]*The Stephan Angeloff Institute of Microbiology, Bulgarian Academy of Sciences, Sofia, Bulgaria,* [5]*Authors for correspondence, Sofia, Bulgaria.*

To address the structure and evolution of the Bulgarian paternal gene pool, we have examined the Y chromosome variation in 809 Bulgarian males. The analysis was performed by high-resolution genotyping of biallelic markers and by analyzing the STR variation within certain haplogroups. The biallelic markers were analyzed by PCR/RFLP and PCR/DHPLC assay. Seventeen fast-evolving Y-STRs were amplified using the multiplex AmpFlSTR Yfiler PCR Amplification Kit (Applied Biosystems) and were read on ABI 310 genetic analyzer with GeneMapper software.

We found that the Bulgarian Y chromosome gene pool is primarily contained within haplogroups common in Europe and surrounding areas. Furthermore, when patrilineal relationships are visualized in a broader context by principal component analysis, Bulgarians are located among European populations. The analysis of molecular variance shows that the genetic variation within the country is structured among Western, Central and Eastern Bulgaria, rather than among the Black Sea coast, the Danubian Plane, Thrace and the Southwest mountainous region; which indicates that the Balkan Mountains have been permeable to human movements.

Y-STR variation ages and median joining networks of haplogroups E-V13, J-M241, R-M458, R-L23 and I-M423 were calculated together with data from other populations. For this purpose, the analyses of STR variation within haplogroups were based on 8 STR loci, with the exception of haplogroup R-M458, for which the STR profiles were further reduced to 7 loci. In general, the Y-STR data reveal that different prehistoric and historic events have left detectable traces in the Bulgarian Y chromosome gene pool.

P10.59
Ethnogenetic Estimation of Baltic ancestry

A. Puzuka[1], *L. Pliss*[2], *L. Piekuse*[1], *S. A. Limborska*[3], *A. Krumina*[2];
[1]*Riga Stradins University, Laboratory of Molecular Genetics, Riga, Latvia,* [2]*Latvian Biomedical Research and Study Centre, Riga, Latvia,* [3]*Institute of Molecular Genetics, Russian Academy of Sciences, Moscow, Russian Federation.*

Background. Y chromosome is widely used as marker in population genetic studies. The aim of this study was to estimate the possible genetic origin of Balts performing Y chromosome haplogroup (Y-Hg) analysis of Russian individuals that inhabit historical regions of Baltic tribes and to compare Y-Hg frequencies with incidence of Y-Hg in Latvian population.
Material and methods. A study encompassed 192 men that represent four Northern-Western and Central Russian regions and 153 unrelated ethnic Latvians. DNA samples were hierarchically genotyped (using appropriate PCR followed by RFLP or sequencing of corresponding PCR products) by 10 Y chromosomal binary markers (M9, SRY-1532, Tat, P21, M170, P37, M253, M172, YAP, M35) to establish their haplogroup.
Results. Similar incidence of main Y-Hg's - N1c, R1a, and I was found in analysed Russian regions and Latvian population. Significant differences in Y-Hg distribution in comparison to other regions under study were observed only in Mezen (Archangelsk district, Russia). In Mezen the Slavic component representing R1a haplogroup had the lowest frequency (20%) in comparison to other Russian (~55%) and Latvian (~40%) subpopulations. On the other hand the Fino-Ugric speaking population representing haplogroup N1c was the most common in Mezen (51%) in comparison to other Russian (~15%) and Latvian (~45%) subpopulations.
Conclusions: No significant differences in common Y-Hg distribution among analysed Russian and Latvian populations were found. The analysis of Y-Hg genofund in Mezen indicates possible Fino-Ugric ancestry that could be confirmed after Y haplotype (Y-STR) analysis.

IonTorrent: 2nd generation sequencing in a diagnostic laboratory

B. Dworniczak[1], *S. Fleige-Menzen*[1], *N. Bogdanova-Markov*[1], *P. Pennekamp*[2];
[1]*University Hospital Muenster, Institute of Human Genetics, Muenster, Germany,* [2]*University Children's Hospital Muenster, Department of General Pediatrics, Muenster, Germany.*

Molecular diagnosis of complex human genetic disorders is still challenging since in most cases multiple genes harboring putative deleterious mutations have to be investigated. Currently Sanger sequencing is applied, however capillary sequencing is excessive time-consuming and expensive for the screening of multiple genes. In the last years next generation sequencing technologies have been developed, but because these technologies are especially made for large sequencing projects it is not easy to scale them down for screening a set of disease causing genes in a diagnostic setting. In order to fill this gap IonTorrent recently introduced a sequencing device with mean throughput utilizing sequencing technology based on the detection of hydrogen ions that are released during the polymerization of DNA.
Based on our established sequencing approach we tested the performance of this technology especially in respect to usability, software requirements and accuracy. As templates we used exclusively PCR amplicons left over from the routine analysis without further normalization. Per sequencing run (314 chip) we analyzed simultaneously 600-800 fragments using barcode technology generating ca 40.000.000 bp of sequence. Although results might be preliminary and improvements should be expected our data will be crucial for the decision whether this technology can be implemented for diagnostic purposes.

P11.003
Screening of 50 Cypriot patients with autism using 400K custom array-CGH

L. Kousoulidou[1], *M. Moutafi*[1], ***P. Antoniou***[1], *P. Nicolaides*[2], *C. Christophi*[2], *A. Paradisiotou*[3], *V. Anastasiadou*[4], *P. C. Patsalis*[1];
[1]*Department of Cytogeneitcs and Genomics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus,* [2]*The Cyprus Paediatric Neurology Institute, Nicosia, Cyprus,* [3]*Department of child and Adolescent Mental Health, Archbishop Makarios III Hospital, Nicosia, Cyprus,* [4]*Department of Clinical Genetics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus.*

A standard method of whole-genome screening for subtle genetic defects is array-based Comparative Genomic Hybridization (array-CGH) with a variety of platforms applied in diagnostic and research centers. One of the arrays that combines high resolution and relatively low complexity of analysis is the Agilent 400K custom array (Agilent Santa Clara, CA), which can reliably identify deletions and duplications as small as 13 kb. Here we exploit the potential of the above platform to enter the little understood area of genetic basis of autism, limiting our sample heterogeneity by focusing on the population of Cyprus.
A cohort of 50 patients, their parents and 50 ethnically matched normal control samples were tested using aCGH with Agilent 400K custom array, after chromosomal imbalances and Fragile X syndrome were ruled-out. Microarray results were confirmed with real-time PCR and Fluorescence in situ Hybridization (FISH). As a result, 18 patients were found to carry potentially causative aberrations, one of which was de novo and 17 were inherited from unaffected parents. Four aberrations reside within genes, known to cause autism susceptibility and six are associated with schizophrenia and/or developmental delay and/or mental retardation. None of the above aberrations is found in copy number variation databases or normal ethnically matched population. Moreover, population comparison revealed an increased rate of rare disease-associated variants in normal parents of children with autism. The above data supports the multifactorial model of autism aetiology and the sum of genetic and environmental factors that lead to the disease are yet to be identified.

P11.004
Explore thefeatures of brain-derived neurotrophic factor in mood disorders

F. Yeh[1], *P. Kuo*[1,2];
[1]*Department of Public Health and Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan,* [2]*Research Center for Genes, Environment and Human Health, National Taiwan University, Taipei, Taiwan.*

The neurotrophic hypothesis for major affective disorders (MD) has been proposed over a decade. Brain-derived neurotrophic factor (BDNF) is one of the most studied, which plays an important role in neuronal survival and differentiation. However, the features and underlying mechanisms of BDNF for MD is yet clear. Previous studies using different designs often reported inconsistent results for the relationship between BDNF and MD. This study aims to explore the features of BDNF for its role in MD, including aspects in molecular evolution, literature review of genetic association studies, and pathway analysis. Results of sequence alignment among different species revealed that BDNF is a highly conserved gene, having 75% identity in chordates with human and 85.9%-100% in vertebrates. Molecular evolutionary analysis found no signs of recent positive selection. Literature review and meta-analysis exhibited inconsistent association results for rs6265 in MD, which is the most studied marker that locates in the coding region of precursor BDNF (pro-BDNF). Mature BDNF was produced from pro-BDNF and the two proteins have opposite biological functions. Studies in European seabass showed that stress changed the ratio of pro-BDNF and BDNF, implicating the necessity to study pro-BDNF for MD. We identified proteins that interact with BDNF and mapped these genes to genome-wide association datasets of MD. Pathway analyses identified possible biological pathways that involved with BDNF for MD. We concluded that examining the features of BDNF systematically can provide opportunities to have a better understanding for the mechanisms underlying mood disorders.

P11.005
Anticipation in Beckwith-Wiedemann syndrome: Gradual increase in maternal H19/ICR1 methylation associated with tall-statured mothers and BWS in their children

S. Berland[1], *M. Appelbäck*[1], *O. Bruland*[1], *D. Mackay*[2], *I. Temple*[2], *G. Houge*[1];
[1]*Center for medical genetics and molecular medicine, Bergen, Norway,* [2]*Wessex Genetics Service, University of Southampton, Southhampton, United Kingdom.*

Beckwith-Wiedemann syndrome (BWS) was diagnosed in two sisters and their male cousin. Both sisters had classical BWS features including Wilms tumour. Their male cousin (DZ twin) died from medical complications after a caesarian section in week 29. Birth weight was 2,1 kg and he had visceromegaly, macroglossia and general subcutaneous oedema. The children's two mothers and their sister were tall statured (178, 185 and 187 cm) and one had mild BWS features as a child. Their parents had average heights of 173 cm (mother) and 180 cm (father). This 2nd generation's increased stature and 3d generation BWS correlated with increased methylation of the maternal H19-locus, from 0.49 (normal range 0,50±0.20) in the grandmother to on average 0.70 in the next generation and 0.85 in the affected children. This data was reproduced by bisulphite treatment and subclone sequencing to quantitate the degree of CpG-methylation in a part of the H19 imprinting control region (ICR1). Long-range PCR did not detect any microdeletions in ICR1 that could explain the lack of maternal allele demethylation. However, ICR1 sequencing revealed the same maternal point variant g.1979595T>C that had been described previously as a cause of BWS in three brothers (Demars et al., Hum Mol Genet 19, 803-14, 2010). This point variant was on the paternal allele in the non-affected grandmother. Mutations in this region affect OCT binding, and our data suggests that this interferes with gonadal switching from paternal to maternal imprinting and that H19 interallelic interaction might play a role in this process.

P11.006

Methylation index as a prognostic marker in bladder cancer patients

M. Nemtsova[1,2], *A. Babayan*[1,3], *O. Karyakin*[4], *D. Zaletaev*[1,2];
[1]Research Centre for Medical Genetics, Moscow, Russian Federation, [2]Sechenov Moscow Medical Academy, Moscow, Russian Federation, [3]Institute of Tumor Biology, University Medical Center Hamburg Eppendorf, Hamburg, Germany, [4]Medical Radiology Research Centre, Obninsk, Russian Federation.

Bladder cancer (BC) is a common malignancy worldwide. At the time point of diagnosis 70% of BCs present as superficial BC (SBC), which do not penetrate the muscle layer of the bladder. The rest 30% of cases present muscle-invasive BC (MIBC). SBC has better prognosis, though recurrences happen in 30% of cases after the primary tumor removal. MIBC has much worse prognosis and survival. Therefore it is of a prior importance to reveal possible markers of recurrences or progression of SBC into MIBC. It is proposed that methylation pattern might reflect the ability of BC to recur and/or to progress.

We examined 119 tumor samples from 108 SBC patients and 11 MIBC patients. Recurrence status after 1 year was known for 39 SBC patients: 31 patient developed relapses, 8 did not. Genomic DNA was extracted from fresh tissue. We investigated the status of promoter hypermethylation of *RASSF1A, RARb, P16, p14, CDH1* using methyl-sensitive PCR. Methylation index (MI) (or mean frequency of methylation) was defined as the ratio between the numbers of methylated genes to total number of examined genes in each sample. Statistical significance was evaluated using the Mann Whitney U-test.

SBC had a significantly lower extent of methylation (median MI 0.1) than MIBC (median MI 0,25) (p 0,017). Recurrent within 1 year SBCs showed median MI 0,0 while non-recurrent tumors had median MI 0,2 (p 0,047). Our results show that MI might be used as a sensitive marker for the assessment of recurrence and progression potential of SBCs.

P11.007

Identification of an integrated molecular network for congenital anomalies of the kidney and urinary tract

K. Y. Renkema[1], *G. Poelmans*[2], *N. Nicolaou*[1], *L. F. van der Zanden*[2], *I. A. L. M. van Rooij*[3], *N. Roeleveld*[2], *B. Franke*[2], *E. M. H. F. Bongers*[2], *N. V. A. M. Knoers*[1];
[1]University Medical Center Utrecht, Utrecht, Netherlands, [2]Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, [3]Radboud University Nijmegen Medical Center, Nijmegen, Netherlands.

Congenital anomalies of the kidney and urinary tract (CAKUT) form a spectrum of developmental malformations, including multicystic dysplastic kidney, renal hypoplasia, and duplex collecting system. CAKUT are the most common cause of end-stage renal disease in children. Based on previous disease modelling, it is anticipated that variants in genes expressed during embryonic kidney development play an important role in CAKUT aetiology. To gain insight into protein signalling cascades contributing to CAKUT and to visualize these molecular pathways, an analysis of 185 CAKUT candidate genes was conducted using Ingenuity Pathway Analysis software. The 185 candidate genes were selected based on experimental evidence implicating them in CAKUT pathogenesis. Extensive literature mining was subsequently performed to identify the biological mechanisms through which the CAKUT candidate genes interact during embryonic development. The bioinformatics analysis revealed a significant enrichment of molecular pathways regulating Wnt/beta-catenin signalling (28/185 genes, $p=9.72*10^{-26}$), basal cell carcinoma signalling (18/185 genes, $p=1.31*10^{-20}$), and stem cell pluripotency (22/185 genes, $p=1.62*10^{-20}$). In addition and based on the subsequent and extensive literature search, we built an integrated protein signalling network for CAKUT. Within this network, glial cell line-derived neurotrophic factor (GDNF)-dependent signalling, which is essential for growth, maintenance and differentiation of epithelial and mesenchymal cells during kidney and urinary tract development, plays an important role. Our results provide important clues for improving our understanding of the molecular background of CAKUT, which in turn is essential for identifying novel treatment targets for these disorders.

P11.008

Identification and functional characterization of trans-acting factors involved in the post-transcriptional regulation of CDK5R1

P. Zuccotti[1], *A. Barbieri*[1], *C. Colombrita*[2], *S. De Palma*[3], *S. Moncini*[1], *C. Gelfi*[3], *A. Ratti*[2], *M. Venturin*[1], *P. Riva*[1];
[1]Department of Biology and Genetics for Medical Sciences, University of Milan, Milan, Italy, [2]Department of Neurological Sciences, University of Milan, Milan, Italy, Milan, Italy, [3]Department of Biomedical Sciences and Technologies, University of Milan, Milan, Italy, Milan, Italy.

CDK5R1 encodes p35, an activator of CDK5, a proline-directed serine/threonine kinase that phosphorylates proteins involved in CNS development and maintenance. CDK5 and p35 were found to show an important role in neuronal migration and differentiation during CNS development and were also implicated in some neurodegenerative and cognitive disorders. Both the CDK5R1 3'-UTR remarkable size and its conservation during the evolution are strongly indicative of an important function in post-transcriptional regulation. We recently reported that CDK5R1 3'-UTR contains regulatory elements affecting transcript stability. In particular, a 138 bp region, that does not contain known miRNA binding sites, has been identified as the most destabilizing portion of the 3'-UTR by luciferase assays. UV cross-linking and site directed mutagenesis experiments allowed us to delimit potential binding site for RNA binding proteins (RBPs), among which we identified the nELAVs, showing a stabilizing activity on CDK5R1 transcript after overexpression and silencing experiments. To search for putative destabilizing factors, pull-down experiments have been carried out, allowing us to identify further binding factors, among which hnRNPA2/B1. The validation of hnRNPA2/B1 binding and the study of its silencing/over-expression might help to disclose the possible role of this protein on CDK5R1 post-transcriptional regulation.

This study will help to define the functional role of the gene, addressing studies on the CDK5R1 implication in the pathogenesis of neurodegenerative and cognitive diseases.

Fast and cost effective ChIP-Sequencing with PGM™ system reviews epigenomic landscape change in the MCF-7 cells upon estrogen stimulation

Z. Chen[1], ***C. Allen***[2], *L. Pickle*[3], *R. Bennett*[3];
[1]Life Technologies, Calsbad, CA, United States, [2]Life Technologies, Paisley, United Kingdom, [3]Life Technologies, Carlsbad, CA, United States.

ChIP-Seq provides a digital high resolution map of genome-wide protein and DNA interactions. With continuing evolving of next generation sequencing technologies, more and more sequencing platforms become well suited for the ChIP-Seq application. PGM™ system is a revolutionary semiconductor based low cost next generation sequencing system, offers long read length and the fastest sequencing turnaround time. It provides a new tool for ChIP-Seq application. We evaluate PGM™ system performance on ChIP-Seq application in comparison with SOLiD system. Human breast adenocarcinoma MCF7 cells were treated with estrogen. Chromatin immunoprecipitation with RNA pol II and ER-alpha antibodies were performed with MAGnify™ Chromatin Immunoprecipitation System, which enabled fast enrichment of chromatin complexes and efficient DNA recovery from small number of cells. The ChIP DNA samples were further constructed into ChIP-Seq libraries with an efficient ChIP-Seq library construction procedure, which enabled us to construct a library using as low as 1 ng ChIP DNA. Barcoded ChIP-Seq libraries were prepared for SOLiD system, while non-barcoded individual ChIP-seq libraries were constructed for PGM™ system. Both types of libraries were sequenced on SOLiD and PGM™ systems, respectively. The ChIP-Seq data from both systems showed expected response upon estrogen treatment in the MCF7 cells. The effect of different sequencing read length, ranging from 50bp to 200bp, on the ChIP-Seq profiling was investigated. In depth analyses of the ChIP-Seq data from both systems will be presented.

P11.010

Comparative Analysis of CHO Cell Transcriptional Dynamics under Different Cell Culture Conditions using Next Generation RNA Sequencing Technology

J. J. Schageman[1], *M. Liu*[1], *F. Raffaldi*[2], *S. Wang*[3], *C. Mueller*[1], *L. Donahue-Hjelle*[4], *S. Gorfien*[4], *R. A. Setterquist*[1];
[1]Life Technologies, Austin, TX, United States, [2]Life Technologies, Monza, Italy, [3]Life Technologies, Frederick, MD, United States, [4]Life Technologies, Grand Island, NY, United States.

Next Generation RNA-Sequencing (RNA-Seq) is a methodology for comprehensive measurements of cellular transcription at a scale, accuracy and precision never seen with previous technologies. We conducted a comparative RNA-Seq study of basic cell growth conditions to understand and improve high quality therapeutic protein production in CHO cells. In this study, we examined global changes in gene expression in CHO cells across differing cell subtype and media- specific parameters. Eight CHO RNA samples from different cultures were sequenced on two full slides of a SOLiDTM System resulting in approximately 760 million, 50 base pair sequence reads. These reads were mapped to multiple reference sequences including CHO ESTs, mRNAs and well as mouse chromosomes with annotated genes with cognate functional data. From this, we report estimates of transcript expression levels and use known annotation to infer functional differences that can be associated with changing basic bioproduction growth conditions. These findings may uncover novel genetic mechanisms that could be optimized for improved bioproduction. This analysis of this data set represents the characterization of the CHO transcriptome at an unprecedented depth.

P11.011

Chromatin changes in human mesenchimal stem cells during cultivation and differentiation

***A. V. Lavrov**, Y. I. Voldgorn;*
Research Center of Medical Genetics, Moscow, Russian Federation.

Epigenomics is one of the most exciting branches of modern cell biology. Role of chromosome territories (CT) in cell physiology in norm and disease remains poorly understood though chromatin structure is highly important for epigenetic regulatory mechanisms. Mesenchimal stem cell (MSC) is a useful model for studying CT role in stem-cells and during differentiation. Our aim is to study CT changes in MSC during cultivation and differentiation in vitro.

Human MSC derived from adipose tissue and bone marrow were prepared at early (before 4) and late (after 5) passages, and also after adypogenic and osteogenic differentiation. Over 2000 nuclei were analyzed using FISH with centromeric probes to chromosome 6 and 18. It was found that chromosome 6 holds a more distant radial position than chromosome 18 with medians of 0,65 and 0,47 respectively. Homologues of both chromosomes are always placed at different radial distances keeping medium (0,48-0,67) and outer (0,71-0,87) layers for chromosome 6 and inner (0,35-0,46) and medium layers (0,48-0,67) for chromosome 18. Comparison of cells at early and late passages, adypogenic and osteogenic differentiation revealed significant (p=0,0008 for chromosome 18 and p=0,03 for chromosome 6) distal displacement of both chromosomes in cells at late passages and after both differentiations also. Described particular chromatin pattern in cultivated MSCs differs from CT structure in both differentiated (i.e. lymphocytes) and embryonic stem cells. This pattern could be unique characteristics of MSC necessary for epigenetic regulation of their activity; and observed changes may reflect similar processes during differentiation and prolonged cultivation.

P11.012

A next generation sequencing panel based approach in ciliopathy diagnostics

***N. Ortiz Brüchle**, M. Begemann, A. Venghaus, J. von Bothmer, T. Eggermann, K. Zerres;*
RWTH University Hospital Aachen, Aachen, Germany.

Many primary ciliopathies are syndromal autosomal recessive diseases characterized by defects of primary cilia function. Cystic kidneys, brain abnormalities and liver fibrosis are overlapping findings in the often severe ciliopathies as Meckel syndrome (MKS) or Joubert syndrome related disorders (JSRD). To identify the underlying gene defect is often challenging because of the genetic heterogeneity with 10 and 16 known genes respectively.

Our aim was to develop a bench top NGS instrument based approach to efficiently analyze the most relevant MKS/JSRD genes and concurrently achieve the wherewithal coverage. The overall detection rate is about 50%. MKS1, MKS3/JBTS6 (TMEM67), MKS4/JBTS5 (CEP290), MKS6/JBTS9 (CC2-D2A), JBTS3 (AHI1) are the mainly contributing loci. Taking into account own data and data from the literature mutation frequencies divide approximately as follows: MKS1 (7%), MKS3 (7-16%), MKS4 (10%), MKS6 (10%) for MKS and JBTS3 (8%), JBTS5 (7-20%), JBTS6 (9%), JBTS9 (9-10%) for JBTS respectively. Further known genes play only little role for the overall detection rate.

We used the GS Junior system (Roche) and chose the amplicon protocol. We designed gene specific oligonucleotides for the above named genes including adapter sequences. The corresponding PCR amplicons were pooled followed by emulsion PCR and enrichment. The data were analyzed with the SeqNext module (Seqpilot/JSI). We analyzed about 20 patients (including controls) and hereby present our experiences regarding this approach: detection rates (false negative and positive rates), average coverage for the investigated amplicons, influence of homopolymeres on the data quality and number of fragments to be reanalyzed by Sanger sequencing.

P11.013

Comparison of different reference genes used for qPCR-based CNV quantification

***N. Fang**, F. Di Pasquale, C. Beckmann, U. Deutsch, A. Missel;*
QIAGEN GmbH, Hilden, Germany.

Copy Number Variant (CNVs), the change of the DNA copy number in the genome, has been recently shown to be a widely-spread phenomenon that affects about 10-20% of the human genome. The occurrence of the CNVs has been associated with various diseases such as autism, autoimmune disorders, and cancer.

The most commonly used molecular biology tools for discovery of CNVs are array and next-generation sequencing (NGS). These two high-throughput methods can discover multiple potential CNVs, which normally need to be validated with an independent method. Once validated, the confirmed CNVs can also be examined in a large number of samples to identify the statistically significant association of the CNV and phenotype. Quantitative PCR (qPCR), with its ease of use, sensitivity, and scalability, is often the method of choice for CNV validation and association studies. Relative quantification principle is used to determine any possible change of gene copy numbers. Since the consistent copy number of the reference gene is essential for the qPCR-based CNV quantification, we evaluated the reliability of commonly-used single copy reference genes such as Tert. Our results suggest that, compared to single copy genes, stable multi-copy regions can serve as a more sensitive and reliable CNV quantification reference.

P11.014

Comprehensive cancer gene research panel sequencing using fast, efficient and scalable Ion AmpliSeq technology and semiconductor sequencing

***S. Chen**, A. Li, M. Shannon, B. Kong, I. Casuga, D. Joun, D. Ruff, J. Leamon, R. Bennett, J. Rothberg;*
Life Technologies, Carlsbad, CA, United States.

Targeted enrichment of exon regions from genomic DNA has proven useful for mapping somatic disorders in cells. Whole exome sequencing has adaptation barriers associated with the extensive time needed for hybridization-based capture methodologies. Exon centric sample preparation methods are especially challenged in applications that require gDNA analysis from degraded sources, such as archived FFPE specimens. We have developed a fast, easy-to-use, highly multiplex PCR-based selection procedure for next generation sequencing. This process merges the specificity and speed of highly efficient PCR amplification with extremely scalable single-tube amplicon multiplex ranging from 12 to 3,000. This technology has been used to design primer pools to enrich coding gDNA sequence regions from an array of key cancer genes. The Ion AmpliSeq™ Comprehensive Cancer Panel interrogates exons in hundreds important cancer genes, covered by over 12,000 amplicons which can be sequenced on a Ion318™ chip. This kit is suited for archival (FFPE) samples, requiring only 10 ng of DNA per reaction. When the libraries are processed and sequenced with the Ion OneTouch™ and PGM™ Sequencer, mutations present at low frequency can be quantified from DNA to results within a day. The typical sequencing per base uniformity exceeds 96% for the amplicon panel. Using bi-directional sequencing protocols, per base accuracy exceeds 99.5+%. We report cancer gene somatic variant frequencies from studies using paired normal/tumor samples. This technology enables rapid and efficient focused sequencing in a variety of both basic and translational research settings.

Delineation of the reliability of in silico copy number variation (CNV) calls from different Illumina SNP arrays

*S. Herms[1,2], L. Priebe[1,2], F. Degenhardt[1,2], M. M. Nöthen[1,2,3], S. Cichon[1,2,4], **P. Hoffmann**[1,2];*
[1]Institute of Human Genetics, Bonn, Germany, [2]Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany, [3]German Center for Neurodegenerative Disorders (DZNE), Bonn, Germany, [4]Institute of Neuroscience and Medicine (INM-1), Structural and Functional Organization of the Brain, Genomic Imaging, Research Center Juelich, Jülich, Germany.

Illumina SNP arrays are widely used to identify common and rare susceptibility variants involved in the etiology of multifactorial diseases. Besides SNP-based genome wide association studies, SNP-arrays allow to in silico analyze Copy Number Variants (CNV). There has been a comprehensive discussion in the field to what extent in silico CNV calls are reliable. For individual associated CNVs, validation by quantitative PCR (qPCR) is usually performed which is labour-intense and requires large amounts of DNA. Moreover, it is almost impossible to qPCR-validate CNVs from in silico burden analyses which test the genome-wide frequency of CNVs between patients and controls. In order to get an objective overview of the reliability of in

silico CNV calls and the influence of batch effects, we compared in silico CNV calls from a larger number of technical replicates which were genotyped as internal quality controls in different genotyping projects over the last three years. These data had been acquired on different Illumina arrays such as the Human660W, HumanOmniExpress, HumanOmni1S and HumanOmni1M-Quad.
We compared these replicates on basis of genotypes and copy number variants to evaluate technical artifacts arising from batch effects. We will present data on deviances arising from quality parameters (e. g. gentrain score, logR ratio, B -allele frequency, intensity, chemistry batches) and the implications thereof.

P11.016

Generation of Customized and Read-To-Use Genetically Engineered Mice

M. BIRLING;
ICS, ILLKIRCH, France.

The Institut Clinique de la Souris - ICS- is a research infrastructure that provides extensive services ranging from the development of mouse models to comprehensive phenotyping. The Genetic Engineering and Model validation Department is dedicated to the development and molecular validation of new mouse models.
Mouse model can be valuable models to better understand the molecular processes of monogenic diseases or to test drugs in vivo. We can generate duplications and deletions of defined genomic fragment (CNVs) as observed in human disease. We always work in strong interaction with the scientists and make sure to define their needs. Many publications have already arised from mice generated at ICS.
The department is also driving several internal R&D programs and is involved in several international consortium (EUCOMM, EUCOMMtools, GENCODYS, IMPC, PHENOMIN).
We have generated a CreERT2 zoo (http://www.ics-mci.fr/mousecre/). When bred with conditional knock-out mice these lines allow the generation of time and cell specific knock-out after injection of Tamoxifen.
We will give you an example of a fully characterized mouse line: Insulin1-CreERT2. The Cre expression is observed in the β-cells, the translocation in the nucleus is confirmed in the presence of Tamoxifen as expected for an inducible line. By breeding this line with Rosa26 reporter line, a specific LacZ staining is observed in the β-islet cells. This line was phenotyped (under chow diet) and no glucose intolerance was observed at the difference of the Rat Insulin Promoter (RIP)-Cre line. A comparative study (Ins1-CreERT2 versus RIP-Cre) was performed and will be detailed.

P11.017

Performance of seven mutation pathogenicity prediction methods in the classification of missense variants of the CYP1B1 gene

G. Chavarria-Soley;
Universidad de Costa Rica, San Jose, Costa Rica.

Nonsynonymous single nucleotide polymorphisms (SNPs) in the coding regions of genes can lead to aminoacid changes and potentially affect protein function and, therefore, susceptibility to disease. Several computational methods have been developed for the classification of SNPs according to their predicted effect on protein function and resulting pathogenic potential. In this study, we evaluated the performance of seven commonly used pathogenicity prediction methods available on the Internet (SIFT, nsSNPAnalyzer, Panther, pMut, PolyPhen, PhD-SNP, and SNAP). In order to test them, nonsynonymous SNPs in the CYP1B1 gene- which codes for the cytochrome P450 1B1 enzyme-were selected. A total of 129 missense variants in CYP1B1 were identified in the literature, from which 87 could be classified as pathogenic or neutral according to criteria such as segregation with disease phenotype, and effect on function, among others. The algorithms showed significant variation in the assignment of the variants to three categories (non-neutral, neutral, no prediction), with a low 37% prediction rate for Panther. Pairwise concordance between methods in the classification of variants as pathogenic or neutral varied between 37% and 94%. The accuracy in the prediction of the pathogenicity of the variants was higher than 68% with all methods except pMut (47%). The highest false positive and false negative rates were found for SIFT and pMut, respectively. Taking into account the rate of prediction, accuracy of prediction, false positive, and false negative rates, the method with the overall best performance in the present study was nsSNP-analyzer, closely followed by SIFT, Polyphen and SNAP.

P11.018

Fine characterization of the recurrent c.1584+18672A>G deep-intronic mutation in the CFTR gene

D. Rusconi[1], *L. Costantino*[1], *M. Seia*[1], *R. Asselta*[2], *G. Soldà*[2], *V. Paracchini*[1], *L. Porcaro*[1], *C. Colombo*[3], *S. Duga*[2];
[1]*Laboratorio di Genetica Medica, Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Italy,* [2]*Dipartimento di Biologia e Genetica per le Scienze Mediche, Università degli Studi di Milano, Milan, Italy,* [3]*Cystic Fibrosis Center of Milan, Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Italy.*

Splicing mutations account for ~12% of the 1,890 CFTR mutations described in cystic fibrosis (CF); however, their impact on pre-mRNA processing frequently remains unclear. An interesting opportunity to study CFTR transcripts in vivo is the use of RNA from nasal brushings. We previously identified through this approach a deep-intronic mutation (c.1584+18672A>G), which activates a 104-bp out-of-frame pseudoexon by creating a donor splice site.
Screening of 481 CF patients identified c.1584+18672A>G in two additional individuals, demonstrating that it is a recurrent, and potentially overlooked, mutation among Italian patients. Haplotype analysis suggests that it originated from at least two independent events.
To further characterize the mutation, a genomic region including the activated pseudoexon and surrounding intronic sequences was cloned into an expression vector and transfected into HeLa cells. RT-PCR analysis identified two alternative splicing products, produced by the activation of two different cryptic acceptor splice sites: one including the 104-bp pseudoexon (78.7% of transcripts), the other leading to the inclusion of a 65-bp pseudoexon (21.3% of mRNAs). Allele-specific measurement of wild-type and aberrant splicings in the probands' (genotype F508del + c.1584+18672A>G) RNA from nasal brushing demonstrated: i) a low level of pseudoexon inclusion in the F508del transcript (not containing the splicing mutation); ii) a residual wild-type splicing in the c.1584+18672A>G mRNA; iii) the allele-specific degradation of aberrant transcripts; iv) the relative strength of the different cryptic splice sites. Interestingly, the residual wild-type splicing detected in transcripts bearing the c.1584+18672A>G mutation well correlates with the milder clinical phenotype of patients.

P11.019

Identification of novel Intellectual Disability genes through detection of *de novo* mutations

J. de Ligt, *M. H. Willemsen, B. W. M. van Bon, T. Kleefstra, T. Kroes, A. T. Vulto-vanSilfhout, P. de Vries, B. B. A. de Vries, H. G. Brunner, J. A. Veltman, L. E. L. M. Vissers*;
Department of Human Genetics, Nijmegen Centre for Molecular Life Sciences and Institute for Genetic, Nijmegen, Netherlands.

De novo mutations may play an important role in Intellectual Disability (ID). Here we evaluate the frequency and role of *de novo* mutations in an unbiased cohort of 100 ID patients using family-based exome sequencing. To identify the recurrence of mutations in certain genes in the population a targeted sequencing experiment was performed for 17 ID-related genes in 540 additional ID patients.
In the 76 trios sequenced thus far 60 unique coding *de novo* mutations were identified and validated in 58 different genes. On average 0.73 (0-4) *de novo* mutations were observed per patient. 47 of these mutations were non-synonymous, of which 9 introduced a premature stop or frame-shift. Pathogenicity analyses were performed for all non-synonymous variants based on evolutionary conservation (DNA and protein level) and mutation impact on the protein.
Combined with the targeted resequencing we identified 30 *de novo* mutations which likely explain the ID phenotype. Nine involved known ID genes (*RAB39B, SYNGAP1, GRIN2A(n=2), PDHA1, LRP2, TUBA1A, TCF4, GRIN2B*), eight occurred in new, but recurrent, ID genes (*DEAF1, YY1, DYNC1H1, GATAD2B*) and 13 additional events had a high pathogenicity score and were present in genes with a potential biological link to ID.
Our findings provide strong support for a *de novo* paradigm for ID, and further strengthen the causality of several previously identified genes. This study comprises the largest cohort of non-syndromal ID patients and suggests an expected diagnostic yield of approximately 35% for *de novo* mutation detection through exome sequencing.

P11.020

Deep-sequencing of TALENs targeted embryonic stem cells to estimate their efficacy in genome editing

S. Anvar, *C. Breukel, M. H. A. M. Veltrop, J. F. J. Laros, J. T. den Dunnen, A. M. Aartsma-Rus, S. Verbeek*;
Leiden University Medical Center, Leiden, Netherlands.

Engineering of biological systems that recapitulate human genetic disorders relies on efficient manipulation of the genome. Recently, transcription activator-like effector nucleases (TALENs) have shown promising potential in site-specific genome editing. Their modular structure enables the design and simple construction of TALENs that can specifically recognize virtually any DNA sequence. Upon delivery into embryonic stem cells (ESCs), TALENs initiate a double strand break that is repaired by non-homologous end-joining, introducing a large variety of mutations. Since this method lacks a selection procedure the applicability depends largely on its efficacy.

Here we focused on altering the hDMD transgene, introduced into the genome of mouse ESCs. So far, editing by homologous recombination of hDMD transgene has failed. Thus, we engineered a TALENs-pair targeting intron 52 of the hDMD gene. The utility of the assembled TALENs-pair was determined by measuring the variation within the targeted sequence of the hDMD transgene among TALENs-transfected mouse ESCs. The 135bp locus of hDMD was PCR-amplified and sequenced for 100,000 TALENs transfected and non-transfected cells using IonTorrent semiconductor sequencing. The targeted locus was covered ≥450,000x. In TALENs-transfected ESCs, the rate of editing events, mainly small deletions and insertions, was 4-fold higher (~11%) than in non-transfected cells. Furthermore, we assembled a list of the most frequently occurred structural variations and cleavage sites to facilitate follow-up functional studies.

Our data endorse the use of TALENs for modifying the hDMD transgene in ESCs. The TALENs efficacy in genome editing can be further estimated using the Pacific Biosciences Single Molecule Real-Time sequencing.

P11.021

Screening of muscular disease genes with the Access Array™ System of Fluidigm and Roche's GS Junior

***J. E. Bach**, A. Gehrig, S. Rost, C. R. Müller;*
Department of Human Genetics, University of Wuerzburg, Wuerzburg, Germany.

Sequencing of large genes like the *DMD* gene or of a group of genes, e.g. muscular disease genes, for many patients in parallel is a major application in our diagnostic laboratory. In addition to Sanger sequencing, we have established next generation sequencing (NGS) with the 454 GS Junior (Roche). For target enrichment, the Access Array™ System of Fluidigm is used which allows parallel amplification of 48 target regions for 48 samples in one single PCR setup. By the combination of target-specific primers and individual-specific barcode primers with 454 adaptors, sequencer-ready amplicon libraries can be produced in a single step.

The Access Array System is being established for the parallel screening of multiple candidate genes in patients with muscle diseases. In a first step, the *DMD* gene has been resequenced in a total of 80 patients in whom mutations and SNPs had already been identified by classical Sanger sequencing. The sequence coverage was satisfying (at least 15-fold by default) and all known variations could be retrieved. We are now extending the system to other genes for muscular diseases, especially the genetically heterogeneous limb-girdle muscular dystrophies (LGMD).

The combination of Access Array System and GS Junior sequencing has proven reliability and practicability as a time and cost efficient alternative for classical PCR and Sanger sequencing. The system seems to be particularly suitable for diagnostics as it is easy-to-use and requires only small amounts of genomic DNA and PCR reagents in order to obtain a sufficient amount of sequence data within three days.

P11.022

High throughput qPCR DNA methylation marker testing and validation

***A. Weinhaeusel**, M. Wielscher, M. Sonntagbauer, W. Pulverer, M. Hofner, A. Kriegner, K. Vierlinger, C. Noehammer;*
AIT, Vienna, Austria.

Over recent years elucidation of genomewide epigenetic changes has become a routine application. As with other genomewide approaches confirmation of elucidated DNA methylation changes have to be validated using alternate methods and also on additional samples.

In principle several strategies either based on bisulfite DNA conversion or methylation sensitive restriction enzyme (MSRE) digestion are suitable for confirmation of methylation changes. During our biomarker-research efforts on several cancer entities we have found that quantitative methylation analyses are inevitably for analyses. Therefore we have set up a cost efficient MSRE-based qPCR strategy and have qualified 576 methylation markers according MIQE guidelines. For enabling high throughput analyses of 96 samples x 96 different assays performing 9216 qPCRs in a nanoliter scaled microfluidic qPCR array per run, DNA target concentrations several hundreds of copies per 5 nanoliter reaction have to be warranted for proper analyses. Therefore we evaluated preamplification protocols and optimised conditions for high throughput DNA methylation testing.

Here we will introduce this procedure and present performance data as well as data generated on clinical tumor samples. Classifiers derived from these analyses have already been confirmed by

bisulfite deamination based tests (like qMSP, Sequenom's MALDI assay and pyrosequencing) and obtained very good correlation of results. Nanoliter scaled MSRE based HTqPCR outperforms standard qPCRs with respect to material costs, data quality and efficiency. Preamplification enables also paralleled analyses of up to 96 targets starting with 5-10ng DNA with high reliability and is currently under investigation for methylation testing of cell free DNA in serum.

P11.023

Placental lipoprotein lipase DNA methylation levels are associated with impaired glucose tolerance and maternal and fetal blood lipid profiles

***A. A. Houde**[1,2], M. F. Hivert[3], P. Perron[2,3], J. St-Pierre[4], D. Gaudet[2,5], D. Brisson[2], L. Bouchard[1,2];*
[1]Department of Biochemistry, Université de Sherbrooke, Sherbrooke, QC, Canada, [2]ECOGENE-21 and Lipid Clinic, Chicoutimi Hospital, Saguenay, QC, Canada, [3]Department of Medicine, Université de Sherbrooke, Sherbrooke, QC, Canada, [4]Department of Pediatrics, Chicoutimi Hospital, Saguenay, QC, Canada, [5]Department of Medicine, Université de Montréal, Montréal, QC, Canada.

Background: According to the fetal programming (or Barker's) hypothesis, newborns exposed to a detrimental fetal and perinatal environment are more susceptible to develop obesity, type 2 diabetes (T2D) and related chronic disorders but the underlying molecular mechanisms are poorly understood. Lipoprotein lipase gene *(LPL)* is an important regulator of lipid metabolism and transport and has been associated with obesity, T2D and dyslipidemia. The aim of this study was to determine the impact of impaired glucose tolerance (IGT) exposure on newborn *LPL* gene DNA methylation levels and lipid profile.

Methods/Results: Placental tissues and blood samples were obtained from 128 women (31 with IGT) and their offspring. Glucose tolerance was assessed using a 75-g oral glucose tolerance test (OGTT) between weeks 24 and 28 of pregnancy. *LPL* DNA methylation was determined by bisulfite pyrosequencing. There were up to 9% ($p<0.05$) differences in *LPL* DNA methylation levels between women with or without IGT. Placental *LPL* gene DNA methylation levels were associated with 2h-glucose post-OGTT levels (r=-0.204, $p=0.022$) and first trimester maternal triglycerides concentration (r>-0.201, $p<0.05$) and total cholesterol/HDL ratio (r=-0.207, $p=0.021$). Cord blood (n=93) cholesterol (r=-0.216, $p=0.041$), HDL (r>-0.208, $p<0.05$) levels and total cholesterol/HDL ratio (r>0.248, $p<0.05$) were also correlated with placental *LPL* DNA methylation.

Conclusion: These results suggest that fetal *LPL* DNA methylation levels are dysregulated by maternal glucose tolerance with a possible functional impact on cord blood lipid profile. They provide insights on the molecular mechanisms that may be involved in fetal programming and long-term development of obesity and dyslipidemia.

P11.024

DNA methylation patterns of mitotic and meiotic chromosomes from human spermatogenic cells

***I. A. Galembo**[1], A. A. Pendina[2], O. A. Efimova[2], I. D. Fedorova[2], E. M. Shilnikova[1,2], A. V. Tikhonov[1,2], T. V. Kuznetzova[2], A. M. Gzgzyan[2], V. S. Baranov[2];*
[1]Saint-Petersburg State University, Saint-Petersburg, Russian Federation, [2]D.O.Ott's Institute of Obstetrics and Gynecology, Saint-Petersburg, Russian Federation.

We studied DNA methylation patterns of mitotic and meiotic chromosomes from human spermatogenic cells. Samples were obtained from 5 patients with fertility problems in IVF clinic by testis biopsy. Chromosomes were fixed on slides with ethanol:acetic acid (3:1) after colchicines treatment in hypotonic solution. Analysis of DNA methylation was performed by immunocytochemistry with monoclonal antibodies against 5-methylcytidine. Chromosomes were identified by QFH/AcD staining. Among 119 analyzed dividing cells several types were detected by their specific morphological features: mitotic diploid and polyploid spermatogonia and meiotic spermatocytes at the pachytene, diplotene and diakinese stages.

DNA methylation pattern (MeC-pattern) of mitotic chromosomes appeared to be a specific banding pattern, resembling R-banding. It differed by number of bands and DNA methylation intensity from that in lymphocytes and human mesenchymal stem cells, described in our previous study. DNA methylation level of heterochromatic blocks of chromosomes 1,9,16 and Y demonstrated the most feasible difference: in most mitotic spermatogonia these regions were hypomethylated.

Pachytene chromosomes showed less obvious MeC-banding pattern, probably due to the increased length of chromosomes. The most intensive DNA methylation was registered at the peritelomeric regions of pachitene chromosomes. Diplotene and diakinese cells demonstrated high, but fairly homogeneous DNA methylation along chromosomes with increased intensity of signal in chiasmas and heterochromatic regions.

Thus, chromosomes of spermatogenic cells demonstrate unique DNA methylation patterns, different from these in somatic cells, possibly explained by their crucial role in chromatin stability and faciliating recombination events.

Supported by RFBR, Carl Zeiss, State Contract 02.740.11.0698 and Administration of Saint-Petersburg.

P11.025

A genomic approach for DNA methylation & hydroxymethylationanalysis

M. Krispin, *X. Sun, R. Leavitt, T. Chung, E. Bacon, A. Petterson, M. Van Eden, X. Jia;*
Zymo Research, Irvine, CA, United States.

DNA methylation and hydroxymethylation are some of the most important epigenetic modifications that can occur in the human genome. For instances, DNA methylation plays a vital role in the regulation of gene expression in normal cell development and aging, but also in the formation and progression of cancer and other diseases. Large scale identification of putative epigenetic biomarker candidates is achievable with the ability to profile DNA methylation and hydroxymethylation at the genomic level. Once validated, specific biomarkers could be applied to clinical and molecular diagnostic fields. Due to the availability of Next Gen sequencing technology, a number of new technologies have been developed for interrogating DNA methylation and hydroxymethylation at the genomic scale. Zymo Research has recently perfected sample prep and bioinformatic analysis as part of its new DNA Methylation and Hydroxymethylation Profiling Services. These epigenetic services combine next generation sequencing with Zymo's well-established epigenetic technologies and innovative bioinformatic algorithms for the most streamlined, comprehensive genome scale data generation to date. With these new services··· hundreds of epigenomic biomarker candidates can be discovered simultaneously.

A genome-wide search for novel imprinted genes

J. Beygo[1], *M. Heitmann*[1], *D. Gritzan*[1], *J. Richter*[2], *O. Ammerpohl*[2], *R. Siebert*[2], *B. Horsthemke*[1], *K. Buiting*[1];
[1]*Institut fuer Humangenetik, Universitaetsklinikum Essen, Essen, Germany,* [2]*Institut fuer Humangenetik, Universitaetsklinikum Schleswig-Holstein, Campus Kiel, Kiel, Germany.*

NLRP7 is a maternal effect gene as mutations in this gene cause recurrent hydatidiform moles, spontaneous abortions and stillbirths, whereas live births are very rare. We have studied a patient with multiple developmental defects born to a mother with a heterozygous *NLRP7* mutation. By genome-wide CpG methylation analysis of blood DNA from the patient, his parents and 18 normal controls on Illumina 27K arrays we found that the patient had methylation changes (delta ß>0.3) at almost all known imprinted loci as well as at 77 other loci. Using each control as a pseudoproband, we found methylation changes at only 11-26 (median 17) loci not known to be imprinted. In order to identify novel imprinted genes among the 77 conspicuous loci in the patient, we selected 22 genes (mainly hypomethylated genes) for deep bisulfite sequencing on the ROCHE/454 Genome Sequencer in the patient and at least two additional controls who were heterozygous at the test locus. Apart from FAM50B, which we proved to be imprinted, we did not observe allele-specific DNA methylation at these loci. We conclude that the patient has methylation defects at almost all imprinted loci as well as an excess of methylation changes at apparently non-imprinted loci. Our data also suggest that the number of genes that are imprinted in blood cells is rather low and that most of them have been discovered.

P11.027

Genome wide DNA methylation profiling of monozygotic twins discordant for trisomy 21

A. Letourneau[1], *M. R. Sailani*[1], *F. Santoni*[1], *A. Sharp*[2], *P. Makrythanasis*[1], *S. E. Antonarakis*[1];
[1]*University of Geneva, Geneva, Switzerland,* [2]*Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY, United States.*

DNA methylation is essential in mammalian development and has an effect in gene expression. We hypothesize that methylation differences induced by trisomy 21(T21) contribute to the phenotypic characteristics and variations in T21 patients. In order to determine the methylation differences in T21 without the noise of the genomic variation, we studied samples from monozygotic twins discordant for T21. We also collected samples from monozygotic twins concordant for T21, normal monozygotic twins without T21, and unrelated normal and T21 individuals to use as controls. We applied Reduced Representation Bisulfite Sequencing (RRBS) to generate nucleotide resolution of DNA methylation based on high throughput sequencing (HiSeq 2X 100bp) between each pair of twins. Methylation state of 4,278,488 CpGs with at least 8X coverage was obtained for the monozygotic twins discordant for T21. An initial analysis of methylation percentages differences between these twins identified 1000 differentially methylated regions (DMRs) (FDR<0.001 and at least 4 fold change in methylation differences). These DMRs were correlated with the deregulation of gene expression. The analyses of the control samples are ongoing. The study of methylation differences in monozygotic twins discordant for genetic abnormalities is a promising approach to understand the molecular mechanisms of aneuploidies.

P11.028

Comprehensive DNA methylation profiling with the SureSelect target enrichment system

K. Jeong[1], *F. Useche*[1], *R. McInnes*[1], *M. Corioni*[1], *D. Roberts*[1], *J. A. Stamatoyannopoulos*[2], *E. LeProust*[1];
[1]*Agilent Technologies, Santa Clara, CA, United States,* [2]*University of Washington, Seattle, WA, United States.*

DNA cytosine methylation is a critical epigenetic modification involved in human diseases such as cancer and imprinting disorders. Various cellular processes including gene regulation, embryonic development, X chromosome inactivation, and chromatin remodeling are strongly associated with DNA methylation changes. Next-generation sequencing combined with sodium bisulfite treatment allows identification of methylation changes at single base resolution. However, whole genome bisulfite sequencing is prohibitively expensive. Additionally, many of the regions in whole genome bisulfite sequencing are in repetitive regions, and provide little information. In many cases, the researcher is only interested in profiling a subset of biologically relevant regions. To address these needs, we have developed SureSelect Methyl-Seq, which combines Agilent's SureSelect Target Enrichment platform with bisulfite sequencing to detect methylation changes. Our Methyl-Seq design targets human genomic CpG sites within CpG islands/shores, promoters, known differentially methylated regions (DMRs) and previously determined regulatory regions. This comprehensive design covers 84Mb making it well suited to study cancer- and tissue-specific DMRs. Here we describe the SureSelect Methyl-Seq workflow and demonstrate efficient target enrichment and precise methylation level detection. Further, we show high concordance with whole-genome bisulfite sequencing of known model systems and describe the detection of tissue and cancer specific DMRs.

DNA-methylation in Dutch and Texan NTD children

L. Stolk[1,2], *M. I. Both*[3], *N. H. van Mil*[3], *M. M. P. J. Verbiest*[1], *P. H. C. Eilers*[4], *L. Suarez*[5], *A. G. Uitterlinden*[1,2,6], *R. P. M. Steegers-Theunissen*[3,6,7];
[1]*Department of Internal Medicine, Erasmus MC, Rotterdam, Netherlands,* [2]*Netherlands Consortium of Healthy Aging, Rotterdam, Netherlands,* [3]*Department of Obstetrics & Gynecology, Erasmus MC, Rotterdam, Netherlands,* [4]*Department of Biostatistics, Erasmus MC, Rotterdam, Netherlands,* [5]*Environmental Epidemiology & Disease Registries Section, Deptartment of State Health Services, Austin, TX, United States,* [6]*Department of Epidemiology, Erasmus MC, Rotterdam, Netherlands,* [7]*Department of Clinical Genetics, Erasmus MC, Rotterdam, Netherlands.*

Neural tube defects (NTDs) are congenital malformations developing during the first weeks of pregnancy. Interactions between environmental and genetic factors are involved in the pathogenesis and prevention of NTDs. Maternal folate shortage during the sensitive period of neural tube development contributes to the occurrence of NTD. Folate is an important B vitamin and donor of methyl groups, essential for DNA methylation, a key epigenetic mechanism to explain gene-environment interactions. We hypothesize that folate-related NTD are due to derangements in DNA methylation in the child of (non)imprinted genes implicated in neural tube development.

Methylation levels of three imprinted genes (IGF2, H19, and KCNQ1OT1), and three non-imprinted genes (MTHFR, VANGL1, and LEKR) were measured using Sequenom MASSARRAY EpiTYPER in 34 cases and 78 controls from a Texan study and in 48 cases and 62 controls from the Dutch population. Linear mixed model analysis was used to calculate the association of DNA-methylation levels with NTD.

The Texan samples revealed no significant association of DNA-methylation levels of any of the genes with NTD. In the Dutch samples we found a borderline significant association of MTHFR methylation levels with NTD (-1.3% methylation in cases, P-value=0.072). In the combined analysis of the Texan and Dutch samples we observed a borderline significant association of MTHFR DNA-methylation with NTD (-0.6% methylation in cases, P-value=0.067).

In conclusion, slightly lower MTHFR DNA-methylation levels may be associated with NTD. Additional studies are warranted to confirm our results.

P11.030
Differential expression of microRNAs in peripheral blood mononuclear cells of Down syndrome children

J. M. Biselli[1], B. L. Zampieri[1], D. G. Pinheiro[2], W. A. Silva[2], D. M. Carraro[3], E. N. Ferreira[3], E. H. Tajara[1], T. Henrique[1], E. M. Goloni-Bertollo[1], ***E. C. Pavarino***[1];
[1]São José do Rio Preto Medical School - FAMERP, Department of Molecular Biology, São José do Rio Preto, Brazil, [2]Sao Paulo University, Department of Genetics, Medical School of Ribeirao Preto, Ribeirão Preto, Brazil, [3]International Center of Research and Training (CIPE), AC Camargo Hospital, São Paulo, Brazil.

Down syndrome (DS) or Trisomy 21 is the most common human chromosomal disorder. DS phenotype includes several dysmorphic features, intellectual disability, immunological alteration, congenital heart disease, high risk for specific types of leukemia and neurological alterations. Recent studies show that DS results in the over-expression of microRNAs, which could result in low expression of specific proteins and contribute to DS phenotype. To identify differentially expressed microRNAs in peripheral blood mononuclear cells of six DS and six non-DS children and the biological processes relevant to DS pathogenesis associated with their predicted gene targets of microRNAs differentially expressed, we investigated the expression pattern of 754 mature microRNAs using TaqMan® Low Density Arrays (Applied Biosystems). Of the 490 mature microRNAs expressed in this cell type, 49 are low-expressed in DS group. The microRNAs located in chromosome 21 did not present differential expression between the groups. Target prediction was performed using TargetScanHuman v. 5.2. software and information about gene targets was obtained using the Bioprocess, a database that obtains data from NCBI. Bioinformatics analysis showed that genes involved in relevant biological process to DS, including apoptosis, reactive oxygen species metabolism, mitochondrial metabolism, immune system, cell aging, cycle and division and control of gene expression, are predicted targets of microRNAs differentially expressed in DS children. In conclusion, DS children present low expression of microRNAs not located on chromosome 21 in peripheral blood mononuclear cells and biological processes relevant to DS pathogenesis are associated with predicted gene targets of these microRNAs differentially expressed in DS chidren.

P11.032
Epimutations of imprinting genes and early pregnancy loss

E. A. Sazhenova*, I. N. Lebedev;*
Institute of Medical Genetics, Tomsk, Russian Federation.

Genomic imprinting is one of the most significant epigenetic phenomena, which is involved in reproduction and fetal development. We have performed DNA methylation analysis of the cytotrophoblast (CT) and extraembryonic mesoderm (EM) from 5 first-trimester spontaneous abortions (6.8±1.1 weeks) with normal karyotype and 6 induced abortions (7.5±0.7 weeks) as a control group using HumanMethylation27 BeadChip (Illumina, USA) comprising 409 CpG sites oriented near promoter region of 60 imprinting genes. Sixteen (26.6%) imprinting genes have revealed abnormal methylation in most miscarriages. Most CpG sites of these genes (ATP10A, CDKN1C, DIRAS3, GNAS, GRB10, KCNQ1, MEST, MKRN3, SLC22A3, SNRPN, TP73, WIF1, WT1, ZIM2) were hypomethylated, whereas only in two genes (INS, OSBPL5) hypermethylation of CpG sites was detected. The presence of several epimutations affected from 1 to 9 imprinting genes in CT and from 1 to 6 ones in EM was observed in each embryo. All epimutations had a postzygotic origin since were confined by EM or CT, that indicates forming epimutations after differentiation of these tissues. Most imprinted genes with epimutations participate in cell cycle (CDKN1, DIRAS3, INS, TP73, GO:0007049), in cell differentiation (CDKN1C, GNAS, INS, TP73, WIF1, GO:0030154), in cell death (INS, TP73, WT1, GO:0008219), cell proliferation (CDKN1C, INS, WT1, GO:0008283) and growth (GNAS, INS, WT1, GO:0040007). This study was supported by Federal Program (contracts P303).

Methylation analysis of three imprinted genes in ICSI versus IMSI sperms by limiting dilution bisulfite pyrosequencing

J. Kuhtz[1]*, T. Hansmann[1], N. El Hajj[1], E. Schneider[1], B. Linek[2], T. Hahn[3], M. Schorsch[3], T. Haaf[1];*
[1]Institute of Human Genetics, University of Wuerzburg, Würzburg, Germany,
[2]Department of Gynecology and Obsteterics, University Medical Center, Mainz, Germany,
[3]Fertility Center, Wiesbaden, Germany.

Optimum selection of sperm cells may increase the success rate of intracytoplasmatic sperm injection (ICSI) for human infertility treatment. For standard ICSI the embryologist selects normal looking sperm under an inverted microscope. Recently, a new method, intracytoplasmatic morphologically selected sperm injection (IMSI), was introduced. For IMSI only the most normally shaped sperms without a vacuole in the nucleus are retrieved using a higher definition microscope. Several recent studies have shown that abnormal sperm parameters are associated with aberrant methylation imprints. To compare the epigenetic quality of different sperms from the same males, we have used limiting dilution bisulfite pyrosequencing, which allows one to study the methylation levels of multiple genes in pools of about 10 sperms each. First, we have analyzed the methylation patterns of two maternally imprinted genes, *hLIT1* and *hPEG3*, and one paternally imprinted gene, *hGTL2*, in ICSI versus IMSI sperm samples from 5 males. Secondly, we have compared IMSI sperms versus sperms with a clearly visible vacuole from 10 males. Thirdly, we compared IMSI sperms versus abnormally shaped sperms with a vacuole from 5 males. Overall, we found a low rate (0-4%) of epimutations (abnormal allele methylation) in all groups and no between-group differences. Although we cannot exclude epigenetic differences in genes other than those studied, our results do not support the hypothesis that IMSI selects better quality sperms, improving fertilization and pregnancy outcome.

P11.034
Utilizing next generation sequencing for exome analysis

K. A. Stangier*, F. Ernst, Y. Kumar, T. Paprotka;*
GATC Biotech AG, Konstanz, Germany.

Next generation sequencing has changed the possibilities for analyzing human exomes. Several commercial kits are available allowing exome enrichment with subsequent library preparation in a cost efficient way. These libraries can be directly analyzed on e.g. an Illumina HiSeq. Enrichment is performed by pull down of coding regions with baits, which differ in overall design depending on the manufacturer. The depth of analysis can be enhanced by increasing the number of reads by using higher sequencing coverage mapped on the genome or the targeted region.

We used commercially available exome enrichment kits and designed a pipeline for data quality analysis, mapping and especially SNP detection. The mapping of reads was analyzed in detail to determine the efficiency of enrichment for the targeted exons. Variants were filtered according to several criteria like base quality, read quality, thresholds for coverage, and the overall mapping quality.

In order to improve the overall quality of reads for data processing, a quality score which represents the probability of a particular base mismatch in the reference genome was established. This highly increased the probabilities of validating certain mismatches.

In addition, FFPE samples were used for exome enrichment and the mapping and SNP detection compared to other starting material.

Utilizing exome sequencing in clinical and genetic diagnosis and personalized disease risk profiling is expected in the near future. Optimizing the sensitivity and data analysis pipelines will help to integrate exome analysis into a common clinical setup.

P11.035
Accurate detection of *de novo* mutations in rare and common neurodevelopmental disorders

A. Hoischen[1]*, L. E. L. M. Vissers[1], B. W. M. van Bon[1], J. M. Beechem[2], K. Lao[2], J. de Ligt[1], H. G. Brunner[1], C. Gilissen[1], J. A. Veltman[1];*
[1]Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, [2]Life Technologies, Foster City, CA, United States.

Many dominant Mendelian disorders occur sporadically because the severity and early onset of the disorder preclude transmission to subsequent generations. Exome sequencing represents the first systematic approach to identify many genes that cause sporadic diseases. *De novo* mutations causing rare syndromic forms of dominant Mendelian disease, such as Schinzel-Giedion syndrome and Kabuki syndrome were first identified by applying overlap strategies, *i.e.* identifying mutations in the same gene in multiple independent affected individuals. Subsequent studies focused on the role of *de novo* mutations in common neurodevelopmental disorders, such as intellectual disability, autism and schizophrenia by applying a trio design, i.e. exome sequencing of patient-parent trios.

In order to establish a robust approach optimized for *de novo* analysis, we used latest SOLiD 5500XL sequencing technologies in combination with the recently announced wildfire product (Life Technologies, Foster City, CA). The latter allowed the highest number of analyzed DNA molecules (>1 billion raw reads per lane), a fast process, long reads, high throughput and importantly allowed reliable calling of disease causing *de novo* mutations by applying exome sequencing to patient-parent trios. As a proof-of-concept for this novel technology we studied a patient with Baraitser-Winter syndrome, a well-defined disorder characterized by distinct craniofacial features, ocular colobomata and a neuronal migration defect. Using whole-exome sequencing of a patient-parent trio, we identified a *de novo* missense mutation in the cytoplasmic actin-encoding gene *ACTB*.

P11.036

Detection of Interstrand and Intrastrand DNA Crosslinks with Two-Dimensional Strandness-Dependent Electrophoresis

*B. Gudmundsson[1], H. G. Thormar[1,2], S. Thongthip[3], A. Smogorzewska[3], **J. J. Jonsson**[4,1];*
[1]Dept. of Biochemistry and Molecular Biology, University of Iceland, Reykjavik, Iceland, [2]BioCule Inc.,, Reykjavik, Iceland, [3]Laboratory of Genome Maintenance, Rockefeller University, New York, NY, United States, [4]Dept. of Genetics and Molecular Medicine, Landspitali, Reykjavik, Iceland.

Two-Dimensional Strandness-Dependent Electrophoresis (2D-SDE) is a novel technique for nucleic acid analysis to assess quality of samples, efficiency of molecular procedures and DNA damage. In the first dimension nucleic acid fragments are separated based on length and strandness i.e. double-stranded DNA, single-stranded DNA and RNA•DNA hybrids. The nucleic acids are heat denatured before the second dimension electrophoresis and thereafter fragments separate only based on length. After 2D separation, different arcs can be seen representing different strandness and lengths of the nucleic acids in the original sample.

We tested if 2D-SDE could be used to detect DNA crosslinks. Patients with Fanconi anemia (FA), a group of rare recessive disorders with heterogenic clinical features, are extremely susceptible to DNA crosslinking agents. Human genomic DNA in solution and fibroblast cell cultures with mutations in *FANCA* and *FANCD1* genes were treated with the different crosslinking agents diepoxybutane, mitomycin C and cisplatin and analysed with 2D-SDE. Increased amount of DNA migrating behind normal dsDNA was observed as expected for molecules with interstrand crosslinks since they prevent full denaturation of dsDNA. Intrastrand crosslinks causing bending of nucleic acids and ssDNA migrating in front of arc dsDNA were also observed. Lesions were dosage-dependent and correlated with cytogenetic abnormalities. Repair efficiency, as measured with 2D-SDE, was lower in the FA cell types compared to the wild-type cells.

2D-SDE has potential use in research, for Fanconi anemia diagnosis, and in chemosensitivity testing as the cytotoxicity of many cancer medications depends on their DNA crosslinking ability.

Application of next generation sequencing to identify causative variant at the BCL11A locus

***F. Danjou**[1], L. Usala[2], L. Perseu[2], C. Sidore[2,3,4], F. Busonero[2], R. Berutti[3,5], F. Reinier[5], A. Angius[2,5], A. Maschio[2,4], C. Jones[5], F. Anni[1], S. Satta[1], F. Demartis[1], N. Ramaiah[6], G. Abecasis[4], D. Schlessinger[6], R. Galanello[1], F. Cucca[2,3], S. Sanna[2], M. Uda[2];*
[1]Clinica Pediatrica 2a, Dipartimento di Scienze Biomediche e Biotecnologie - Università di Cagliari, Ospedale Regionale Microcitemie ASL8, Cagliari, Italy, [2]Istituto di Ricerca Genetica e Biomedica (IRGB), Consiglio Nazionale delle Ricerche (CNR), Cittadella Universitaria di Monserrato, Monserrato, Italy, [3]Dipartimento di Scienze Biomediche, Università di Sassari, Sassari, Italy, [4]Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI, United States, [5]Center for Advanced Studies, Research, and Development in Sardinia (CRS4), AGCT Program, Parco Scientifico e tecnologico della Sardegna, Pula, Italy, [6]Intramural Research Program, National Institute on Aging, Baltimore, MD, United States.

In the past few years, genome-wide association studies have improved our understanding of the molecular basis of fetal hemoglobin (HbF) levels, which is one well known ameliorating factor of both beta-thalassemia and sickle cell anemia disorders. This approach led to the identification of the BCL11A transcription factor as one of the main genetic modifier of the two disease phenotypes.

Although several studies have shown that BCL11A functions as a developmental stage-specific repressor of HbF expression controlling globin switching both in human and mouse, the specific contribution of associated variants in gene action is still unclear. Here we report the integration of data from genotyping and targeted and whole-genome sequencing using next generation technology to identify causative variants at the BCL11A locus.

We performed at two steps imputation using BCL11A targeted sequencing of 33 patients with Thalassemia Intermedia (300x coverage, on average) and low pass whole-genome sequencing of 347 unrelated individuals from the SardiNIA project (4x coverage, on average) to impute the discovered variants in 2343 individuals, from the same cohort, genotyped with Affymetrix 500K and 6.0 arrays. Accounting for all known HbF levels modifiers, the association at the BCL11A locus can be explained by two independent variants, mapping 304 bp apart. They represent the strongest haplotypic signal within the gene and are likely to be the causative polymorphisms. Experimental assays are ongoing to assess their specific impact in BCL11A function.

P11.038

The contribution of histone modifications to fetal programming of adult disease - studies in offspring of mothers with gestational diabetes

***A. Fitzner**[1], M. Wolf[1], N. El Hajj[2], G. Pliushch[2], E. Schneider[2], M. Aretz[3], H. Lehnen[3], T. Haaf[2], U. Zechner[1];*
[1]Institute of Human Genetics, University Medical Center of the Johannes Gutenberg University Mainz, Mainz, Germany, [2]Institute of Human Genetics, University Würzburg, Würzburg, Germany, [3]Städtische Kliniken, Mönchengladbach, Germany.

Several human epidemiological studies and experimental animal studies link in utero conditions very early in development with adverse effects on the risk of developing obesity, diabetes and other metabolic diseases later in life. Children born to mothers with obesity and/or diabetes have been shown to have a greater prevalence of metabolic disorders later in childhood, adolescence and adulthood. Epigenetic modifications of gene expression by DNA methylation and histone modifications are very attractive candidates for modulating these fetal programming effects. To investigate the impact of maternal overnutrition on the epigenome of the offspring, we aim at analyzing the histone modification profiles of candidate genes in chorionic villi of newborns from mothers with insulin-dependent gestational diabetes (GDM), dietary-treated GDM, and healthy controls (without GDM and overweight) using Chromatin immunoprecipitation (ChIP) real-time PCR. We started our analysis with the maternally imprinted MEST gene since our previous studies detected a significantly decreased DNA methylation at this gene in offspring of mothers with GDM. First experiments revealed a marked increase of the activating histone H3-lysine 4 trimethylation and histone H3-lysine 9 acetylation marks that is associated with maternal GDM. No significant changes in the repressive histone H3-lysine 27 trimethylation mark were observed. Histone modification analysis of several other candidate genes is also in progress. These preliminary results support the view that early exposure to overnutrition involves not only altered DNA methylation but also changes in histone modifications that possibly lead to increased MEST gene expression and effects on fetal programming of adult disease.

P11.039

Elucidating the role of *FOXP1* in striatal development

*C. Bacon, **G. Rappold**;*
Department of Human Molecular Genetics, University of Heidelberg, Heidelberg, Germany.

De novo heterozygous *FOXP1* gene deletions were recently identified in 3 patients with intellectual disability and language impairment. These findings, together with support from independent studies, show that *FOXP1* may play a role in both cognitive as well as language development. This is supported by the fact that Foxp1 is strongly expressed in specific brain structures, particularly in the striatum. To date, very little is known about the role of FOXP1 in brain development. Examination of different developing brain structures in the absence of FOXP1 would shed light on the neurodevelopmental pathways in which it is playing a role. We have used a knockout mouse model to investigate the role of Foxp1 in early striatal development. The striatum is composed mainly of medium spiny neurons (MSNs) which can be divided into patch and matrix MSNs and form axonal connections with other components of the basal ganglia. Analysis of the Foxp1 knockout brain using various immunohistochemical and histological stains, which identify patch and matrix MSNs, have revealed that these specific neuronal populations are seemingly unaffected up to E14.5. We have additionally used axon tracing techniques to trace the striatal projections to the substantia nigra and these experiments revealed no misprojection of these axons. Taken together our results show that Foxp1, which is strongly expressed in the striatum is not essential for early striatal development and that its function is likely to be rather more central in later developmental stages.

P11.040

Role of CTCF protein in regulating FMR1 gene transcription.

***M. Goracci**[1,2], S. Lanni[1,2], L. Borrelli[1,2], E. Tabolacci[1,2], G. Neri[1,2];*
[1]Institute of Medical Genetics, Rome, Italy, [2]Catholic University, Rome, Italy.

Fragile X syndrome (FXS) is mostly caused by expansion and subsequent methylation of the CGG repeat at the 5' UTR of the FMR1 gene (full mutation). Rare individuals of normal intelligence, carrying an unmethylated full mutation (UFM), have been reported and the epigenetic modifications in their FMR1 gene were previously characterized. CTCF (CCCCTC-binding factor), a zin-finger protein, is an important regulator of the transcription of genes harbouring trinucleotide repeats, acting as chromatin insulator. We investigated the role of CTCF in regulating FMR1 gene expression and observed that the amount of CTCF bound to FMR1 was higher in the UFM cell lines and in normal controls, compared to FXS cells. Knock-down of CTCF with anti-CTCF siRNA resulted in a reduction of FMR1 transcripts (both sense and antisense) in normal and UFM fibroblasts. After CTCF knock-down, the epigenetic analysis of the FMR1 promoter demonstrated a reduction of H3-K4 methylation and an increase of H3-K9 methylation, while the DNA methylation of the FMR1 promoter region and of the upstream methylation boundary remained unmodified. CTCF knock-down affected its binding to the 5' UTR of the FMR1 gene. These results suggest that CTCF is a modulator of the FMR1 transcription, given that its depletion causes FMR1 transcript reduction and the transition to a heterochromatic configuration. The elucidation of the mechanism sparing UFM males from inactivating their full mutation is important for planning therapeutic attempts at converting methylated into unmethylated full mutations, restoring FMR1 gene expression. Supported by FRAXA Foundation and Telethon Onlus.

P11.041

The prediction of Pathogenesis of Mitochondrial 12397 A>G substitution in Friedreich's ataxia with Bioinformatic Procedures

M. Heidari, *M. Khatami;*
Department of Biology, Science School, Yazd University, Yazd, Iran, Yazd, Islamic Republic of Iran.

Friedreich's ataxia (FRDA) is the most common ataxia that has an autosomal recessive inheritance. The disorder caused by mitochondrial defects. The prediction of pathogenesis of nucleotide changes by bioinformatics is useful method for Geneticians. In this study, Mitochondrial NADH dehydrogenase IV (ND5) gene was investigated by PCR-SSCP in 25 patients. The samples with shift bands sent for sequencing. Sequencing results were determined 12397 A>G substitution in 2 patients. This substitution causes to change of Thr to Ala (T21A). The determination of pathogenesis of this mutation were performed by SIFT database (Sorts Intolerant from Tolerant amino acid substitutions). The Substitution at position 21 from T to A is predicted to affect protein function with a score of 0.00 and median sequence conservation is 4.32. Although the prediction of this database is sequence homology-based tool, but that is useful method for the determination of effect of mutation on phenotype.

Correlation analysis of clinical parameters with epigenetic modifications in the DUX4 promoter in FSHD

J. Balog[1], *P. E. Thijssen*[1], *J. C. de Greef*[2], *B. Shah*[3], *B. G. M. van Engelen*[4], *K. Yokomori*[5], *S. J. Tapscott*[6], *R. Tawil*[7], *S. M. van der Maarel*[1];
[1]*Department of Human Genetics, Leiden University Medical Center, Leiden, Netherlands,* [2]*Leiden University Medical Center, Leiden, Netherlands,* [3]*University of Rochester Medical Center, Department of Neurology, Rochester, NY, United States,* [4]*Department of Neurology, Radboud University, Nijmegen Medical Center, Nijmegen, Netherlands,* [5]*Department of Biological Chemistry, School of Medicine, University of California, Irvine, CA, United States,* [6]*Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA, United States,* [7]*Department of Neurology, University of Rochester Medical Center, Rochester, NY, United States.*

Aim of our study was to identify relationships between epigenetic parameters correlating with a relaxed chromatin state of the DUX4 promoter region and clinical severity as measured by a clinical severity score or muscle pathologic changes in D4Z4 contraction-dependent (FSHD1) and -independent (FSHD2) facioscapulohumeral muscular dystrophy patients.

21 primary fibroblast and 26 primary myoblast cultures originating from patients with FSHD and controls were analyzed. Histone modification levels were determined by chromatin immunoprecipitation. We examined correlations between the chromatin relaxation score (CRS) defined by the H3K9me3:H3K4me2 ratio and an age corrected clinical severity score (CSS) or muscle pathology score (MPS). Possible relationships were investigated using linear regression analysis and significance was tested by Pearson's product-moment coefficient.

We found a significant difference of the CRS between controls and patients with FSHD1 and between controls and patients with FSHD2. Tissue specific differences in CRS were also observed. We also found a near-significant relationship between CRS and the age corrected CSS in fibroblasts but not in myoblasts. Surprisingly, we found a strong correlation between the MPS of the vastus lateralis and the CSS.

Our results confirm the D4Z4 chromatin relaxation previously shown to be associated with FSHD in a small number of samples. A possible relationship between clinical and epigenetic parameters could be established in patient fibroblasts, but not in myoblasts. The strong correlation between the MPS of the vastus lateralis and the CSS suggests that this muscle can be used to study for surrogate markers of overall disease severity.

P11.043

Gene expression analysis using functional genomics techniques

Background: This work presents an overview of evolutionary models and some functional genomics methodologies in the specific context of analyzing the gene expression.

Functional genomics techniques are intended to aid in rapidly identifying gene function by correlating gene expression with cell or tissue phenotype. Despite many complex studies performed, the clinical utility of genotype-phenotype associations remains unclear.

Profiling transcriptomes and examining the coordinate expression of genes in diverse pathobiologic pathways is now possible with techniques such as gene array analysis.

Functional genomics techniques compare mRNA transcript pools (transcriptomes), they can also be used to compare genomes, and to study the proteome. We use those methods in which no prior gene sequence is required (open architecture systems), as well as those in which prior sequence data are required (closed architecture systems).

The aim of this work is the most widely used functional genomics methodology, gene array analysis applied to gynecological fields for diagnose the future diseases of the new born and to prevent the surgical complications of the malformative interventions in the first days of life.

Key words: gene expression, microarray technology, evolutionary models.

Abbreviations: mRNA - messenger ribonucleic acid

Systematic Characterization of PRR-activated Monocyte Transcriptional Program

S. Kim[1,2], *J. Becker*[1], *J. Schumacher*[1], *V. Hornung*[2];
[1]*Institute of Human Genetics, Bonn, Germany,* [2]*Institute of Clinical Chemistry, Bonn, Germany.*

Dynamic cellular processes, such as the response to an invading pathogen, are governed by complex transcriptional regulatory networks. These networks typically involve a large number of transcription factors (TFs) that are activated in different combinations and in a certain temporal order to produce a particular cellular response.

Here, we pursued a gene expression profiling strategy to systematically explore regulators of transcription after stimulation with prototypical microbial ligands. To this effect, we isolated monocytes from four healthy donors and exposed the cells to pathogenic compounds such as viral nucleic acids. We measured mRNA expression at six time points after stimulation. Clustering differentially expressed genes via smoothing spline clustering (SSC) method revealed a broad range of activation kinetics. We hypothesize that clustered genes are to some extent co-regulated by common TFs. To find overrepresentation of transcription factor binding sites (TFBS) we conducted promoter analysis using TFs whose expression was validated in our microarray data set. These results revealed a systematic overview of novel transcriptional regulators that may play a role in the response to pathogens. Elucidating the transcriptional network and identifying key regulators and their functions will greatly enhance our understanding of the innate immune response and its role in infection.

P11.045

Generation and comprehensive phenotyping of mouse models at the ICS

H. Meziane;
ICS, Illkirch, France.

The Institut Clinique de la Souris (ICS) is a research infrastructure of excellence for translational research and functional genomics. Founded in 2002 by Prof. Pierre Chambon, it provides a comprehensive set of highly specialized mouse services to scientists from academia and industry. The ICS combines the capacity of generating mutant mice on a large scale with a high-throughput and comprehensive phenotypic analysis of mice, but also customized protocols to better answer the scientist's needs. The ICS phenotyping platforms are adapted for the study of genetically engineered mouse models, as well as for pharmacological and toxicological studies, allowing better understanding of human diseases and their underlying physiological and pathological basis. More than 250 assays are available for evaluation of various functions including behavior, cognition, sensory systems, nutrition, metabolism, clinical chemistry, cardiovascular, respiratory function and anatomopathology. Beside its services, the ICS is a member of several European programs: EUCOMM (www.eucomm.org) to generate the mutant strains, EMMA (www.emmanet.org) to archive and distribute them, and EUMODIC (www.eumodic.org) to phenotypically characterize 500 knock-out models. The EUMODIC is extended to the 20 000 potential genes identified in the mouse genome and continued by the International Mouse Phenotyping Consortium (www.mousephenotype.org). ICS is also a partner of the Fondation Maladies Rares. Up to now, about 80 mouse mutant lines were phenotyped and around 80% of the analyzed lines show at least one phenotypic trait. The data are available to the scientific community (www.europhenome.org), as well as the mouse models through EMMA.

P11.046

Integrating genomic technologies in clinical practice: A novel approach

Y. J. Trakadis;
McGill University Health Centre, Montreal, QC, Canada.

Medical genetics is shifting from the present "phenotype-first" medical model to a "data-first" model which leads to multiple complexities. This abstract discusses a "phenotype-first" approach, Individualized Mutation-weighed Phenotype On-line Search (I-MPOS), which could render widespread use of Exome Sequencing (ES) and Whole Genome Sequencing (WGS) in the immediate future practical, ethical and clinically useful. In brief, patients have their exome/genome sequenced and their encrypted data stored on a password-protected platform which remains at the disposal of the individual patient. A patient presents to clinic with a specific medical concern. The physician performs a clinical evaluation and identifies some important features. After obtaining authorization, the clinician temporarily and anonymously uploads the patient's encrypted genomic data to a search engine (I-MPOSE) which simultaneously operates on the patient's encrypted data and on a regularly updated database containing all well characterized genetic diagnoses. I-MPOSE identifies the genetic changes present in the patient's sequenced encrypted genome relative to the reference genome. Using preset criteria, I-MPOSE automatically assigns a weight score to each variant based on the level of certainty for its pathogenicity. The physician performs a database search using keywords related to the clinically assessed phenotype thereby providing an initial ranking of possible genetic diseases. This initial ranking is then adjusted by I-MPOSE based on the weight scores automaticaly assigned to the variants identified by ES/WGS. The proposed approach allows for a more efficient prioritization of the genes to be tested in a clinical lab and an incremental integration of genomic technologies into clinical practice.

Genome-wide association studies (GWAS) have uncovered susceptibility loci for a large number of complex traits. Functional interpretation of candidate genes identified by GWAS and confident assignment of the causal variant still remains a major challenge. Expression quantitative trait (eQTL) mapping has facilitated identification of risk loci for quantitative traits and might allow prioritization of GWAS candidate genes. One major challenge of eQTL studies is the need for larger sample numbers and for replication. The aim of this study was to evaluate the robustness and reproducibility of whole blood eQTLs in humans and test their value in identification of putative functional variants involved in the etiology of complex traits. In the current study, we performed comphrehensive eQTL mapping from whole blood. The discovery sample included 322 Caucasians from a general population sample (KORA F3). We identified 363 cis eQTLs and 14 trans eQTLs after stringent Bonferroni correction for multiple testing. Of these, 98.6% and 75% of cis and trans eQTLs respectively could be replicated in two independent populations (KORA F4 (n = 740) and SHIP-TREND (n = 653)). Furthermore, we identified evidence of regulatory variation for SNPs previously reported to be associated with disease loci (n = 59) or quantitative trait loci (n = 20), indicating a possible functional mechanism for these eSNPs. Our data demonstrate that eQTLs in whole blood are highly robust and reproducible across studies and highlight the relevance of whole blood eQTL mapping in prioritization of GWAS candidate genes in humans.

P11.048

The novel BTB-kelch Protein, KBTBD8, is ubiquitously expressed but specifically localized in the Cis-Golgi-Apparatus

S. Lührig, S. Kolb, J. Adamczyk, N. Mellies, ***J. Nolte***;
Institute of Human Genetics, Göttingen, Germany.

Proteins of the BTB/Kelch family are known to be involved in multiple biological processes such as migration, cytoskeletal arrangement, regulation of cell morphology, protein ubiquitination and gene expression. Kbtbd8 is a new undescribed member of this family. The gene was found to be highly expressed in mouse pluripotent stem cells by analyzing their transcriptome and was therefore suggested to be a putative pluripotency regulating gene. Comparative analysis of the gene and protein sequences revealed a high conservation throughout evolution especially in the characteristic domains of BTB, BACK and Kelch.

Starting with expression analysis on RNA level, Kbtbd8 was found to be ubiquitously expressed in mouse and human cell lines and tissues. In mice two transcripts can be detected - one full length and a shorter one lacking a part of exon 1 - which encode for two isoforms of the protein. Next we performed Western Blot and indeed both suggested isoforms were detectable at the predicted size. By immunocytochemistry on mouse and human cell lines we found a striking staining pattern next to the nucleus which we later identified as cis- Golgi apparatus by staining with GM130 antibody. Specificity of the KBTBD8 antibody was confirmed by tagging the KBTBD8 protein with an E2 tag. Detection of E2 and endogeneous KBTBD8 in transfected NIH-3T3 cells showed a perfect overlap suggesting the specificity of the antibody.

In conclusion, Kbtdb8 is a new member of the BTB/Kelch superfamily that is specifically expressed in the cis-Golgi apparatus in mouse and human.

Epigenome-wide association study for HDL-cholesterol levels in familial hypercholesterolemia

S. P. Guay[1,2], *G. Voisin*[3], *D. Brisson*[2], *J. Munger*[1,2], *B. Lamarche*[4], *D. Gaudet*[2,5], *L. Bouchard*[1,2];
[1]*Department of biochemistry, Université de Sherbrooke, Sherbrooke, QC, Canada,* [2]*ECOGENE-21 and Lipid Clinic, Chicoutimi Hospital, Saguenay, QC, Canada,* [3]*Genome Québec Innovatioin Centre, Montréal, QC, Canada,* [4]*Institute of Nutraceuticals and Functional Foods, Univerisité Laval, Québec, QC, Canada,* [5]*Department of Medicine, Université de Montréal, Montréal, QC, Canada.*

Background: A low high-density lipoprotein cholesterol (HDL-C) level is a well-known cardiovascular disease (CVD) risk factor. Although its heritability estimate is high, a few associated genetic variations accounting for a small percentage of its heritability has been reported. The aim of this study was to assess whether epigenetic changes, a non-traditional heritable mechanism, may account for HDL C variability. The study was conducted in familial hypercholesterolemia (FH), a recognized human model to study CVD risk modulators.

Methods/Results: A genome-wide DNA methylation analysis (Infinium HumanMethylation27 BeadChip, Illumina) was performed on blood DNA samples obtained from FH men subjects with low (L-HDLC; n=11) or high (H-HDLC; n=11) HDL-C concentrations. A total of 619 loci (β-value between 0.10 and 0.90; $p<0.05$) were found differentially methylated between groups. Among these loci, 232 were hypomethylated in the L-HDLC group compared to the H-HDLC group, whereas 387 were hypermethylated. According to gene ontology analyses (GeneCodis 2.0 software), hypomethylated regions revealed a pathway related to lipid metabolism ($p<0.02$), whereas hypermethylated regions were more likely to be associated with inflammatory ($p<0.0003$) and oxidative stress pathways ($p<0.003$). Furthermore, the initial association with one of the top differentially methylated locus located in the promoter of Troponin T type 1 gene was replicated in a cohort of 276 FH subjects using bisulfite pyrosequencing.

Conclusion: These results suggest that epigenome-wide changes contribute to the interindividual variations in plasma HDL-C levels in FH patients. If replicated, these findings could influence our understanding of the molecular mechanisms involved in the pathophysiological processes of CVD.

Hearing impairment (HI) is the most frequent sensory disorder, with a big impact in the quality of life of affected individuals. About 1 of 500 children present with prelingual HI. Genetic causes underlie over 60% of cases. Early detection is essential for the success of special education and treatments. To date, conventional techniques have been insufficient to provide a comprehensive molecular diagnosis, given the high number of genes that are implicated in HI.

We designed an NGS targeted resequencing panel for 69 genes, including: i) all genes currently known to be involved in non-syndromic HI (NSHI), with autosomal dominant, recessive, X-linked and maternal-mitochondrial inheritance patterns; ii) genes involved in some syndromic conditions, in which HI is the clinical sign that is earliest observed. The panel includes a total of 0.49 Mb comprising coding exons, splice sites and 5' and 3' UTR regions of the 69 genes. These regions were fully sequenced in 12 control patients with known mutations and in two HapMap cell lines (NA12144 and NA12892). Enrichment of the exonic regions was carried out using SureSelect Enrichment System (Agilent) and sequencing was performed with a SOLiDv4 Genetic Analyzer (Life Technologies). Sequencing reads were mapped and aligned against a reference sequence (GRCh37/hg19); variants were identified and classified. We present the results obtained during the validation of our panel, showing a high level of efficiency. Our targeted re-sequencing system offers massive analysis of 69 genes involved in HI, making the comprehensive molecular diagnosis of this disorder feasible.

Generating complex descriptions of sequence variants using HGVS nomenclature based on sequence comparison.

J. F. J. Laros*;*
LUMC, Leiden, Netherlands.

Descriptions of sequence variants can be checked and corrected with the Mutalyzer sequence variation nomenclature checker to prevent mistakes and uncertainties which might contribute to undesired errors in clinical diagnosis. Construction of variant descriptions accepted by Mutalyzer requires comparison of the reference sequence and the variant sequence and basic knowledge of the Human Genome Varia- tion Society sequence variant nomenclature recommendations. With the advert of sophisticated variant callers (e.g., Pindel) and the rise of long read sequencers (e.g., PacBio), the chance of finding a complex variant increases and so does the need to describe these variants. An algorithm performing the sequence comparison would help users to describe complex variants. The algorithm closely follows the human approach to describe a variant. It will first find the „area of change", and then finds the largest overlap between the original area and the area in the observed sequence. This process is repeated until the smallest description is found. This algorithm ensures that the same description will be generated every time researchers observe this variant. Furthermore, no knowledge of the HGVS nomenclature is required to generate this description. This not only helps clinicians to generate the correct description, but its implementation also allows automation of the description process. We have incorporated this algorithm in the Mutalyzer suite under the name Description Extractor.

P11.052

Minigene study of cryptic exons inclusion controlled by competition of hnRNP C with the core splicing machinery

M. Tajnik*[1], J. König[2], K. Zarnack[3], D. Glavač[1], J. Ule[2];*
[1]University of Ljubljana, Ljubljana, Slovenia, [2]MRC Laboratory of Molecular Biology, Cambridge, United Kingdom, [3]The European Bioinformatics Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, United Kingdom.

It was previously shown that heterogenous nuclear ribonucleoprotein C1/C2 (hnRNP C) silences inclusion of alternative exons by binding to long uridine tracts at the 3' splice sites of pre-mRNAs. With genome-wide approach using iCLIP and RNAseq methods, we identified its binding to the polypyrimidine tracts is mediated by direct competition with the core splicing factor U2AF65. Observed binding at deep-intronic sequence positions was shown to prevent inclusion of cryptic exons, of which majority is represented by ALU elements. Further, we performed more detailed study with use of reporter minigene assays, so far the most effectual choice to study regulation of alternative splicing by RNA-binding proteins in vivo. The competition of hnRNP C and U2AF65 was confirmed with minigenes containing mutations in polypyrimidine tracts, with aim of disrupting long uridine tracts to prevent hnRNP C binding and maintain binding of U2AF65. Cryptic exonization under hnRNP C regulation was verified in control and hnRNP C knock-down conditions. Introduced mutations lead to constitutive inclusion of ALU elements even in the presence of hnRNP C, what confirmed that hnRNP C regulates exonization of ALU elements through competition with U2AF65. Moreover, exonization of Alu elements in hnRNP C knock-down conditions was shown to regulate inclusion of neighbouring alternative exons, as well as effecting normal polyadenylation process. By constructing examples of minigenes with naturally occurring sequence polymorphisms, we demonstrated important role of Alu exonization in primate evolution and in disease.

Loss of heat shock protein HSPA4 aggravates pressure overload-induced myocardial damage

B. A. Mohamed*[1], A. Z. Barakat[1], W. Zimmermann[2], R. E. Bittner[3], C. Mühlfeld[4], M. Hünlich[5], W. Engel[1], L. S. Maier[5], I. M. Adham[1];*
[1]Institute of Human Genetics, University of Göttingen, Germany, Göttingen, Germany, [2]Department of Pharmacology/Heart Research Center, University of Göttingen, Germany, Göttingen, Germany, [3]Department of Neuromuscular Research/Center of Anatomy & Cell Biology, University of Vienna, Austria, Vienna, Australia, [4]Institute of Anatomy and Cell Biology, University of Giessen, Germany, Giessen, Germany, [5]Department of Cardiology and Pneumology/Heart Research Center, University of Göttingen, Germany, Göttingen, Germany.

Failure of molecular chaperones to direct the correct folding of newly synthesized proteins leads to the accumulation of misfolded proteins in cells. HSPA4 is a member of the heat shock protein 110 family (HSP110) that acts as a nucleotide exchange factor of HSP70 chaperones. We found that the expression of HSPA4 is upregulated in murine hearts subjected to pressure overload and in failing human hearts. To investigate the cardiac function of HSPA4, *Hspa4* knockout (KO) mice were generated and exhibited cardiac hypertrophy and fibrosis. *Hspa4* KO hearts were characterized by a significant increase in heart weight/body weight ratio, elevated expression of hypertrophic and fibrotic gene markers, and concentric hypertrophy with preserved contractile functions. Cardiac hypertrophy in *Hspa4* KO hearts was associated with enhanced activation of gp130-STAT3, CaMKII, and calcineurin-NFAT signaling. Further analyses revealed a significant increase in cross sectional area of cardiomyocytes, and in expression levels of hypertrophic markers in cultured neonatal *Hspa4* KO cardiomyocytes suggesting that the hypertrophy of mutant mice was a result of primary defects in cardiomyocytes. Gene expression profile in hearts of 3.5-week-old mice revealed a differentially expressed gene sets related to ion channels and stress response. Taken together, these results reveal that HSPA4 is implicated in protection against pressure overload-induced heart failure.

P11.054

Development of a single comprehensive gene screening test for Familial Hypercholesterolaemia using Next Generation Sequencing

P. Dean*[1], L. Yarram[1], G. Bayly[2], A. Taylor[3], A. Day[4], K. Haralambos[5], S. Whatley[5], I. McDowell[5], M. Greenslade[1], M. Williams[1];*
[1]Bristol Genetics Laboratory, Bristol, United Kingdom, [2]Bristol Royal Infirmary, Bristol, United Kingdom, [3]Royal United Hospital, Bath, United Kingdom, [4]Weston General Hospital, Western-super-Mare, United Kingdom, [5]University Hospital of Wales, Cardiff, United Kingdom.

Bristol Genetics Laboratory provides a comprehensive three level genetic testing service for Familial Hypercholesterolaemia (FH) using; level 1 FH20 ARMS for 20 common mutations; level 2 MLPA and Sanger sequencing of *LDLR*; level 3 Sanger sequencing of *PCSK9* and the *APOB* exon 26 mutation hotspot. Over a three year period of service provision a variant was identified in 93/232 index cases (40%). The ARMS methodology detected 48% of positive cases, *LDLR* sequencing 46% and the MLPA assay 6%.To reduce test costs, reduce turn around times and increase throughput we are developing a single assay for FH to detect all point mutations and copy number variation in *LDLR*, *APOB* and *PCSK9*. The coverage of *APOB* has increased to include all coding exons and an additional gene, *LDLRAP1*, which is associated with autosomal recessive hypercholesterolaemia, is included in the panel. The assay uses a targeted capture next generation sequencing approach (Haloplex PCR, Illumina MiSeq) and a bioinformatic analysis pipeline is under development using the Galaxy platform. The assay is currently being validated using 32 known positive control samples comprising: 25 samples with point mutations and indels, and 7 samples with exon duplications/deletions. To explore the benefits of extended screening we are analysing a cohort of previous test-negative patients with a high scoring clinical/biochemical index for FH. A comprehensive high throughput assay at reduced cost should facilitate extended uptake and commissioning of FH testing in the UK and be generally applicable to all European populations.

Hypertrophic cardiomyopathy (HCM), the most common hereditary cardiovascular disease, affecting 1:500 individuals in the general population, is typically characterized by genetic and allelic heterogeneity (more than 1000 mutations in 30 genes). The understanding of the genetic basis of HCM, namely the identification of new pathological biomarkers of heterogeneity that could contribute to genotype -phenotype correlations is of extreme importance. In this regard, the correlation between genomic and transcriptomic profiling and their integration into the clinical data was performed for 120 Portuguese Caucasian HCM-patients. DNA was extracted from peripheral blood samples and genotyping was performed by iPLEX Mass Array and High Resolution Melting to detect known and novel DNA variants in sarcomeric/non-sarcomeric genes, respectively. RNA extracted from cardiac and skeletal biopsies from HCM-patients were used for both sarcomere and non-sarcomere transcript levels and microRNAs profiling. Unsupervised machine learning methods were used to distinguish differences between groups of patients, tissues and genes. 85 of the 120 genotyped patients presented genetic alterations, 14 of them are novel ones and not presented in 200 chromossomes from healthy control individuals. All the novel mutations affected highly conserved residues. The most frequently mutated genes were MYH7 and TNNT2. Statistical analysis revealed a strong correlation between MYH7 and TNNI3 expression pattern in cardiac and skeletal muscles. Transcriptional profile also revealed an upregulation of CSRP3 gene in cardiac tissue. microRNAs expression profile changes observed during HCM remodeling, seems very promising to identify novel pathological biomarkers.

P11.056
Heterodisomy at 20q as a cause of Pseudohypoparathyroidism-Ib

I. Garin[1]*, R. L. Poole*[2]*, L. Suarez*[3]*, L. Martorell*[4]*, D. Mackay*[2]*, G. Perez de Nanclares*[1]*;*
[1]*Molecular (Epi)Genetics Laboratory, Vitoria-Gasteiz, Spain,* [2]*Wessex Regional Genetics Laboratory, Salisbury District Hospital, Salisbury, United Kingdom,* [3]*Endocrinology Department, Hospital Sant Joan de Déu,, Barcelona, Spain,* [4]*Molecular Genetics Department, Hospital Sant Joan de Déu, Barcelona, Spain.*

Introducction: Pseudohypoparathyroidism-Ib results from epigenetic GNAS defects. Familial and sporadic forms of PHP-Ib have been reported with distinct GNAS imprinting patterns: familial PHP-Ib patients have an exon A/B-only imprinting defect whereas sporadic cases have abnormal imprinting of the four differentially methylated regions (DMRs) in GNAS. In addition, they present a different underlying genetic alteration.

Objective: to analyze the methylation pattern at GNAS locus in a patient diagnosed with Pseudohypoparathyroidism-Ib and to identify underlying molecular genetic defect(s).

Design: We have studied dosage and methylation pattern at GNAS locus in the patient and her family by MS-MLPA. We also analyzed microsatellite and SNP markers along chromosome 20 looking for causative molecular alteration.

Results: We found that the index case and one of her brothers presented an altered methylation pattern at GNAS locus. It seems that the genetic alteration causative of this epigenetic defect was a paternal heterodisomy at least at 20q13.13.

Conclusion: Our work underlines the importance of analyzing apparently healthy family members of affected patients because of the subtle clinical features. Additionally, we emphasize that obtaining parental samples is essential to exclude/confirm uniparental disomy (isodisomy or heterodisomy) as a molecular underlying defect of Pseudohypoparathyroidism-Ib.

P11.057
In silico approach to Identification of novel cancer/testis-antigen genes by Expressed Sequence Tag(EST)

M. Foroutan[1]*, R. Molania*[2]*, F. Mahjoubi*[2]*;*
[1]*Shahid Beheshti University, Tehran, Islamic Republic of Iran,* [2]*Medical Biotechnology Division, National Institute of Genetic Engineering and Biotechnology (NIGEB)., Tehran, Islamic Republic of Iran.*

Cancer testis antigens (CTAs) expressions are restricted to normal testis tissue. CTAs have been also recognized to be found in some tumor tissues .It has been reported by many researchers that the expression of CTAs could be served as biomarkers to diagnosis, prognostic and immunotherapy in some cancers. Computational approaches have been used for the identification CTAs mRNA expression pattern and led to subsequent identification of many novel genes with similar characteristics to known CTAs.

In this work we have used the UniGene database for gene clusters composed of expressed sequence tags (ESTs) generated from normal testis and tumor-derived cDNA libraries. Using this data base, we analyzed the entire human genome in order to identify new CTAs gene by some selective ESTs.

These candidate genes subsequently can be assayed with experimental approaches to reconfirm their roles as CTAs genes.

In this presentation we will introduce some of the possible novel CTAs genes.

P11.058
Gene-Specific DNA Methylation Analysis in Inflammatory Bowel Disease

L. Merten[1]*, M. Wolf*[1]*, M. Götz*[2]*, U. Zechner*[1]*;*
[1]*Institute of Human Genetics, University Medical Center of the Johannes Gutenberg University Mainz, Mainz, Germany,* [2]*Department of Internal Medicine I, University Medical Center of the Johannes Gutenberg University Mainz, Mainz, Germany.*

The two main types of Inflammatory bowel diseases (IBD) are Crohn's disease (CD) and Ulcerative colitis (UC): CD can affect the whole bowel wall of each part of the gastrointestinal tract, while UC is restricted to the mucosa of the colon and the rectum. The etiology of IBD is unknown but thought to involve environmental, immunological, microbiological and genetic factors. A contribution of epigenetic factors to IBD pathogenesis has been assumed but not been studied in detail up to now. We used using bisulfite pyrosequencing to investigate the methylation levels at the promotor regions of nine IBD candidate genes in inflammatory and non-inflammatory terminal ileal and colonic mucosal biopsies from IBD patients as well as terminal ileal and colonic mucosal biopsies from non-IBD patients (controls). Our analysis revealed no significant methylation differences between terminal ileal biopsies of CD patients and controls. MUC6 and IL17REL, however, displayed significantly increased methylation levels in inflammatory colon samples of CD patients compared to non-inflammatory patient samples and control samples. Methylation levels of MUC2, MUC6 and IL17REL were even more significantly increased in non-inflammatory and inflammatory colon samples of UC patients compared to controls. MUC15 was the only gene with a significantly decreased methylation detected in both non-inflammatory and inflammatory colon samples of UC patients. Overall, the detected DNA methylation changes appeared to correlate with the progression of IBD. A comprehensive understanding of the epigenetic mechanisms contributing to IBD will likely enable development of new therapeutic agents and strategies targeting epigenetically dysregulated genes.

CHERISH - Improving Diagnoses of Mental Retardation in Children in Eastern Europe and Central Asia through Genetic Characterisation and Bioinformatics/Statistics - a GENOMIC PROJECT

C. Graziano[1]*, E. Bonora*[1]*, J. A. Hettinger*[2]*, K. Männik*[3]*, P. Magini*[1]*, M. Badura-Stronka*[4]*, E. Õiglane-Slik*[3]*, J. Kasnauskienè*[5]*, I. Lebedev*[6]*, M. Havlovicova*[7]*, D. Babikyan*[8]*, L. A. Livshits*[9]*, T. Sarkisian*[8]*, A. Latos-Bieleńska*[4]*, V. Kučinskas*[5]*, Z. Sedlacek*[7]*, P. C. Patsalis*[2]*, A. Kurg*[3]*, G. Romeo*[1]*;*
[1]*U.O. Genetica Medica Università di Bologna, Bologna, Italy,* [2]*Department of Cytogenetics and Genomics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus,* [3]*IMCB Dept. of Biotechnology University of Tartu, Tartu, Estonia,* [4]*"Poznań University of Medical Sciences" Department of Medical Genetics, Poznań, Poland,* [5]*Department of Human and Medical Genetics, Vilnius, Lithuania,* [6]*Institute of Medical Genetics, Russian Academy of Medical Sciences, Tomsk Scientific Centre, Tomsk, Russian Federation,* [7]*Charles University Prague 2nd Medical School, Department of Biology and Medical Genetics, Prague, Czech Republic,* [8]*Laboratory of Molecular Genetics Center of Medical Genetics and Primary Health Care, Yerevan, Armenia,* [9]*National Academy of Sciences of Ukraine IMBG, Kiev, Ukraine.*

The CHERISH consortium was funded by EU FP7 under grant agreement #223692 and its first aim was the creation of a large collection of patients with developmental delay (syndromic and non-syndromic), mainly from Eastern Europe. General information and updates can be retrieved through http://www.cherishproject.eu/.

During the first 2 years of the project, 233 patients underwent analysis through a 44K (135 patients) or 105K (the remaining 98) array platform, to search for cryptic chromosome rearrangements. Of these, 166 patients were carriers of benign CNVs only, while 34 patients had "pathogenic" anomalies and 33 patients were carriers of a total of 39 variants of uncertain pathogenicity. Analysis of these last variants is underway.

SNP-array analysis was performed on another group of patients (~450). Analysis of variants is more complex due to high resolution of this assay and is being carried out by each partner. For instance, out of 95 patients analyzed in the Armenian cohort, 7 had known micro-del/dup syndromes, 11 had variants interpreted as pathogenic, while 7 variants are still under investigation.

A subset of patients with X-linked intellectual disability underwent analysis through a highly specific array, covering most exons from known X-chromosome genes. Out of 46 cases, 41 turned out normal while 5 cases need further investigation.

Global analysis of the identified variants will be presented.

As a last part of the project, selected familial cases (1 autosomal dominant, 3 X-linked and 8 autosomal recessive), where chromosome rearrangements had been excluded, will undergo exome analysis through next generation sequencing.

P11.060

Seeking for novel genes for autosomal recessive intellectual disability in overlapping runs of homozygosity in a large sample of consanguineous families

J. Bauer[1], *K. Eberlein*[1], *R. Buchert*[1], *S. Uebe*[1], *A. Abboud*[2], *A. Al-Khateeb*[2], *M. Fakher*[2], *S. Hamdan*[2], *A. Ismael*[2], *S. Muhammad*[2], *A. Ekici*[1], *J. Schumacher*[3,4], *M. Nöthen*[3,4], *A. Reis*[1], *R. Abou Jamra*[1];
[1]*Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany,* [2]*Practising Paediatricians, Syria, Syrian Arab Republic,* [3]*Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany,* [4]*Institute of Human Genetics, University of Bonn, Bonn, Germany.*

A significant part of the unsolved cases of intellectual disability is probably of autosomal recessive inheritance pattern and shows an extreme heterogeneity. To discover novel genes causing autosomal recessive intellectual disability (ARID), 93 simplex, consanguineous families of Syrian descent with affected members were clinically examined and 316 individuals were genome-wide genotyped using SNP chips (Illumina 610K and CytoSNP as well as Affymetrix 6.0). We conducted autozygosity mapping and identified 552 runs of homozygosity (ROH). Fourteen families showed one ROH, 44 families showed two, three or four ROHs, and 35 families showed five or more ROHs. We considered highly interesting candidate regions, i.e. with five or more overlapping ROHs, and selected 31 candidate genes based on expression, function, and results of association studies of neurological phenotypes. We Sanger sequenced the genes in all candidate families. Subsequently, we identified 14 not annotated (dbSNP 132) candidate mutations and *in silico* analyzed them with help of the programs *MutationTaster*, *PolyPhen*, and *SIFT*. In 4 cases, the analysis predicted a pathogenic effect of the candidate mutations and those were examined by genotyping in a Syrian healthy control sample of 95 individuals. All candidate mutations were excluded because of relatively high frequencies in controls. Our analysis shows an extreme heterogeneity of ARID and suggests that massive parallel sequencing is a better strategy to elucidate its causes.

P11.061

Screening of a cohort of patients with intellectual disabilities from Cyprus using a high-resolution 400K microarray

J. Hettinger[1], *P. Evangelidou*[1], *C. Sismani*[1], *V. Anastasiadou*[2,3], *P. C. Patsalis*[1];
[1]*Department of Cytogenetics and Genomics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus,* [2]*Department of Clinical Genetics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus,* [3]*Department of Pediatrics, Arch Makarios III Hospital, Nicosia, Cyprus.*

Intellectual Disabilities (ID) are very heterogeneous conditions with an estimated prevalence of ~1-3%. While it is estimated that genetic factors contribute to ID in ~50% of affected individuals, the identification of autosomal loci and chromosomal regions associated with ID has been challenging. One approach for the identification of copy number changes unique to individuals with ID is by array-CGH. The availability of custom-designed high-resolution oligonucleotide arrays enables interrogation at an extraordinary resolution and coverage not previously experienced with older platforms. The purpose of our study was to screen a cohort of patients from Cyprus using a new whole-genome 400K microarray which we designed, optimized and validated. Our new high-resolution array consists of >400,000 probes, and includes the entire 4X180K ISCA design as well as comprehensive coverage of >9,000 CNV regions identified by the WTCCC. In addition, ~200,000 probes were used to generate a high-resolution backbone spanning the entire genome. Here we report the preliminary results obtained from the initial screening of 12 patients and family members from 9 Cypriot families. CNCs were identified in 7 patients and included 5 duplications and 3 deletions that ranged in size from ~99kb to ~7Mb. All of the duplications and two of the deletions harbored several genes while one deletion resided in a single gene. Family studies are in progress to determine segregation of the aberrations with the disease and association with the phenotype. In addition, the performance of this new platform for the detection of CNCs associated with ID will be assessed.

P11.062

Large-scale validation and genotyping of inversions in the human genome by inverse PCR

C. Aguado[1], *S. Villatoro*[1], *D. Izquierdo*[1], *X. Estivill*[2], *M. Cáceres*[1,3];
[1]*Institut de Biotecnologia i Biomedicina, Universitat Autonòma de Barcelona, Bellaterra, Barcelona, Spain,* [2]*Genes and Disease Program, Center for Genomic Regulation (CRG-UPF), Barcelona, Spain,* [3]*Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain.*

In the last years, different types of structural variants (SVs), have been discovered in the human genome and their importance to human health has become increasingly clear. Typically arrays have been used to characterize unbalanced changes. Inversions, however, are more difficult to study and less known. In this study we investigate the general applicability of inverse PCR (iPCR) for the analysis of inversions. We have tested different reagents and conditions to optimize the iPCR method and designed a high-throughput iPCR protocol to genotype inversions in a large number of individuals in just one day and with a small amount of DNA (10 ng for each inversion). As an example of the potential use of this method, we have analyzed 19 inversions predicted in humans with a size between 8 kb to 200 kb and mediated by inverted repeat sequences of 1.5-25 kb. First, we validated 17 of the 19 inversions in a panel of 9 Hapmap individuals (Yoruba, European, and Asian). Then, we genotyped these inversions in >60 additional European individuals and found total frequencies for the inverted allele between 1.5% and 62%. For these inversions we also checked the genetic transmission in ~10 mother-father-child european trios. Finally, we have determined the possible gene effects of the validated inversions, with around half of them changing the orientation of genes or exchanging the 3´or 5´ regions. In conclusion, the iPCR is a powerful, simple and fast method for high-throughput validation and genotyping of a wide range of inversions.

P11.063

Producing iPS cells: a biobank service for translational genetic research

D. A. Coviello[1], *M. Castagnetta*[1], *C. Baldo*[1], *S. Viaggi*[1], *F. Fruscione*[2], *F. Zara*[2], *C. Minetti*[2];
[1]*E.O. Ospedali Galliera, Genova, Italy,* [2]*IRCCS Istituto G. Gaslini, Genova, Genova, Italy.*

The goal of this project is to use the expertise of the Laboratory of Human Genetics and the Galliera Genetic Bank (GGB) to provide researcher with the possibility to obtain induced Pluripotent Stem Cells (iPSCs) from samples of patients involved in a specific research project. The iPS cell lines are validated using classical cytogenetic karyotype, immunofluorescence assay and RT-PCR, in order to be ready to be used by the researcher requesting the service. The iPSCs are a powerful tools to perform in vitro functional analysis of mutation causing diseases. The application of this tool will be to investigate the effects of mutations causing epilepsy and to assess the effect on neuronal membrane excitability of different neuron subtypes, to shed light into molecular pathways regulating brain functions and biological events leading to epileptic seizures. We have generated iPS cells using STEMCCA vector, that allows the most efficient generation of iPS cells, combined with the high availability of the cell lines stored in GGB/TGB Network. STEMCCA vector is a single lentiviral „stem cell cassette“ encoding all four reprogramming factors, OSKM in a single polycistronic vector. By combining all reprogramming transgenes in a single cassette, STEMCCA accomplish reprogramming of fibroblasts with high efficiency and allow the derivation of iPSC containing a single viral integration. It is also available a excisable version of gene cassette vector flanked by loxP sites to achieve highly efficient reprogramming of normal or diseased fibroblasts to allow the derivation of human iPSC free of exogenous transgenes.

P11.064

Assessment of promoter DNA methylation for an entire family of laminin-encoding genes in normal and tumorous breast tissues

O. A. Simonova[1], *E. B. Kuznetsova*[1,2], *V. V. Rudenko*[1,2], *O. V. Babenko*[1,2], *T. V. Kekeeva*[1,3], *D. V. Zaletaev*[1,2], *V. V. Strelnikov*[1,2];
[1]*Research Centre for Medical Genetics, Moscow, Russian Federation,* [2]*I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation,* [3]*Hertzen Cancer Research Institute, Moscow, Russian Federation.*

Laminins are key components of the extracellular matrix playing important roles in morphogenesis of breast tissues and involved in normal development and pathological processes. We evaluated methylation status for 12 promoter regions of laminin-encoding genes in 106 samples of breast cancer, 106 paired adjacent nonmalignant samples, 4 samples of normal mammary gland from autopsy, 30 samples of peripheral blood and 7 samples of buccal epithelium of healthy donors.

Promoters of 6 genes, *LAMA1, LAMA2, LAMA3B, LAMA4, LAMB1*and *LAMC3* have demonstrated abnormal methylation in 2% to 42% samples of breast cancer and/or adjacent tissues.

Promoters of the *LAMA3A, LAMB2, LAMB3* genes were constitutively methylated in breast tissues as well as in normal lymphocytes and buccal swabs, and of the *LAMC2* in breast tissues only. Our findings contradict previously reported abnormal methylation of laminin-5-encoding genes *LAMA3A, LAMB3* and *LAMC2* in 44%, 4%, and 20% of breast tumors respectively against the background of next to never methylated nonmalignant breast tissues, normal lymphocytes and buccal swabs (Sathyanarayana et al., 2003). Our results are supported by recently published Reduced-Representation-Bisulfite-Sequencing and our own bisulfite sequencing data. Constitutive methylation of laminin-5-encoding genes abandons its use as a marker of the pathological process and requires revision of the mechanisms of disregulation of these genes in cancer.

This study is among the first to evaluate promoter methylation for the whole family of cancer-related genes.

	Methylation in breast cancer and/or adj. nonmalignant samples (%)	Methylation in normal mammar gland from autopsy (%)	Methylation In buccal epithelium (%)	Methylation In peripheral Blood (%)

New non-invasive test for Limb Girdle Muscle Dystrophies type 2

B. Lace[1], *I. Innaskina*[1], *E. Jankevics*[1], *I. Vasiljeva*[1], *M. Naudina*[1], *J. Strautmanis*[1], *J. Stavusis*[1], *I. Micule*[2];
[1]*Latvian Biomedical Research and Study centre, Riga, Latvia,* [2]*Childrens' University Clinical Hospital, Riga, Latvia.*

One over 8000 persons worldwide are effected by inherited or acquired neuromuscular diseases (NMD) presenting with muscle weakness, skeletal deformities, early loss of functions and mortality. The most common type of NMD is muscular dystrophies, which also have the most unfavourable outcome. Diagnostic pathway requires invasive muscle biopsy, later molecular confirmation.

Aim of the study was to develop non-invasive DNA based test for the common Limb Girdle muscle dystrophies (LGMD) mutations.

Materials and methods. Twenty patients with symptoms of LGMD without muscle biopsy data were recruited in various NMD centres. Illumina GoldenGate technology was applied for the 82 selected mutations in DYSF (35 sequence variations), CAPN3 (28), SGCA (8), SGCB (4), SGCD (3) and SGCG (4) genes.

Results. LGMD diagnosis was confirmed in six persons (30%) with applied DNA diagnostics technique. CAPN3 gene mutation 550delA were identified in 59 % of identified mutations, 2184G>A in 6 %, 664G>A in 5%, DYSF 2372C>G in 12 %, 1566C>G in 12 %, 1368C>A in 6%.

Conclusions. 550delA mutation in the CAPN3 gene is considered as a Slavic founder mutation, and it is frequently met in LGMD2A patients from Eastern Europe.

Non invasive DNA test is advisable for patients with LGMD prior muscle biopsy.

P11.066

Limb Girdle muscle dystrophies mutation analysis using Illumina's VeraCode GoldenGate Genotyping Assay

I. Inashkina[1], *I. Vasiljeva*[1], *E. Jankevics*[1], *J. Stavusis*[1], *I. Micule*[2], *B. Lace*[1];
[1]*Latvian Biomedical Research and Study Centre, Riga, Latvia,* [2]*Children's University Clinical Hospital, Riga, Latvia.*

Limb-girdle muscular dystrophies (LGMDs) are a group of muscular dystrophies characterized by a predominant involvement of the scapula, pelvic girdle and trunk muscles without affecting the facial muscles. Different autosomal recessive LGMDs (>10) have been identified as distinct entities with a similar phenotype and clear clinical overlap that makes their differential diagnosis difficult. To date, several hundreds different mutations have been described with their biological relevance remain unclear.

We have developed genotyping analysis of 96 mutations - insertions/deletions and SNP, within different genes related to LGMDs (SGCA, SGCB, SGCD, CAPN3, DYSF, several more mutations, and 4 control SNP within X/Y chromosomes) using Illumina's VeraCode GoldenGate Genotyping Assay.

Here we report study analysing a group of 107 unrelated Latvian controls with no sign of neuromuscular diseases matching general Latvian population by gender and nationality with our developed assay. 31 mutations had minor allele frequency (MAF) higher that 0.01 (0.014 - 0.294) suggesting no confirmation of their pathological effect.

Our data suggest that miscellaneous mutations found in LGMD patients and described as pathological need to be studied more intensively in terms of general population to clarify their effect.

VarioML micro-framework for comprehensive variation data representation and exchange

M. Byrne;
Institute for Molecular Medicine Finland, Helsinki, Finland.

The VarioML micro-framework is a set of tools and practices improving the availability, quality, and comprehensivity of human variant information. It enables researchers and clinics to share that information with ease, clarity, and without ambiguity. Sharing of variation data is a critical need, yet attempts to meet this need have come up against difficulties at each level of design and implementation. Variant information can be arbitrarily complex, making a single standard vocabulary elusive and re-formatting difficult. Complex standards have proven too time-consuming for clinicians to implement.

The GEN2PHEN project addressed these difficulties by developing a comprehensive data model for capturing biomedical observations, Observ-OM, and building the VarioML micro-framework around it. VarioML pairs a simplified open specification for describing variants, with a toolkit for adapting the specification into one's own research or clinical workflow. Straightforward variant data can be captured, federated, and exchanged with no overhead; more complex data can be described, without loss of compatibility. The open specification enables push-button submission to gene variant databases (LSDB's) e.g., LOVD (http://lovd.org), using the free Cafe Variome data publishing service (http://cafevariome.org/), while the micro-framework bidirectionally transforms data between semantic and web-application code formats, opening up new possibilities for open source web applications building on shared data. Semantic vocabularies and translation schemas allow variant data to be part of the semantic web. A JAVA implementation toolkit makes VarioML easily integrated into biomedical applications.

VarioML has received funding from the European Community's Seventh Framework Programme (FP7/2007-2013) under the GEN2PHEN project (grant agreement number 200754).

Genomic organization of macrosatellite repeats

M. Schaap[1], *R. Maassen*[1], *P. J. van der Vliet*[1], *L. F. Hoogerheide*[2], *H. K. van Dijk*[3], *R. J. L. F. Lemmers*[1], *P. de Knijff*[1], *S. M. van der Maarel*[1];
[1]*Leiden University Medical Center, Leiden, Netherlands,* [2]*VU University, Amsterdam, Netherlands,* [3]*Erasmus University, Rotterdam, Netherlands.*

Macrosatellite repeats (MSRs) comprise a significant proportion of the human genome, usually spanning hundreds of kilobases of genomic DNA. Because of their highly polymorphic nature, MSRs represent an extreme example of copy number variation, but their structure and function is largely understudied. This study comprises the genetic analysis of autosomal and X chromosomal MSRs of HapMap individuals representing Caucasian, Asian and African populations. Copy number variation, repeat stability and genetic heterogeneity of the autosomal macrosatellite repeats RS447 (chromosome 4p), MSR5p (5p), FLJ40296 (13q), RNU2 (17q) and D4Z4 (4q and 10q) and X chromosomal DXZ4 and CT47 were investigated. Repeat array size distributions show that these MSRs are indeed highly polymorphic with the highest genetic variation among Africans and the least among Asians. A mitotic mutation rate of 0.4-1.5% was observed, exceeding meiotic mutation rates and explaining the high size variability found for these MSRs. Rather than a uniform size distribution we observed a multimodal size distribution in seven MSRs using a Bayesian approach for the estimation, where for five of these MSRs the posterior probability was larger than 99.33%. In three of these five MSRs equidistant intervals between the modes were very likely as well, suggesting that MSR sizes are restricted and that MSRs are possibly organized into higher order chromatin structures. This study represents the first comprehensive study of MSRs in world populations identifying novel commonalities and differences in the organization and function of the human genome.

Intellectually disabled children with normal molecular karyotypes: Genome-wide screening for altered methylation

I. Tangen[1], P. Sporns[1], S. Bens[1], J. Gutwein[1], U. Jacobsen[1], M. Rydzanicz[2,3], U. Stephani[4], G. Gillessen-Kaesbach[5], R. Siebert[1], O. Ammerpohl[1], ***A. Caliebe[1]****;*
[1]Institute of Human Genetics, Christian-Albrechts-Universitaet zu Kiel and UKSH, Campus Kiel, Kiel, Germany, [2]Institute of Human Genetics, Polish Academy of Science, Poznan, Poland, [3]Institute of Molecular Biology and Biotechnology, Faculty of Biology, University of Adam Mickiewic, Poznan, Poland, [4]Department of Neuropaediatrics, Christian-Albrechts-Universitaet zu Kiel and UKSH, Campus Kiel, Kiel, Germany, [5]Institut fuer Humangenetik, Universitaet zu Luebeck, Luebeck, Germany.

The aim of this study was to evaluate the impact of epigenetic alteration for intellectual disability (ID). We evaluated 81 clinically well characterised patients with ID. Most of them showed in addition muscular hypotonia, short stature, obesity or epilepsy. In these patients a monogenetic disorder could clinically not be diagnosed. All showed normal results on ArrayCGH (105K or 244K Agilent Array). Epigenetic alterations were analysed using the Illumina HumanMethylation450K Bead Chip, covering more than 485.000 CpG sites. The control group consisted of age and sex matched patients mainly affected by recurrent upper airway infections.

The analysis for differences in methylated loci between the patient and control group revealed 266 differentially methylated loci which were enriched for HLA, the interferon gamma-pathway, and antigen presentation. As this global comparison of both groups is not suited to detect private DNA methylation aberrations we are currently investigating local enrichment of DNA methylation changes aiming to identify methylation changes over several consecutive CpGs being typical e.g. for epimutations at imprinted loci. This strategy is driven by the observation that we identified one proband in the patient group with hypomethylation in MEG3. This finding was corroborated by bisulfite pyrosequencing.

Our results show that imprinting disorders are still underdiagnosed and may have a possible impact on ID. This is in agreement with the results of (1) who analysed a comparable cohort of 90 patients for known imprinting disorders and found two patients with Silver-Russell- respectively Beckwith-Wiedemann syndrome.

P11.070
Molecular and cytogenetic screening of children with idiopathic mental retardation in Ukrainian population

L. A. Livshits[1]*, E. Bonora[2], P. Magini[2], P. Patsalis[3], J. A. Hettinger[3], N. Hryshchenko[1], O. Soloviov[1], A. Kucherenko[4,1], C. Graziano[5];*
[1]Institute of Molecular Biology and Genetics, Kiev, Ukraine, [2]U.O. Genetica Medica, University of Bologna, Bologna, Italy, [3]Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus, [4]Taras Shevchenko Kiev National University, Kiev, Ukraine, [5]U.O. Genetica Medica, University of Bologna, Bologna, Cyprus.

Mental retardation (MR) is a generalized term, which includes disorders of adaptive behavior associated with a lack of cognitive development. MR occurs in 2-3% of the general population. In the majority of MR individuals a specific cause can not be identified.

We represent the data of 113 patients from 96 Ukrainian families with well clinically characterized MR included in the CHERISH project (grant agreement n°223692). Preliminary analysis (metabolic investigation, karyotype, molecular tests of known syndromes, MLPA for subtelomeric rearrangements) have been done. We found 1 patient with FRAXE expansion and 2 patients with Prader-Willi Syndrome. In 57 patients with normal results or with complex chromosomal rearrangements search for cryptic chromosome rearrangements was carried out through 44K, 105K or 400K array-CGH analysis in partner laboratories in Bologna (Italy) and Nicosia (Cyprus). Quantitative Real Time PCR were used to confirm the array-CGH findings. In total, copy number variations (CNVs) in patients from 26 Ukrainian MR families were detected (size: from 11Kb to 24378 Kb). CNVs with potential clinical significance were found in 9 cases. These CNVs were characterized as pathogenic or probably pathogenic, based on their size, position and genes involved in.

The obtained results show the strong genetic heterogeneity of hereditary forms of MR in our group of patients. These results generally agree with those of previous array-CGH cohort studies, showing, however, previously unreported genomic rearrangements in MR and a higher incidence of clinically relevant CNVs.

P11.071
Mutation screening of new candidate genes for mental retardation by next generation sequencing

S. Boppudi*, I. Schanze, I. Wieland, D. Schanze, M. Zenker;*
Institut für Humangenetik, Universitätsklinikum, Otto-von-Guericke-Universität, Magdeburg, Germany.

Next-generation sequencing (NGS) technologies generate high throughput sequence data very rapidly at a lower cost by massively parallel sequencing of clonally amplified DNA molecules. NGS is anticipated to transition into clinical-diagnostics use by avoiding massive PCR preparation and sequencing of multiple large regions of interest simultaneously. For the successful transition streamlining of processes is required, especially sample preparation, coupled with improvements in technology robustness and characterization of accuracy through validation studies. The purpose of this study was to establish the amplicon-based NGS technology for screening novel mutations in mental retardation (MR) patients. In this pilot project, 'Universal Tailed' Amplicon sequencing method was used. The amplicon library preparation was optimized by using multiplex PCR. We performed mutation detection of complete coding regions of two genes (total 32 amplicons) implicated in MR in 40 individuals on a bench-top 454 GS Junior platform (Roche). The 10-hr run was able to generate approximately 72,000 reads and about 22 million high-quality bases at an average read length of 308 bp. Altogether, 12 sequence variants were found in this study with seven known SNPs and five novel changes. All the variants were confirmed by traditional Sanger sequencing providing evidence of NGS accuracy. In conclusion, next-generation amplicon sequencing with enhanced efficiency and accuracy can be used as an efficient tool for high sensitive mutation detection in large patient cohorts and complex phenotypes. We identified one mutation in these two genes that may potentially be involved in MR and need to be studied in larger patient samples.

P11.072
Methylation analysis of breast cancer in Cyprus and Slovenia

M. Loizidou[1]*, I. Zouvani[2], S. Novakovic[3], V. Stegel[3], M. Krajc[3], K. Kyriacou[1], A. Hadjisavvas[1];*
[1]Department of EM / Molecular Pathology, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus, [2]Histopathology Department, Nicosia General Hospital, Nicosia, Cyprus, [3]Institute of Oncology, Ljubljana, Slovenia.

The best-studied epigenetic alteration in cancer is DNA methylation. It has been demonstrated that during tumorigenesis methylation is usually decreased at a genome-wide level, with selective hypermethylation of CpG islands occurring within the promoter regions of a number of tumor-suppressor genes. This leads to transcriptional silencing of these genes and subsequent tumor progression. Analysis of abnormally methylated genes has received a lot of attention lately since it is a feature of most cancers and is speculated to play a role in cancer etiology. Within the scope a bilateral project between Cyprus and Slovenia we investigated quantitative methylation changes in twenty four tumor suppressor genes, with the ultimate goal of identifying novel biomarkers applicable to the management of breast cancer patients. Methylation study was performed on 100 matched normal and tumor paraffin-embedded breast tissues from Cyprus and Slovenia, using methylation-specific MLPA. The cumulative methylation index (CMI) was calculated as the sum of the percentage methylation for all genes. Mann-Whitney and Kruskal-Wallis tests were used for comparing medians between groups. The χ2-test was used for comparing proportions. Hierarchical clustering was applied using R and SPSS statistical packages. Our results showed promoter methylation of in a number of tumor suppressor genes. The prognostic value of promoter hypermethylation is currently being further evaluated by studying additional samples.

P11.073
Rapid and efficient mutation detection in the mitochondrial DNA using a bench-top next-generation DNA sequencer

M. Bigler, S. Gallati, ***A. Schaller****;*
Division of Human Genetics, Bern, Switzerland.

Mitochondria play an important role in essential cellular functions. Each eukaryotic cell contains hundreds of mitochondria with hundreds of mitochondrial genomes (mtDNA). Human mtDNA is a 16,569-kb circular, double-stranded molecule, which contains 37 genes: 2 rRNA genes, 22 tRNA genes, and 13 structural genes encoding subunits of the mitochondrial respiratory chain, where ATP is generated. Mutant and wild-type mtDNA may co-exist as heteroplasmy, and cause human disease with diverse and variable clinical features and a loose genotype-phenotype relationship. Next-generation sequencing (NGS) technologies can be a boon to human mutation detection given their high throughput: consequently, many genes and samples may be simultaneously studied with high coverage for accurate detection of heteroplasmy. In circumstances requiring the intensive study of a few genes, particularly in clinical applications, a rapid turn around is another desirable goal. To this end, we assessed the performance of the bench-top 454 GS Junior platform as an optimized solution for mutation detection by amplicon sequencing. The purpose of this protocol is to simultaneously determine mtDNA sequence and quantify the heteroplasmic level. This protocol includes two independent PCR amplifications of the entire mitochondrial genome. Resulting PCR products are then mixed at an equimolar ratio. Subsequently, samples of twelve individuals are then barcoded and sequenced with high-throughput, next-generation sequencing technology. A 10-hr run was able to generate ~72,000 reads and ~25 million high-quality bases at an average read length of 348 bp. This technology is highly sensitive, specific, and accurate in determining mtDNA mutations and the level of heteroplasmy.

P11.074

Mitochondrial DNA analysis in the Genome of the Netherlands

M. Vermaat[1]*, M. Li*[2]*, J. T. den Dunnen*[1]*, P. de Knijff*[1]*, M. Stoneking*[2]*, J. F. J. Laros*[1]*;*
[1]*Leiden University Medical Center, Leiden, Netherlands,* [2]*Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany.*

The Genome of the Netherlands (GoNL) is a national collaboration aimed at establishing a map of Dutch genetic variation by whole genome sequencing of 250 trio families consisting of unselected individuals of Caucasian origin. The unprecedented trio-based setup of this scale and the abundance of mtDNA in each sample give us the unique opportunity to study both population-wide and intra-human variation on the mitochondrial genome.

We developed a number of techniques in which mtDNA can assist in quality control of whole genome sequencing experiments. The high coverage (averaging ~1100x) enables us to easily detect

sample contamination with a low percentage of foreign DNA. One such case is present in our data set and its contamination has been confirmed by autosome analysis. By looking for violations of the inheritance pattern we readily identified sample swaps. Indeed, in two of the trios there had been a swap of the parents which was independently confirmed by immunochip data.

One of the goals of our mtDNA study is to refine the Dutch mtDNA phylogenetic tree. Preliminary results show that the data set contains more than 165 different haplogroups, where H and its subclades are most abundant, representing ~40% of individuals. This is in concordance with previous studies on the distribution of haplogroup H in Europe. 127 haplogroups are supported by at least 2 individuals, while 68 are supported by at least 4. Our samples disagree on defining polymorphisms for some haplogroups, indicating opportunities for refinement of the phylogenetic tree.

P11.075

A simplified Sanger sequencing workflow for mitochondrial variant detection provides high data quality

M. Wenz*, P. Ma;*
Life Technologies, Foster City, CA, United States.

Variations in the human mitochondrial genome are frequently used in forensic analyses, disease association research and human evolution. Because of the abundance of variations in mitochondrial DNA, either the complete mitochondrial genome or the critical region is sequenced. We present here a new PCR/sequencing workflow for mitochondrial DNA that uses capillary electrophoresis and that is integrated with data analysis and variant detection. This simplified re-sequencing workflow utilizes novel universal M13 sequencing primers for improved 5' sequence resolution, increased throughput, and reduced hands-on time. This workflow generates high quality bases from base 1 when using POP-7™ polymer comparable to data typically seen when using the considerably slower POP-6™ polymer and standard Sanger sequencing chemistry. In addition to improved 5' data quality the new workflow eliminates the need for a separate PCR clean-up step. Taken together these improvements reduce the entire workflow from PCR to finished sequence data to under 5 hours, compared to approximately 8 hours for the standard workflow. The sequencing output is analyzed with Variant Reporter® Software that applies quality control metrics, including the use of Quality Values for DNA trace values and confidence values for variant validity. We will present examples to demonstrate this mitochondrial re-sequencing workflow for variant detection.
Research Use Only

P11.076

Changes of DNA mismatch repair MLH1 promoter methylation and expression in DMT2 patients after a dietary intervention

O. J. Switzeny[1]*, E. Müller*[1]*, K. Wagner*[1]*, H. Brath*[2]*, A. G. Haslberger*[1]*;*
[1]*Department of Nutritional Sciences of the University of Vienna, Vienna, Austria,* [2]*WGKK Gesundheitszentrum Wien Süd, Vienna, Austria.*

The genotoxic effects caused by reactive oxygen species (ROS) are among the most common DNA damage causes. Oxidative stress may lead to an increased level of unrepaired cellular DNA damages, discussed for tumor initiation. Mismatch repair (MMR) enzymes act as proofreading complexes that maintain the genomic integrity. MMR-deficient cells show an increased mutation rate. A diet containing a high amount of antioxidants lowers the potential harmful effects of ROS. The MutL homolog 1 (MLH1) gene belongs to the MMR complex.

Objectives: The influence of an antioxidant and vitamin rich diet on the epigenetic pattern of MLH1 was analyzed in non-insulin depended diabetes Mellitus type 2 (NIDDM2), impaired fasting glucose (IFG) patients and a lean control (LC) group.

Methods: CpG methylation of the MLH1 and MGMT promoter region was analyzed by pyrosequencing. Gene expression of MLH1 was measured by quantitative RT-RCR cDNA. DNA integrity was evaluated by COMET Assay.

Results and Discussion: The region on the forward strand of the MLH1 had higher methylation level in both intervention groups ($p<0.05$) after the intervention. The expression of the MLH1 gene decreased ($p<0.15$) in both groups. IFG and NIDDM2 groups showed makeable differences. The COMET Assay data suggests that the DNA stability was increased and a correlation between the expression of MLH1 and the DNA damage was found in the IFG group ($p<0.05$). The down-regulation of the MLH1 expression correlating with the observed increased CpG promoter methylation might reflect a lower MMR requirement by the higher DNA stability following the dietary intervention.

P11.077

A DNA resequencing array for genes involved in MODY/Type 2 Diabetes: a new era in clinical and molecular diagnosis

S. Giglio[1]*, A. Provenzano*[1]*, B. Mazzinghi*[2]*, R. Artuso*[2]*, E. Contini*[2]*, L. Giunti*[2]*, S. Toni*[3]*, M. Salvadori*[4]*, O. Zuffardi*[5]*, E. Mannucci*[6]*;*
[1]*Dept. of Clinical Pathophysiology and Medical Genetics Unit- Meyer Children Hospital, Florence, Italy,* [2]*Medical Genetics Unit- Meyer Children Hospital, Florence, Italy,* [3]*Paediatric Diabetology Unit- Meyer Children Hospital, Florence, Italy,* [4]*Clinical Biochemistry Unit- Meyer Children Hospital, Florence, Italy,* [5]*Medical Genetics, University of Pavia, Pavia, Italy,* [6]*Section of Geriatric Cardiology and Medicine, Department of Cardiovascular Medicine, Careggi Hospital, Florence, Italy.*

Genetic testing for MODY has become a routine procedure allowing to set up proper treatment and discriminate from type 2 diabetes (T2D) whose symptoms are often overlapping. Common variants implicated in risk of diabetes explain only a minor proportion of the familial clustering observed in sporadic cases. We apply targeted resequencing technology to detect both known and novel mutations on a single high-throughput platform. We until now resequenced 12 cases with clinical diagnosis of MODY/T2D for 46 genes involved in this disorder. All the detected variations were confirmed by direct sequencing and potential pathogenicity was assessed by functional predictions and frequency in controls. We identified modest associations with common variants and a trend suggestive of an overrepresentation of rare variants in cases compared to controls for several genes, although it is plausible that combinations of rare and/or common variants in genes already implicated might explain the genetic basis of the disease. Between detected variants, we focus on 11, of which 2 are double heterozygous and plausibly pathogenic. In addition, our data show that, at least in the Italian population, mutations in the *PDX1* are likely the second cause of MODY/T2D, and that many patients resistant to traditional therapies are double heterozygous for some genes individually associated with diabetes/hyperglycemia.Next-generation sequencing technologies are becoming the first tier for an immediate understanding of the molecular basis of most diseases. Altogether, these efforts should allow to better understand the disease pathogenesis, find new targets for clinical therapy, and allow prediction of disease.

P11.078

Mosaic Homozygosity Reporter: A tool to detect low levels of revertant mosaicism in SNP array data.

E. T. P. Verwiel[1]*, J. Y. Hehir-Kwa*[1]*, E. J. Kamping*[1]*, R. Pfundt*[1]*, Y. Heijdra*[2]*, T. Vulliamy*[3]*, I. Dokal*[3]*, A. Geurts van Kessel*[1]*, N. Hoogerbrugge*[1]*, M. J. L. Ligtenberg*[1]*, M. C. J. Jongmans*[1]*, R. P. Kuiper*[1]*;*

and Molecular Science, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, United Kingdom.

Revertant mosaicism is a phenomenon that occurs when the replacement of a pathogenic allele by the wild type allele favors cell-survival. Especially within a tissue with high turnaround time, such as blood, this can lead to near complete replacement of the pathogenic allele by the wild type allele. The presence of two copies of one allele can be detected by genome-wide single nucleotide polymorphism (SNP) arrays. However, when stretches of homozygosity are present in a small percentage of cells, like in the early stage of revertant mosaicism, these are often missed by allelic algorithms.

Here we present Mosaic Homozygosity Reporter, a method that facilitates the detection of low levels of allelic imbalance using the genotyping data from SNP arrays. The method detects mosaic stretches of homozygosity with high sensitivity by comparing the signal distribution of heterozygous calls between telomeric regions.

We have applied this method on Affymetrix SNP6.0 array data from 19 individuals with an autosomal dominant form of Dyskeratosis Congenita (DC), a multisystem disorder. The Mosaic Homozygosity Reporter detected mosaic reversion in blood cells of six patients with high significance (P<7.9•10-25), two of which could not be detected by visual inspection of the array's B-allele frequency plots. These data show that revertant mosaicism may be a common event in autosomal dominant DC and that Mosaic Homozygosity Reporter is able to detect low level mosaic stretches making it a valuable tool for the reanalysis of previously unsolved clinical cases where mosaic homozygosity may play a role.

P11.079

Searching for Multiple sclerosis genomic candidate regions by genome-wide synthesis of heterogeneous data sources

***A. Maver**, B. Peterlin;*
Institute of Medical Genetics, Ljubljana, Slovenia.

Multiple sclerosis (MS) is a debilitating autoimmune condition characterized by demyelination in central nervous system, leading to symptoms of severe motosensory neurological disturbances. Development of high -throughput technologies opened the possibility of scrutinizing complete profile of molecular alterations in MS. Inherent statistical issues of multiple testing and high false-positive rates have, however, hampered attempts to entirely elucidate molecular background.

To propagate discovery and increase detection specificity of these studies, we performed an integrative synthesis of data originating from heterogeneous sources of global molecular alterations in MS. Data for inclusion was collected from 39 studies or bioinformatic sources. Altogether, 158.520 distinct significant signals discovered on 16 different biological levels were included. Custom rank product prioritization approach based on genomic position of included results was utilized for data synthesis. Nested permutational cycling was employed to determine significant accumulation of most significant results discovered on most diverse biological levels.

In total, 381 genomic regions were characterized with significant accumulation of results, reaching local permutation p-value minima below 0.001. Follow-up characterization of selected regions revealed them to contain 409 genes of which 87 (21.3%) overlapped with those tracked by HuGENet disease-gene associations database, while a notable proportion have not been investigated in MS. This suggests that there exists a substantial body of genes, whose involvement in MS is suggested by evidence in a complex body of data from 'omic' studies, but focused studies of their direct role in MS have yet to be performed and they thus present plausible targets in further validation studies.

P11.080

Molecular characterization of human sialidase Neu4 gene promoter region

***M. Delman**, V. Seyrantepe;*
Izmir Institute of Technology, İzmir, Turkey.

Sialidase Neu4 is one the four mammalian sialidases. We characterized previously that human Neu4 sialidase has activity against sialic acid containing substrates including ganglioside GM2. Biological role of human sialidase Neu4 enzyme has been shown by the transfection of neuroglia cells from a Tay-Sachs patient that Neu4 clears accumulated GM2. It has been also shown that sialidase Neu4 enzyme is responsible for degradation of ganglioside GD1a in brains of Neu4 knock-out mice. To expore human sialidase Neu4 gene regulation, we aimed to determine minimal promoter region and identify several transcription factors. We used TESS (Transcription Element Seach System) tool to predict the sequence motifs. We amplified seven different DNA fragments from human Neu4 promoter region, cloned into luciferase expression vector and performed reporter assays. We used electrophoretic mobility shift assay to demonstrate binding of transcription factors to candidate promoter region. Human sialidase Neu4 gene has TATA-less promoter but contains CCAAT elements. Luciferase reporter assay demonstrated that 187 bp upstream of Neu4 gene is minimal promoter region which regulate transcription. Electrophoretic mobility shift assay showed that 187 bp upstream region recruits several transcription factors such as c-myc. Overall, our results show some of cis- and trans- acting factors involved in the human sialidase Neu4 gene regulation. The data we obtained might be useful to discover small molecules which control Neu4 gene expression. Selective high expression of sialidase Neu4 gene might be controlled using drugs or small molecules and the accumulated ganglioside GM2 in lysosomes of Tay-Sachs patients can be reduced.

P11.081

Development of a custom designed aCGH chip (Neuromuscular Chip) for investigation of Neuromuscular Disorders

***V. Oikonomakis**, K. Kekkou, N. Vogiatzakis, S. Kitsiou-Tzeli, E. Kanavakis, M. Tzetis;*
Department of Medical Genetics, Medical School, University of Athens, Athens, Greece.

Neuromuscular disorders (NMDs) are a group of genetically determined diseases encompassing many conditions that impair muscle function (DMD/BMD, LGMD2A, Sarcoglycanopathies, etc). Similar phenotypes may be caused by mutations in many different genes and consequently molecular diagnosis can sometimes be inefficient. Array-based comparative genomic hybridization (aCGH) is a high-throughput technology for detecting copy-number variations (CNVs) in the human genome.

In order to address the NMDs diagnostic problem, a custom Agilent a-CGH oligonucleotide chip (SurePrint G3, 8x60k platform) was designed using the e-Array application. The chip covers a selection of genes most commonly involved in NMDs: *DMD* (>25,513 probes, every 90bp for exons and approximately150bp for introns), *LARGE* Congenital muscular dystrophy type 1D (MDC1D), (5963 probes) Sarcoglycanopathies & Limb Girdle Muscular Dystrophies: *SGCA* (17q21.33), *SGCB* (4q11), *SGCG*(13q12), *SGCD* (5q33.3) (4609 probes), *POMT1/ POMT2/ POMGNT1/ FKTN/ FKRP* (2681 probes), *UTRN, LMNA, EMD, TRIM32, MYL7, ACTA1* (7089 probes), *CAPN3* (1020 probes), *LGMD2A* and Caveolinopathies: CAV3 (141 probes).

The neuromuscular aCGH chip was evaluated by a retrospective analysis, using DNA samples from NMD patients with known deletions or duplications. The expected CNVs, in all previously characterized patients, were successfully confirmed. Additionally, new exonic and intronic CNVs were detected, which possibly contribute/ modify to the patient's phenotype. Clinical application of the custom-designed

for general diagnosis of NMD patients, can therefore, provide significant additional information on the molecular pathogenesis for NMDs. We are planning to add it to our diagnostic investigation for neuromuscular diseases.

P11.083

Accurate determination of the length of homonucleotide stretches by highly parallel sequencing

***H. Cuppens**, M. Jaspers, S. Lehnert;*
Center for Human Genetics, Leuven, Belgium.

The number of nucleotides in long homonucleotidestretches, especially when 7 or more nucleotides long, cannot be accurately determined by highly parallel sequencing based on pyrosequencing or Ion Semiconductor Sequencing. Most genes, however, harbor homonucleotidestretches in this size range. This pitfall prohibits implementation of these sequencing formats in routine genetic diagnostics.

We present a method in which the length of a long homonucleotidestretch is reduced to a series of shorter nucleotide stretches in which each of them can be accurately determined. The combined accurate analysis of the smaller homonucleotidestretches then allows accurate determination of the length of the original longer homonucleotidestretch. The reduction in size of the homonucleotidestretch can be achieved by PCR, which we call homonucleotide-stretch-reduction-PCR (hnr-PCR). An hnr-primer is used, which is complementary against the region of the homonucleotidestretch, which extends in the homonucleotidestretch but not until its end, and which contains at least one non-complementary nucleotide. Since 100% complementary of a primer is not needed to allow DNA synthesis, as long as its 3' end is complementary against its target, non-complementary nucleotides can indeed be incorporated at certain positions of a primer. When a 5'adapter sequence is added to the primers used for hnr-PCR, and a different 5'adapter sequence is added to the primers used for standard PCR, the combined analysis of the standard amplicon and the hnr-amplicon against a given region then concludes the actual sequence. In this way, a 'one-stop'genetic test is obtained for these sequencing formats.

P11.084

Storing and sharing NGS variant data and phenotype information in web-based LOVD3 gene variant databases

***P. E. M. Taschner**, I. F. A. C. Fokkema, I. C. Lugtenburg, J. Hoogenboom, Z. Tatum, G. C. P. Schaafsma, M. Vermaat, J. F. J. Laros, J. T. den Dunnen;*
Center for Human and Clinical Genetics, Leiden, Netherlands.

Exome and genome sequencing studies currently flood us with sequence variants. The free, open-source, platform-independent Leiden Open-source Variation Database software (LOVD, http://www.LOVD.nl) was developed to build standardized databases for curating and sharing gene variants. To cope with the new demands posed by exome/genome studies we have developed a new version of the LOVD platform. LOVD3 is compatible with the Gen2Phen data model, implemented with additional tables for phenotype, screening and transcript information. Genome-wide sequence variant data can be stored in a single LOVD installation using chromosomal nucleotide positions as reference. Web services retrieve gene and transcript information on the fly. Data from exome/genome studies can be stored and displayed in several ways: variant-by-variant or all connected to one patient. To promote early release of exome data, both phenotypes screened but unresolved and variants not-excluded from being causative can be stored (and identified) individually. Data can be public and non-public for both with the option to query. This leaves submitters in control of the data, ensuring that they will be contacted to obtain essential information. Finally LOVD3 supports a new access level, "collaborator", allowing collaborating groups to share otherwise non-public data. Other new features include: display of disease-specific phenotype information, storage of temporal phenotype information, improved interface and speed, and queries in and across data columns. Web services will be developed to communicate between LOVD installations as well as to allow database queries. Funded by the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement nº 200754 - the GEN2PHEN project.

P11.085

Quality control of DNA from formalin-fixed paraffin-embedded and fresh-frozen tissues prior to target-enrichment and next generation sequencing

*M. Liu[1], M. Ramirez[2], **R. Salowsky**[3];*
[1]Agilent Technologies, Inc., La Jolla, CA, United States, [2]Agilent Technologies, Inc., Santa Clara, CA, United States, [3]Agilent Technologies R&D and Marketing GmbH & Co. KG, Waldbronn, Germany.

There are over 400 million formalin-fixed paraffin-embedded (FFPE) tissue samples archived in biobanks worldwide. These diseased and normal tissue collections are valuable resources for molecular genetic studies. However, the challenges of DNA extraction from FFPE tissues, including formaldehyde cross-linking, degradation, and mixtures of single-stranded and double-stranded DNA, result in low amounts of usable high quality material for downstream assays. Hence, assessing the quality of samples to be processed for highly sensitive and costly applications, such as next generation sequencing, becomes a critical consideration. On-chip and automated electrophoretic devices were evaluated for the characterization of FFPE and fresh-frozen DNA samples prior to and during target-enrichment and next generation sequencing workflows.

P11.086

A new horizon - assessment of the GnuBIO next gen clinical sequencing platform

***J. Sram**[1], H. Gao[1], A. Aslam[2], J. Boyce[2], B. Chin[2], J. Emhoff[2], A. Esmail[2], H. Ghandour[2], S. Harborth[2], J. Healy[2], T. Hung[2], S. Kiani[2], P. Mary[2], K. Moulton[2], T. Raz[2], J. Simoneau[2], P. Stokes[2], N. Nerkizian[3];*
[1]City of Hope, Duarte, CA, United States, [2]GnuBIO, Cambridge, MA, United States, [3]GnuBIO, Cambridge, CA, United States.

Next generation sequencing is poised to revolutionize medicine. Current platforms have been optimized for the research market; however, many challenges remain that prevent the technology from being widely used in clinical settings. Target enrichment and sample preparation are laborious and require highly technical personnel. In addition, data analysis is costly and time consuming. These challenges are compounded by high per sample cost, and a need for sample batching to minimize these costs.

GnuBIO's first generation sequencer is a fully integrated platform requiring only raw genomic DNA as starting material. Enrichment for hundreds to thousands of PCR targets occurs on board followed by data analysis and variant calling. Run times are short, e.g. a 500 PCR target run is estimated to take 3 hours. This is the first attempt to highly automate the next gen sequencing process from gDNA to data analysis with a fast turn-around-time while offering high accuracy and long reads in a single product.

The City of Hope and GnuBIO will present results that for the first time demonstrate the detection of unknown mutations in a blinded cohort of clinical patient samples in p53 cancer gene sequenced on the GnuBio platform. The depth of coverage realized from these analyses, combined with the accuracy, turn-around-time, and ease of sample handling, provides the potential framework to make routine clinical diagnostics a reality with the GnuBIO instrument.

P11.087

Sample Quality Control within various Next Generation Sequencing workflows using the new Agilent 2200 TapeStation System

***D. McDade Walker**, A. Lee, J. Ong, E. Lin, M. Gassmann;*
Agilent Technologies, Edinburgh, United Kingdom.

This study evaluates the performance of the 2200 TapeStation System in various Next Generation Sequencing (NGS) workflows. Numerous sample types were checked for quality at different stages of various NGS protocols including pre- and post-shearing, post adaptor ligation as well as pre-hybridisation and post-hybridisation within the SureSelect target enrichment workflow. The data shows that this new automated electrophoresis system provides qualitative information that enables informed decision making in all downstream steps. By providing a range of ScreenTape consumables with standard and high sensitivities along with a tailored analysis package, the system is able to QC gDNA, fragmented DNA, whole genome libraries and target enriched libraries, presenting descriptive analyses at each stage for multiple sequencer protocols. The data described here demonstrates that the 2200 TapeStation System has the range, sensitivity, precision and accuracy to meticulously QC samples within the NGS workflow.

P11.088

Direct in-flowchip isothermal amplification of sequencing libraries at ultra-high density for next-generation sequencing

***T. Rygus**;*
Life Technologies, Darmstadt, Germany.

We have developed a new nucleic-acid template-preparation methodology, called "WildFire", where sequencing libraries are *in-situ* amplified directly in-the-flowchip; no cycling-steps, no sequencing beads, no material exchanges. Sequencing libraries are added directly to the 5500-series Genetic Analyzer flowchip, whose surfaces have been coated with a special library-adaptor capture oligonucleotide. A DNA polymerase reaction mix is added, and in a single isothermal step lasting ~ 30 minutes, individual nucleic acid fragments are amplified *in-situ* on the flowchip. The net density of sequencing-colonies created in this manner far exceeds anything currently utilized in next-generation sequencing, reaching ~ 1 million colonies per mm^2 per flowchip surface (~ 2 million colonies / mm^2 optical viewing surface). During *in-situ* amplification, the capture oligonucleotide is "consumed", and each individual nucleic-acid fragment "spreads" inside the flowchip until reaching an adjacent library fragment(s). When the individually-growing fragments "meet", the amplification step terminates, because all of the surface-bound primer was consumed. These "self-assembled", spatially resolved, monoclonal colonies, are then sequenced-by-ligation. The resulting colony-sequencing reads maintain the same high accuracy as our bead-based method. Ligase-reactions also appear to be more efficiently completed on sequencing colonies (vs. sequencing beads), with the overall chemistry cycle-time decreasing (~ 1.5X) and the read-lengths increasing (towards 100 bps). Full genomes (bacterial to human), exomes (human), and transcriptomes (human) have now been sequenced using WildFire technology (detailed statistics will be presented). WildFire technology greatly improves NGS workflow (*in-situ* amp), increases throughput (via ultra-high density colonies), and significantly decreases net cost-per-genome (elimination of costly template preparation steps).

P11.089

Similar nucleosome occupancy pattern of NF-Y histone substitute family proteins, in human embryonic stem cells and induced pluripotent cells

***M. Shahhoseini**[1], R. Favaedi[1], S. Molla Mohammadi[2], H. Baharvand[2];*
[1]Department of Genetics, Reproductive Biomedicine Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Islamic Republic of Iran, [2]Department of Stem Cell and Developmental Biology, Cell Science Research Center, Royan Institute for Stem Cell Biology and Technology, ACECR, Tehran, Islamic Republic of Iran.

Introduction

Pluripotent ES and iPS cells are indebted their unique properties like their wonderful developmental plasticity to unique structure of their chromatin. The dynamics of this structure is regulated by a variety of complex pro-

cesses such as use of histone substitutes. Transcription factor NF (Nuclear Factor)-Y, is a histone substitute family protein that specifically recognizes the CCAAT box present in the promoter region of many constitutive, inducible, and cell-cycle-dependent eukaryotic genes and plays a key role during eukaryotic development. As induced pluripotent cells show many similarities to embryonic stem (ES) cells also because of their excellent potential to study developmental mechanisms and human disease in addition to new hopes to use of them for regenerative medicine, vast and stringent comparison of them to replacement of ESC by iPSC may resolve ethics limitations.
Material and Methods
In this experiment total level of NFY-A, B and C of a few human cell lines including ESC and iPSC as pluripotent cells, and differentiated ESC and fibroblast cells as differentiated lines was evaluated by the method of nucleosome ELISA (Nu-ELISA) to compare their epiproteome signature.
Results
Results showed remarkable similarities in nucleosome occupancy pattern of NFY-A, B and C in ESC and iPS cells and lower levels in comparison to differentiated ESC and fibroblast.
Conclusion
Current finding implies the dynamic epigenetic role of NF-Y family members in gene regulation involved in development and differentiation.

P11.090

Establishment of a core unit laboratory for ultra deep sequencing

A. B. Ekici, *S. Uebe, A. Reis;*
Institute of Human Genetics, Erlangen, Germany.

With continued advances in sequencing technologies, next-generation sequencing has been successfully used in a variety of targeted and genome-wide analysis techniques to uncover the genetic basis of a number of Mendelian diseases. The analysis of the genome-wide coding region (exome) is now economically feasible and quickly accomplishable.
We established a core unit for ultra-deep sequencing equipped with two systems, a SOLiD-4 and its descendant SOLiD-5500XL (Life Technologies). We are using both with appropriate automation for library and templated bead preparation. The main application is the whole exome sequencing approach with single samples as well as index-parents trios using the Agilent-SureSelect 50Mb-Kit for the exome enrichment. The data analysis pipeline for read mapping and variant calling starts with LifeScope 2.5 (Life Technologies) running on a cluster in the university high performance-computing group (HPC). Subsequently the usage of publicly available annotation tools like ANNOVAR are simplified for end user with own scripting solutions. A commercial software NextGENe (Softgenetics) may also be used by end users for variant calling and annotation. Up to now, we sequenced 135 whole exomes, (86 SOLiD-4 and 49 SOLiD-5500XL). The transition to the newer system resulted in a significant higher coverage at same sequencing parameters (SOLiD-4 54 - 61, SOLiD-5500XL 111 - 114). In particular the detection of homozygous variants in single samples with a recessive model and *de novo* variants in trios with a dominant model was very successful in different projects. More than half of the samples of both models recovered straightaway functionally meaningful candidate variants.

The $1000 exome dilemma: expectations and facts

S. Zuniga[1]*, J. Trivino*[2]*, J. Rosa-Rosa*[2]*, O. Rodriguez-Cruz*[2]*, M. Cabo-Diez*[2]*, C. Collado*[3]*, R. Rodriguez-de Pablos*[3]*, V. Fernandez-Pedrosa*[3]*, L. Perez-Carbonero*[4]*, A. Romera*[4]*, S. Santillan*[1]*;*
[1]*Sistemas Genomicos Foundation, Valencia, Spain,* [2]*Department of Bioinformatics, Sistemas Genomicos Ltd, Valencia, Spain,* [3]*Department of New Technologies, Sistemas Genomicos Ltd, Valencia, Spain,* [4]*Department of Medical Genetics, Sistemas Genomicos Ltd, Valencia, Spain.*

The rapid evolution of Next-Generation Sequencing platforms is transforming today's medical research and diagnostics. Currently, the combination of exome capture enrichment systems and high-throughput sequencing techniques is the method of choice for genomic research in Mendelian disorders and is becoming more popular for genetic diagnostics purposes as the cost per base decreases.
At present, many institutions, both public and private, offer exome analysis services at a very attractive price which can vary in price tremendously from one site to another. Frequently, users with not much expertise in either NGS sample preparation issues or bioinformatics analysis approaches use price as the key selection criteria overlooking other important issues that are critical for the achievement of reliable results.
Here we report the results of the exome sequencing and analysis of a Human controlled cell line, previously sequenced by the HapMap project, that was sent to three different anonymous sequencing sites that offered the "$1000 exome sequencing service" in order to provide an overview of what one can actually expect from such deal and how differences on sequencing data quality, exome capture enrichment systems and bioinformatics analyses influence on the final results.

P11.093

Rapidly profiling thousands of large non-coding RNAs from nanogram amounts of total RNA using a single microarray design

A. Bergstrom Lucas[1]*, V. Kulkarni*[1]*, K. Swaminathan*[1]*, B. Mullinax*[2]*, P. Costa*[1]*, A. DeWitte*[1]*, M. Srinivasan*[1]*, E. LeProust*[1]*, S. Fulmer-Smentek*[1]*;*
[1]*Agilent Technologies, Santa Clara, CA, United States,* [2]*Agilent Technologies, La Jolla, CA, United States.*

Large intergenic non-coding RNAs (lincRNAs) are emerging as key regulators of diverse cellular processes. As researchers face the challenge of investigating the function of lincRNAs, there is a need for tools that can accurately and rapidly measure the expression of both lincRNAs and mRNAs simultaneously. A catalog of more than 8,000 human lincRNAs was recently annotated from more than 4 billion RNA-Seq reads across 24 tissues and cell types by scientists at the Broad Institute of MIT and Harvard. Using this new catalog of lincRNAs we have updated the content of the Human SurePrint G3 microarrays to enable systematic profiling and simultaneous detection of coding and non-coding gene expression from a single sample. We used low nanogram amounts of total RNA from matched tumor and adjacent normal tissues to detect both large and subtle differences in gene expression profiles that were consistent with the current literature. GeneSpring GX software rapidly identified differentially expressed lincRNAs and protein-coding RNAs resulting in expression measurements from total RNA in less than two days. Microarray data demonstrated good reproducibility, wide dynamic ranges and high sensitivity, and the tumor versus normal ratios generated from the microarrays showed high correlation with ratios generated from whole transcriptome sequencing of the same matched RNA samples. In this study we demonstrate that microarrays can provide accurate differential expression measurements of both protein coding and non-coding RNA from very low amounts of total RNA rapidly providing expression data that is equivalent to whole transcriptome sequencing measurements.

P11.094

MicroRNA expression profiling meta-analysis identifies pathways associated with lung cancer development and reveals potential therapeutic drug targets

U. Võsa[1]*, R. Kolde*[2]*, T. Vooder*[3]*, J. Vilo*[2]*, A. Metspalu*[1,4]*, T. Annilo*[1]*;*
[1]*Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia,* [2]*Institute of Computer Science, University of Tartu, Tartu, Estonia,* [3]*Clinic of Cardiovascular and Thoracic Surgery of Tartu University Hospital, Tartu, Estonia,* [4]*Estonian Genome Center, University of Tartu, Tartu, Estonia.*

The development of non-small cell lung cancer (NSCLC) involves a strong enviromental component and alteration of many genes and pathways. MicroRNAs, short non-coding RNAs are important gene regulators on post-transcriptional level and aberrations in their expression are often directly linked to tumorigenesis and disease outcome. During recent years, a number of studies have reported microRNA expression changes in NSCLC. Several platforms with different number of detectable microRNAs have been used for these profiling studies, causing the variance in the results due to the differences in methods of detection and data analysis.
To identify microRNA drivers in lung cancer, we performed comprehensive meta-analysis of 16 available miRNA expression profiling studies using a novel Robust Rank Aggregation method. As a result, we identified a signature of four significantly over- and seven under-expressed microRNAs. To assess the biological function of identified miRNAs, we used several target prediction algorithms and gene enrichment tests to identify possibly perturbed biological processes and pathways.
In conclusion, we have shown that our approach is suitable and effective for meta-analysis of gene expression studies in case when different technological platforms have been used or raw data is unavailable. Our pathway analysis further confirms the link between aberrant regulation of miRNA expression and lung cancer.

P11.095

The importance of alignments in evaluating missense variants

S. Williams, *A. Devereau;*
NGRL Manchester, Manchester, United Kingdom.

Many missense sequence variants have been implicated in human disease phenotypes. However, in the absence of functional assays, the related pathogenicity of many variants remains unclassified. A number of in silico tools have been developed to predict the effect of missense variants. In combination with other evidence, these tools are used routinely by diagnostic labs to advise clinicians of disease likelihood. However, errors may arise through uninformed choice of tools and use of inappropriate parameters which may compromise their accuracy.

We have benchmarked the predictions from a range of algorithms on a set of genes with well characterised missense variants. We find that prediction success is highly gene-specific and that different algorithms perform optimally with different genes. Prediction algorithms based on multiple sequence alignments (MSAs) can be sensitive to the quality of the alignments used. In order to satisfy statistical considerations, certain levels of sequence divergence are required and carefully curated alignment use is recommended. In this respect, we also assessed the impact of alignment quality on these algorithms and find that the majority of possible orthologue alignments do not affect prediction success greatly when assessing a set of variants. However, when assessing individual variants, prediction success can vary with alignment quality and diversity in MSAs is an important consideration to ensure optimum algorithm performance.

We suggest that provision of benchmark data for different algorithms, and of standard MSAs, will allow the optimal use of missense prediction tools.

P11.096

RNA analysis, a diagnostic tool

M. Kulseth*, H. Johnsen, O. Rødningen;*

Department of Medical Genetics, Oslo, Norway.

DNA sequence variants of uncertain significance (VUSs) is a common challenge in all types of genetic testing. Sequence variants located all over the exons and introns have the potential to disrupt proper splicing of mRNA, either by disrupting a normal splice site, by creating a *de novo* splice site or by disturbing the interaction of splice regulatory factors.

In order to reveal the effect of VUSs identified by DNA sequencing, we have offered RNA analysis for genes expressed in blood and with identified sequence variants which might cause aberrant splicing. These are sequence variants located within the normal splice sites, synonymous variants and intron variants which are predicted to create *de novo* splice sites. In the poster we will present the method of choice and some examples of results.

RNA analysis is a simple and straightforward tool to increase the knowledge about the effect of sequence variants identified by DNA sequencing.

P11.097

Enabling next-generation knowledge integration for human genetics

B. Vroling*, T. van den Bergh, R. Kuipers, H. Joosten;*

Bio-Prodict, Nijmegen, Netherlands.

It is widely accepted that information overload, in terms both of the growing volumes of biomedical data and of the associated literature, is making it increasingly difficult for researchers to keep pace. We present 3DM, a suite providing information systems for protein families, relieving many of the burdens that researchers face in dealing with the growing amounts and complexity of biomedical data. For each protein family a large amount of information that is extracted from protein structures, alignments and scientific literature, among others, is available. All this information is integrated, validated, and can be analysed and interacted via a number of methods. As a response to the amount of scientific literature outgrowing researchers' ability to keep pace, we have developed software that can place this integrated data and information from 3DM systems in the context of full-text PDF articles. Users are able to jump seamlessly from a particular paper both to its underlying data and to other related information and literature at the click of a button, thereby allowing readers to extract more knowledge more swiftly from the literature.

Having many heterogeneous data types readily available in an integrated and validated fashion can greatly speed up research, and a wide variety of questions can be answered when such protein-related data from many different origins can be flexibly combined. As an example of particular interest to the human genetics community, by intelligently combining all this heterogeneous information the system is able to provide state-of-the-art predictions about the effects of genetic variations.

P11.098

Comparative Analysis of Strand-Specific RNA Sequencing Approaches

D. Munafo[1], P. Liu[1], C. Sumner[1], ***B. Textor****[2], L. Apone[1], B. Langhorst[1], F. Stewart[1], E. T. Dimalanta[1], T. Davis[1];*

[1]New England Biolabs Inc., Ipswich, MA, United States, [2]New England Biolabs GmbH, Frankfurt, Germany.

Standard RNA-sequencing approaches generally require double-stranded cDNA Synthesis, which erases RNA strand information. Synthesis of a randomly primed double-stranded cDNA followed by addition of adaptors for next-generation sequencing leads to the loss of information about which strand was present in the original mRNA template. The polarity of the transcript is important for correct annotation of novel genes, identification of antisense transcripts with potential regulatory roles, and for correct determination of gene expression levels in the presence of antisense transcripts. This work investigates the performance of different strategies for directional RNA-Seq using multiple next generation sequencing platforms. Here, we examine the effect of different RNA fragmentation methods (divalent cations plus heat versus enzymatic fragmentation). We provide a comparative analysis (library complexity, continuity of gene coverage, strand specificity and 3'and 5'-end bias analysis) of strand-specific RNA methods.

P11.099

GeneTalk: an expert exchange platform for assessing rare sequence variants in personal genomes

P. M. Krawitz*[1], T. Kamphans[2];*

[1]Charite, Berlin, Germany, [2]GeneTalk, Berlin, Germany.

Next-generation sequencing (NGS) has become a powerful tool in personalized medicine. Exomes or even whole genomes of patients suffering from rare diseases are screened for sequence variants. After filtering out common polymorphisms, the assessment and interpretation of detected personal variants in the clinical context is an often time consuming effort. We have developed GeneTalk, a web-based platform that serves as an expert exchange network for the assessment of personal and potentially disease relevant sequence variants. GeneTalk enables a locus centered knowledge management for genetic variants and may assist a clinical geneticist who is searching for information about specific mutations: Our platform gets a geneticist directly connected to other users with expertise for the sequence variant of interest. GeneTalk is available at www.gene-talk.de.

P11.100

The sensitivity of detecting heterozygous variants in next-generation sequencing data is increased by applying an allele frequency distribution derived from a stochastic branching process

V. Heinrich*[1], J. Stange[2], T. Dickhaus[1], P. Imkeller[1], U. Krüger[1], S. Bauer[1], S. Mundlos[1], P. N. Robinson[1], J. Hecht[3], P. M. Krawitz[1];*

[1]Charite, Berlin, Germany, [2]Humboldt University, Berlin, Germany, [3]Berlin Brandenburg Center for Regenerative Therapies, Berlin, Germany.

Next-generation sequencing (NGS) technology allows us to detect genetic variants on a genome-wide scale. A deeper knowledge about the allele distribution at heterozygous loci is essential for sensitive variant detection. We describe the pivotal steps of the library preparation before sequencing as a stochastic branching process and derive a mathematical framework for the expected distribution of alleles at heterozygous loci in a short read alignment. Based on technical replicates of human exomes we demonstrate that the variance of allele frequencies is higher than expected from a simple binomial distribution. As a consequence algorithms for mutation detection that apply this wrong prior distribution are less sensitive for variants that deviate strongly from the expected mean frequency. Due to the stochasticity inherent to the sample preparation we show that there is an upper bound for heterozygous variant detection even with increasing sequencing depth. Our results therefore indicate that technical replicates are an effective means in the reduction of error rates.

P11.101

Assessing the quality and the population background of high-dimensional human variant data sets from next-generation sequencing platforms using similarity metrics

P. M. Krawitz[1], ***S. Bauer****[1], V. Heinrich[1], J. Stange[2], T. Dickhaus[2], P. N. Robinson[1];*

[1]Charite, Berlin, Germany, [2]Humboldt University, Berlin, Germany.

In reference based resequencing projects a list of all detected genetic variants represents an important intermediate step in bioinformatics data processing. Although scores are used to estimate the error probability of single variant calls, the heterogeneity of analysis pipelines as well as the high dimensionality of the data make it difficult to compare the quality of entire data sets. Here we describe a similarity metric that allows a distance-based quality assessment of human variant data on a genome wide scale irrespective of the platform it was generated on. Using the individuals of the 1000 genomes project as a high-quality reference set we are able to robustly identify the population background, answer questions about relatedness and estimate error rates in a data set. Our distance-based scoring system is accessible at www.gene-talk.de and may be applied in high-throughput sequencing laboratories for an easy means of quality control and routine consistency checks in sample workflow.

P11.102

Molecular diagnosis and genotype-phenotype studies in patients with osteogenesis imperfecta by next generation sequencing

C. C. Hung[1,2], *C. N. Lee*[3], *S. Y. Lin*[4,5], *Y. N. Su*[1,2,5];
[1]*Graduate Institute of Clinical Genomics, National Taiwan University College of Medicine, Taipei, Taiwan,* [2]*Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan,* [3]*Department of Obstetrics and Gynecology, National Taiwan University Hospital, Taipei, Taiwan,* [4]*Department of Obstetrics and Gynecology, National Taiwan University Hospital, Hsin Chu Branch, Hsin Chu, Taiwan,* [5]*Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan.*

Background: Osteogenesis imperfecta (OI) is a heritable disorder of bone formation, which is characterized by bone fragility and low bone mass. As reported, autosomal dominant OI is associated with the mutations in *COL1A1* and *COL1A2* genes and autosomal recessive OI is caused by mutations in *CRTAP, LEPRE1* and *PPIB* genes.
Methods: In this study, exon-wide mutation analyses of *COL1A1, COL1A2, CRTAP, LEPRE1* and *PPIB* genes were performed by PCR and next-generation sequencing (NGS). One hundred unrelated patients and their family members diagnosed with OI clinically from Taiwan population were enrolled in this study.
Results: 46 patients had mutation in *COL1A1* gene, and 25 in *COL1A2* gene. The mutation detection rate of *COL1A1* and *COL1A2* genes was 71%. Furthermore, one patient was identified heterozygous mutations in *PPIB* gene. No mutation in *CRTAP* or *LEPRE1* gene was found. In total, there was an overall mutation identification rate of 72%.
Conclusion:To gain more insight into the mutational spectrum in Taiwanese patients with OI, we conducted this study to perform extensive exon-wide mutational analysis of *COL1A1, COL1A2, CRTAP, LEPRE1*and *PPIB* genes based on the high- throughput mutation scanning system with NGS. There are several hot mutation regions in *COL1A1* and *COL1A2* gene had been proposed. PCR followed by NGS is an alternative strategy for molecular diagnosis.

P11.103

A fish-specific transposable element shapes the repertoire of p53 target genes in zebrafish

M. Loviglio[1], *L. Micale*[2], *M. Manzoni*[3], *C. Fusco*[2], *B. Augello*[2], *E. Migliavacca*[1], *G. Cotugno*[2], *E. Monti*[3], *G. Borsani*[3], *A. Reymond*[1], *G. Merla*[2];
[1]*Center for Integrative Genomics - University of Lausanne, Lausanne, Switzerland,* [2]*Medical Genetics Unit, IRCCS „Casa Sollievo della Sofferenza", San Giovanni Rotondo, Italy,* [3]*Department of Biomedical Science and Biotechnology - University of Brescia, Brescia, Italy.*

Transposable elements, as major components of most eukaryotic organisms' genomes, define their structural organization and are known to establish new cellular functions during evolution. Recent discoveries support the hypothesis that TEs can directly mediate gene regulatory novelties at the network level by contributing to transcriptional and post-transcriptional modulation of nearby genes. For instance, TEs participate to the origin of new functional elements, as promoter sequences, transcription factors binding sites and enhancer, silencer and insulator elements. For example, binding sites of the pleiotropic master transcription factor p53 reside in LINE1, Alu and LTR repeats in the human genome. Similarly, here we describe the first case of a mobile element shaping the repertoire of the p53 target genes in zebrafish (Danio rerio). Through their embedded p53 responsive elements, the multiple copies of the non-autonomous DNA transposon EnSpmN6_DR drive in several instances p53-dependent transcriptional modulation of the adjacent genes, whose human orthologs were often previously annotated as p53 targets. These transposons define a set of target genes that contribute to axonogenesis, synaptic transmission and the regulation of programmed cell death. Consistent with these biological functions, the EnSpmN6_DR-colonized loci are enriched for genes expressed in both adult and fetal brain. Our data corroborate the recent findings concerning the role of p53 in the regulation of neural stem cell development and pinpoint a remarkable example of convergent evolution: the exaptation of lineage-specific transposons to establish networks of p53-regulated genes crucially involved in neuronal morphogenesis in both a hominid and a teleost fish.

Rare variants in TMEM132D contribute to the risk for panic disorder in a German sample

C. Quast, *A. Altmann, P. Weber, J. Arloth, D. Bader, A. Heck, H. Pfister, B. Müller-Myhsok, A. Erhardt, E. B. Binder;*
Max Planck Institute of Psychiatry, Munich, Germany.

Background: Genome-wide association studies have identified a large number of common variants associated with common diseases. Most variants, however, explain only a small proportion of the estimated heritability, suggesting that less common and rare variants might contribute to a larger extent to common diseases than assumed to date. Here we use next-generation sequencing to test whether such variants also contribute to the risk for anxiety disorders by re-sequencing 40 kb including all exons of the TMEM132D locus which we have previously shown to be associated with panic disorder and anxiety severity measures.
Methods: DNA from 300 patients suffering from anxiety disorders, mostly panic disorder (84.7 %), and 300 healthy controls was screened for the presence of genetic polymorphisms using the SOLiD 3+ next-generation sequencing platform (Life Technologies) in a pooled approach. Results were verified by individual re-genotyping.
Results: We identified a total 371 variants of which 247 had not been reported before, including 15 novel non-synonymous SNPs. The majority, 76 % of these variants had a minor allele frequency less than 5 %. While we did not identify additional common variants in TMEM132D associated with panic disorders, we observed an overrepresentation of rare functional variants in healthy controls as compared to cases.
Conclusions: Our data suggest that not only common but also rare variants within TMEM132D might contribute to the risk to develop anxiety disorders. In addition, the overrepresentation of rare functional variants in controls supports previous results associating an increased function of this gene with anxiety measures.

P11.105

Isolation and characterization of the RNA content of exosomes derived from blood and cell culture media using the Ion Torrent Personal Genome Machine (PGM™)

R. Setterquist[1], ***N. Kefer***[2], *T. Barta*[1], *A. Vlassov*[1], *M. Li*[1], *R. Conrad*[1], *J. Schageman*[1];
[1]*Life Technologies, Austin, TX, United States,* [2]*Life Technologies, Darmstadt, Germany.*

Exosomes are small (30 - 120 nm) vesicles containing nucleic acid and protein cargo secreted by all cell types in culture. They are found in abundance in body fluids including blood, saliva, urine, breast milk. There is an exponentially growing interest to studying the function exosomes and utilizing them for diagnostics development. At the moment, the mechanism of exosome formation, the make up of the "cargo", biological pathways and resulting functions are poorly understood. There is an urgent need to further our understanding of microvesicles, and critical to this, is the development of reagents and tools for their isolation, characterization and manipulation. We will present data on (1) isolation of exosomes from blood and cell cultures, using modified ultracentrifugation and other protocols; (2) initial characterization of the RNA content from these exosome fractions using next generation sequencing.

P11.106

Enabling Whole Transcriptome RNA-Seq on the Ion Torrent PGM Sequencer

B. Sanderson[1], ***X. Cristina***[2], *N. Supunpong-Hernandez*[1], *C. Burnett*[1], *D. Williams*[1], *K. Bramlett*[1];
[1]*Life Technologies, Austin, TX, United States,* [2]*Life Technologies, Paisley, United Kingdom.*

As processes for the PGM continually improve, library construction has quikkly become one of the most apparent bottlenecks for the RNA-Seq pipeline. Addressing this obstacle is extremely important to enable the developing clinical sequencing market by improving speed of sample to sequence. Also, with the already vast number of stored FFPE samples in tissue banks and a growing impetus to study samples that may be rare or precious, a library method that can start with total, limited, and/or sheared RNA is necessary. Historically, RNA-seq libraries have started with microgram quantities of total RNA in order to perform a polyA selection or ribo minus depletion and make the sample useful for downstream applications. These processes remove up to 95% of the sample, the majority of which being unwanted rRNA and mtRNA. At Ambion, we have developed a library preparation method that can begin with a minimal amount of total RNA and selectively enrich for mRNA using a not-so-random (NSR) priming approach. We will detail the NSR priming strategies to build an RNA library kit for sequencing whole transcriptomes using the Ion Torrent PGM. We will show results from experiments optimizing hybridization parameters and workflows for library using less than 100ng total RNA, significantly reduce the representation of rRNA and mtRNA, and be performed in less than 4 hours. This will permit a clinician to build a library in less than half the time, at a reduced cost, using 1/100th the amount of starting RNA as compared to a ligation-based approach.

Expert system PharmakoGen intended to increase efficacy of drug therapy

I. V. Ugarov[1], **M. M. Litvinova**[2], A. V. Zaborovskiy[1];
[1]Moscow State Medical Stomatological University, Moscow, Russian Federation, [2]I Moscow State I.M. Sechenov Medical University, Moscow, Russian Federation.

Nowadays pharmacogenetics is a very rapidly developing field of knowledge which allows to predict therapeutical effect of different drugs and occurrence of pathologic medical reactions depending on genotype of the patient.

Every day more and more scientific articles are being published worldwide regarding this matter. So extensive data which include information on different genes, mutations, polymorphisms and drug-to-drug interactions cannot be stored in one's mind and that is why cannot be used by the doctors without applying for special literature and databases.

Our aim was to develop expert system for increasing efficacy of drug therapy depending on genotype of the patient. As a result of the project expert system PharmakoGen was created.

Expert system PharmakoGen is developed on the platform xGen IDS, successfully used for creation of diagnostic systems on hereditary neuromuscular diseases, eye illnesses, and chromosomal syndromes.

Our expert system includes following elements: the module of input of patient information, the knowledge base module, the module of results explanation, and finally the module of expert conclusion with special individual recommendations.

The system can be used by doctors of various specialities and will help to prescribe correct dosage of medicine and to prevent undesirable drug effects while treating patients.

Our system also can be helpful in forming the list of genes and polymorphisms which should be tested in patient before beginning of specific treatment.

Thus developed software will be interesting to the practicing doctors and will allow to optimize treatment of diseases depending on specific genetic features of the patient.

P11.108

The distribution of risk alleles for clopidogrel response (CYP2, PON1, ABCB1): pilot study in Czech patients with coronary stenting

P. Schneiderova[1,2], E. Kriegova[1,2], J. Petrkova[3], M. Petrek[1,2];
[1]Lab. of Immunogenomics and Immunoproteomics, Palacky University, Olomouc, Czech Republic, [2]Lab. of Cardiogenomics, University Hospital, Olomouc, Czech Republic, [3]Internal Medicine – Cardiology, University Hospital, Olomouc, Czech Republic.

Clopidogrel - an inhibitor of platelet activation - is widely used in the prevention of atherothrombotic events in patients undergoing percutaneous coronary interventions (PCI) with stent implantation. Genetic variations in genes involved in the absorption (P-glycoprotein/ABCB1) and metabolism (CYP2C19, CYP2C9, PON1) of clopidogrel are thought to influence the response to the drug. The purpose of our study, therefore, was to characterize the distribution of alleles which are associated with altered response to clopidogrel in Czech patients after PCI.

A spectrum of risk genetic variants in genes CYP2C19, CYP2C9, PON1, ABCB1 were assessed in a cohort of 294 patients after PCI employing multiplex PCR analysis by MassArray technology (Sequenom).

Carriage of loss-of-function alleles, which may cause reduced conversion to active metabolite of clopidogrel was as follows: CYP2C19*2 27.9 % (2.4 % homozygotes), CYP2C9*3 16.0 % (0.7 %), PON1 192R 46.9 % (4.4 %). Carriage of CYP2C19*17 - the allele associated with ultra-rapid metabolism - was 42.5 % (4.5 %). Genetic variation of P-glycoprotein influencing drug absorption - ABCB1 3435TT genotype and ABCB1*2 allele (haplotype ABCB1 1236TT-2677TT-3435TT) - was found in 33.3 % and 21.8 % patients, respectively.

In conclusion, more than 40% of our PCI patients possessed alleles and/or their combinations, which have been reported to be associated with impaired efficacy of antiplatelet treatment and/or increased risk of cardiovascular complications. The evaluation of risk allele(s) genotyping on the rate of subsequent cardiovascular events in our PCI patients is under progress.

The human platelet transcriptome: RNA-seq reveals a greater complexity of protein-coding and non-coding transcripts than previously appreciated

E. Londin, I. Rigoutsos, S. E. McKenzie, L. Edelstein, P. Loher, H. Chen, S. Nagalla, K. Delgrosso, A. Ertel, P. F. Bray, P. Fortina;
Thomas Jefferson University, Philadelphia, PA, United States.

Platelets are essential to hemostasis and thrombosis. Having a complete understanding of the platelet transcriptome will give insight into the genetic basis of these disease traits ultimately leading to new methods for treatment. Genome-wide RNA expression studies using microarrays has provided novel insights to the platelet transcriptome. However, limitations of microarrays including the use of probes only to known transcripts and a limited dynamic range for quantifying very low and high levels of transcripts has not yet revealed the complete picture of the platelets transcriptome. To capture the complexity of all the transcripts in human platelets, we performed RNA sequencing (RNAseq) in leukocyte-depleted platelets derived from four healthy donors. The platelet whole transcriptomes for long and short RNA from total and ribosomal RNA-depleted samples were analyzed on the AB SOLiD platform. We estimate that there are ~9500 protein-coding genes expressed in platelets, 85 of which were validated by qRT-PCR. Many classes of non-coding RNAs were identified, including a larger number of miRNAs than previously appreciated, as well as pseudogenes and retroelements. Comparison of microarray results to the RNAseq revealed a significant correlation of well-expressed mRNAs, but RNAseq identified many more transcripts of lower abundance and permitted the discovery of novel transcripts. The RNAseq performed here revealed the complexity of the platelet transcriptome that may permit a better understanding of the molecular mechanisms that regulate platelet physiology and contribute to disorders of thrombosis and hemostasis.

Mazoyer[8], D. Muller[12], A. Remenieras[6], F. Revillion[13], E. Rouleau[1], J. Sokolowska[7], J. Vert[14], R. Lidereau[1], F. Soubrier[15], H. Sobol[6], N. Sevenet[5], B. Bressac de Paillerets[4], A. Hardouin[16], M. Tosi[17], O. Sinilnikova[18], D. Stoppa Lyonnet[1,2];
[1]Institut Curie, Paris, France, [2]université Paris Descartes, Paris, France, [3]centre F Baclesse, Caen, France, [4]Institut Gustave Roussy, Villejuif, France, [5]Institut Bergonie, Bordeaux, France, [6]Institut Paoli Calmettes, Marseille, France, [7]CHU, Nancy, France, [8]Inserm U1052, Lyon, France, [9]APHP pitié Salpétrière, Paris, France, [10]Inserm U614, Rouen, France, [11]CHU, Lyon, France, [12]centre P Strauss, Strasbourg, France, [13]centre O Lambret, Lille, France, [14]Ecole des Mines, Paris, France, [15]APHP Pitie Salpétrière, Paris, France, [16]cetre F Baclesse, Nancy, France, [17]inserm U614, Rouen, France, [18]centre L Berard, Lyon, France.

Assessing the impact of variants of unknown significance (VUS) on splicing is a key issue in molecular diagnosis. This impact can be predicted by *in silico* tools, but proper evaluation and user guidelines are lacking. To fill this gap, we embarked upon the largest *BRCA1* and *BRCA2* splice study to date by testing 272 VUSs (327 analyses) within the *BRCA* splice network of Unicancer. All these VUSs were analyzed by using six tools (Splice Site Prediction by Neural Network, Splice Site Finder, MaxEntScan, ESE Finder, Relative Enhancer and Silencer Classification by Unanimous Enrichment, Human Splicing Finder) and the predictions obtained were compared to transcript analysis results. Combining MaxEntScan and Splice Site Finder gave a 96% sensitivity and a 83% specificity for VUSs occurring in the vicinity of consensus splice sites, i.e. the surrounding 11 and 14 bases for the 5' and 3' sites, respectively. This study was also an opportunity to define guidelines for transcript analysis along with a tentative classification of splice variants. The guidelines drawn from this large series should be useful for the whole community, particularly in the context of growing sequencing capacities that require robust pipelines for variant interpretation.

P11.111

Targeting human *KIAA0649P* into mouse *Rb1*: Pseudogene integration is causative for genomic imprinting of *RB1*

L. Steenpass, D. Kanber, M. Hiber, K. Buiting, D. Lohmann;
Institute of Human Genetics, Essen, Germany.

The human retinoblastoma gene, *RB1*, is imprinted. Gene expression is skewed in favour of the maternal allele. This is due to parent-of-origin specific DNA methylation on the truncated and inverted pseudogene *KIAA0649P*. This pseudogene evolved after integration into intron 2 of the *RB1* and in its present form harbors a new CpG island, CpG85, which serves as promoter for an alternative *RB1* transcript, transcript 2B. CpG85 is methylated on the maternal allele only and, as expected, expression of transcript 2B is restricted to the paternal allele. Transcription of the paternal transcript 2B interferes with transcription of the regular *RB1* transcript on the same allele.

Mouse *Rb1* does not contain *KIAA0649P* and is not imprinted. To determine if *KIAA0649P* is sufficient to result in skewed expression of *Rb1* we generated a knock-in of human *KIAA0649P* in intron 2 of the murine *Rb1* gene. To be able to distinguish expression of the two *Rb1* alleles, mouse embryonic stem (ES) cells were first modified such that they harbor a single nucleotide variant in exon 3 of *Rb1*.

In the generated ES cell lines we could show that integration of a second active promoter leads to transcriptional suppression of the targeted *Rb1* allele. In addition, we determined that the *Rb1* promoter and CpG85 are free of DNA methylation. Currently we determine if an alternative transcript 2B is expressed of CpG85.

At the present stage our analyses of genetically modified mouse ES cells provides evidence that the integration of a pseudogene can suppress gene expression.

P11.112

Amplicon based targeted resequencing analysis of PDE6A and PDE6B in a cohort of patients with a clinical diagnosis of Retinitis Pigmentosa using the Fluidigm 48.48 Access Array™ system and the Roche 454 GS FLX Next Generation Sequencing technology

N. Weisschuh[1], *S. Link*[1], *S. Kotschote*[2], *S. Kohl*[1], *B. Wissinger*[1];
[1]Institute for Ophthalmic Research, Tuebingen, Germany, [2]IMGM Laboratories, Munich, Germany.

The genetic heterogeneity of Retinitis Pigmentosa hampers the identification of the underlying mutation in many cases. Current genetic diagnostics frequently takes several months or even years and, due to the need for investigation of many large genes, is very expensive. Moreover, there is a lack of data about mutations in low-prevalence disease genes due to the technological limits that have hampered comprehensive studies.

We aimed to find all possible disease-associated variants in coding sequences of the *PDE6A* and *PDE6B* genes in a large cohort of patients diagnosed with autosomal recessive Retinitis Pigmentosa (arRP) using a time- and cost-efficient next generation sequencing (NGS) approach.

Ninety-six patients with a clinical diagnosis of arRP were screened for mutations in the *PDE6A* and *PDE6B* genes using an amplicon based targeted resequencing approach. Target enrichment was performed using the Fluidigm 48.48 Access Array™. NGS was performed using the Roche 454 GS FLX technology. Identified variants were confirmed or rejected by Sanger sequencing.

We verified a total of 16 sequence variants in *PDE6A* and 14 variants in *PDE6B*, respectively. Five of these were clearly pathogenic because they fulfilled the criterion of homozygosity or compound heterozygosity and, moreover, have been previously described. The pathogenicity of the remaining variants remains unclear since they were only found in heterozygous state.

Due to the heterogeneity of Retinitis Pigmentosa, genetic diagnostics based on traditional Sanger sequencing is laborious and expensive. We found that the NGS approach is a time- and cost-efficient tool for screening low-prevalence disease genes in large cohorts.

P11.113

Time course RNA-seq: A potential avenue with somewhat different approach in tandem of differential analysis

S. Oh[1], *H. Zhao*[2], *J. P. Noonan*[2];
[1]Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States, [2]Yale School of Medicine, New Haven, CT, United States.

RNA-seq is exponentially becoming the de facto standard approach to compel considerable advantages over conventional technologies such as microarray by directly sequencing transcripts in gene expression profile. Thanks to the reduced cost to sequencing, studies to dynamic change of gene expression in a given biological system over time have shown steady growth over the past few years as microarray, however, statistical approaches to characterize dynamic temporal complexities are currently elusive. In differential gene expression analysis, as somehow limited but intuitive solutions, static differential expression methods without respect to time can be applied, which do not take into account the inherent dependencies in time series explicitly that the expression patterns at later stages are dependent on patterns at earlier stages. We present a statistical framework to define dynamic gene expression patterns over time using empirical trajectory index and Hidden Markov Model (HMM) approach in time series RNA-seq data, and our methods are validated through Markov Chain Monte Carlo (MCMC) simulation study in time dependent data. The utility of the proposed dynamic methods for temporal RNA-seq is demonstrated by application to the analyses of gene expression patterns in RNA-seq real data sets and MCMC simulation study in details.

P11.114

Long term investigation of gene expression variations in venous blood from healthy individuals

S. Lehnert, *H. Cuppens*;
Center for Human Genetics, Leuven, Belgium.

Gene-expression profiles from human venous blood have been applied in diagnostic tests and laboratory settings. A new method to obtain these profiles is RNA-Seq, a high-throughput sequencing technique. This method outperforms hybridization-based array technologies in sensitivity and dynamic range and provides a digital readout of transcript levels. Thus, it creates a high resolution snapshot of the transcriptome. While reproducibility of replicates and technical biases of high-throughput sequencing has been extensively studied, within individual variability has not. By applying RNA-Seq, we will categorize intra-individual variations over a time span of 2 years and analyze the impact on diagnostics. We would like to confirm that sample extraction on a "bad-day" does not sicken a patient.

Human venous blood samples will be collected from 3 healthy volunteers on a day to day, week to week and month to month basis over 2 years. Multiplexed samples will be analyzed on the Illumina HiSeq system and prepared by 3 approaches. The first is designed to analyze only polyadenylated RNAs, the second to investigate rRNA depleted RNA and the third focuses on small non-coding RNAs. The sequence reads will be mapped with Tophat and analyzed at the (gene) transcript isoform level with tools as Cufflinks, edgeR and(or) DESeq.

Defining these limitations is a crucial step in applying RNA-Seq in diagnostics. Characterizing intra-individual transcriptome variations will enable diagnostics to determine the limitations of RNA-Seq's predictive power. This study will provide practical recommendations that will significantly improve the accuracy of RNA-Seq studies.

P11.115

A simple method for improving the limit of detection for capillary electrophoresis DNA sequencing - a comparison of methodologies for KRAS variant detection

C. J. Davidson[1], *K. J. Champion*[2], *M. Gauthier*[1], *F. Wang*[1], *J. Boonyaratanakornkit*[3], *J. R. Jones*[2], *E. Schreiber*[1];
[1]Applied Biosystems, Foster City, CA, United States, [2]Greenwood Genetic Center, Greenwood, SC, United States, [3]AcroMetrix, Benicia, CA, United States.

Fluorescent dye terminator Sanger sequencing (FTSS), with detection by automated capillary electrophoresis (CE), has long been regarded as the gold standard for variant detection. However, software analysis and base-calling algorithms used to detect mutations were largely optimized for resequencing applications in which different alleles were expected at heterozygous mixtures of 50%. Increasingly, the requirements for variant detection are an analytic sensitivity for minor alleles of <20%, in particular, when assessing the mutational status of heterogeneous tumor samples. Here we describe a simple modification to the FTSS workflow that improves the limit of detection of cell-line gDNA mixtures from 50-20% to 5% for G>A transitions and from 50-5% to 5% for G>C and G>T transversions. In addition, we use two different sample types to compare the limit of detection of sequence variants in codons 12 and 13 of the KRAS gene between Sanger sequencing and other methodologies including shifted termination assay (STA) detection, single-base extension (SBE), pyrosequencing (PS), high resolution melt (HRM), and real-time PCR (qPCR).

P11.116

Investigating levels of precision in gene expression measurement by digital PCR

R. Sanders[1,2], *C. A. Foy*[1], *D. Mason*[2], *J. F. Huggett*[1];
[1]LGC, Teddington, United Kingdom, [2]Cardiff University, Cardiff, United Kingdom.

Gene expression studies profiling mRNA are central to biomolecular research offering considerable potential for research, diagnostics and prognostics. Gene expression measured by reverse transcriptase (RT) linked PCR, is commonly used to interpret the effects of specific signals both *in vitro* and *in vivo*, often on low copy transcripts extracted from tissues. The RT step, necessary to convert mRNA to cDNA, is widely accepted as both inefficient and imprecise, with studies reporting variabilities up to 17-fold. This study tested RT measurement variability of synthetic RNA transcripts (ERCC developed targets; European RNA Control Consortium) using RT digital (d) PCR evaluated through one-step reactions; where RT-dPCR is performed in a one-step (one reaction vessel) process rather than the standard two-step approach (independent reactions in different tubes for the RT and then PCR stages). dPCR applies single molecule amplification achieved by sample partition for absolute quantification. The measurement capability and reproducibility of RT to aid quantification of targets spiked into human cell-line derived total RNA was assessed. Furthermore, to compare measurement accuracy of RT-dPCR with more established DNA dPCR, six well-characterised ERCC targets of known concentration were evaluated, enabling assay bias assessment. Our results demonstrate RT reaction sensitivity is assay dependent, with different quantification determined for each target despite evaluation of equal copy numbers. This study is one of the first to demonstrate application of RT-dPCR for absolute quantification of low copy RNA targets. This approach allows RT precision, sensitivity and linearity to be monitored alongside reaction efficiency, facilitating accurate interpretation of gene expression data.

P11.117

Excess of novel nonsense mutations identified in putative susceptibility genes for schizophrenia and autism spectrum disorders

***S. Furlong**, E. M. Kenny, P. Cormican, C. Fahey, R. Anney, G. Donohoe, A. P. Corvin, L. Gallagher, M. Gill, D. W. Morris;*
Trinity College Dublin, Dublin, Ireland.

Schizophrenia (SZ) and autism spectrum disorders (ASD) are complex genetic neurodevelopmental disorders that share certain phenotypes (e.g. cognitive deficits), and may share an underlying pathology due to shared genetic risk variants (e.g. already-identified NRXN1). This study involves next-generation sequencing of the exonic regions of 215 putative susceptibility genes in an Irish sample of 151 cases of ASD, 274 cases of SZ and 287 controls, to identify rare mutations contributing to one or both disorders. A multiplex target enrichment method combined DNA samples using indexes/barcodes followed by enrichment of exonic regions using Agilent SureSelect and paired-end sequencing on an Illumina GAII. Selected genes were categorised as: 1) NRXN1 and interactors, 2) Postsynaptic Glutamate Receptor Complexes (NMDA, mGluR5 and AMPA), 3) Neural cell adhesion molecules, 4) DISC1 and interactors, and 5) Functional and Positional Candidates. Analysis of 2,170 rare variants revealed an excess of nonsense mutations in cases (n=12) compared to controls (n=1; p=0.019). All nonsense mutations were novel and 3 were in DST (2xSZ, 1xControl). The other SZ mutations were in DLG5, FAT1, FYN, INADL, MACF1 and MYO16. Five of 7 SZ nonsense genes have NRXN1-related function. ASD mutations were in CNTNAP1, GRIP1, GRIN2B and NRG1. Rare ASD mutations have previously been reported for GRIP1 and GRIN2B. Analysis of all rare variants in the 11 nonsense genes identified an excess of cases carrying one or more mutations compared to controls (p=0.019). These results supply new supportive data for known ASD risk genes and identify putative new susceptibility genes for both disorders.

P11.118

Determination of methylation profile in patients with schizophrenia

***B. B. Rukova**[1], S. Hadjidekova[1], R. Staneva[1], I. Dimova[1], Z. Hammoudeh[1], V. Milanova[2], G. Kirov[3], D. Toncheva[1];*
[1]Department of Medical Genetics, Medical University, Sofia, Sofia, Bulgaria, [2]Department of Psychiatry, Medical University, Sofia, Sofia, Bulgaria, [3]Department of Psychological Medicine, Cardiff University, UK, Cardiff, United Kingdom.

Schizophrenia is a severe chronic mental disorder that affects most of the higher brain functions. Its prevalence is estimated on about 1% worldwide. The classical symptoms occur in several other psychiatric disorders, which makes difficult the exact diagnosis. Schizophrenia is a serious social and economic healthcare problem. Currently, there is no etiological treatment.

DNA methylation is a major epigenetic modification. It is a biochemical process that is important for normal organismal development and cellular differentiation. DNA methylation stably alters the gene expression pattern in cells. This modification can be inherited through cell division.

Materials and methods: We analyzed age matched pools of 110 female schizophrenia patients and 110 female healthy controls. We've performed high-resolution genome-wide methylation array analysis (Agilent 1x244K). We've analyzed the methylation status of 27 800 CpG islands of both groups to identify methylation profile differences.

Results: Our experiments show significant difference in the methylation profile between patients and controls. In patients we observed significantly higher number of hypermethylated genes compared to healthy controls. In controls we established that hypomethylated genes predominate in comparison to schizophrenia patients.

Conclusions: Our data suggest that there is a major differences is methylation profile between patients and controls. This dysregulation can play a critical role in schizophrenia pathogenesis.

QCTool: an efficient toolkit to automatically generate quality metrics of next-generation sequencing data

***R. Berutti**[1,2], F. Reinier[1], R. Atzeni[1], A. Angius[1,3], R. Cusano[3], M. Marcelli[1], M. Oppo[1], R. Pilu[3], M. F. Urru[1], M. Valentini[1], I. Zara[1], S. Sanna[3], F. Cucca[3,2], C. Jones[1];*
[1]CRS4 - Centre for Research Development and Advanced Studies in Sardinia, Pula, Cagliari, Italy, [2]Dipartimento di Scienze Biomediche, Università degli Studi di Sassari, Sassari, Italy, [3]Istituto di Ricerca Genetica e Biomedica - Consiglio Nazionale delle Ricerche, Cagliari, Italy.

With the wide use of next-generation sequencing platforms and the increase in sample throughput, it is necessary to automate the determination of data quality metrics, not only for sanity check purposes but also to monitor the complex workflow of the sequencing process to locate, and eventually correct, possible errors. To facilitate this process in a large ongoing effort to study the whole genomes, exome and transcriptome of about 1500 Sardinians, we have developed „QCTool".

The software takes as input SAM/BAM files and produces, in addition to standard statistics as base and mapping qualities, reads-to-reference mismatch rate, and genome coverage, also several parameters useful for wet-lab quality validation such as PCR duplicates count, nucleotide relative content, and insert size distribution statistics. It is enriched with contig/chromosome specific breakdowns as well as per-cycle quality plots. Furthermore for exome sequencing, a simple command line option allows the parsing of targeted regions and the determination of quality statistics limited to such regions.

The package produces both PDF reports and an easily parsable file that can be integrated into LIMS systems or analysis tracking tools. For a direct use on presentations or papers, all plots are also generated in JPG format. The toolkit can be run stand-alone, just supplying the input file on a single core machine, or in a multicore fashion. Around 8Gb of memory are required for the complete analysis of a human genome aligned file, but deactivating some analysis options enables execution on desktop machines using only a few kilobytes of memory.

P11.120

Frequency of altered DNA methylation at imprinted loci in children born SGA

***S. Bens**[1], A. Haake[1], J. Richter[1], J. Leohold[1], J. Kolarova[1], G. Gillessen-Kaesbach[2], K. Buiting[3], F. G. Riepe[4], A. Caliebe[1], R. Siebert[1];*
[1]Institute of Human Genetics, Christians-Albrechts-University Kiel& University Hospital Schleswig-Hol, Kiel, Germany, [2]Institut für Humangenetik Lübeck, Universität zu Lübeck, Lübeck, Germany, [3]Institute of Human Genetics, University Hospital Duisburg-Essen, Essen, Germany, [4]Department of Pediatrics, Christians-Albrechts-University Kiel & University Hospital Schleswig-Holstein, Kiel, Germany.

Patients with imprinting disorders show a broad range of phenotypic variability. This leads to the hypothesis that imprinting defects might frequently be undetected in patients that share some, but not all typical symptoms being present in imprinting disorders, e.g. children born small for gestational age (SGA). Furthermore recent studies propose hypermethylation in IGF2R DMR2 to be enriched among patients with growth restriction. Within the BMBF funded German Network "Imprinting Disorders" we here performed quantitative DNA methylation analysis of 10 imprinted loci (PLAGL1, H19DMR, IGF2, GRB10, NDN, SNRPN, NESP, NESPAS, MEG3, IGF2R DMR2) by bisulfite pyrosequencing of 97 patients born SGA and 50 controls. For IGF2R DMR2 we additionally screened 95 parents of patients born SGA (47 parent pairs and one single mother). We established in one child the diagnosis of Temple syndrome most likely due to an epimutation. Furthermore five patients and six individuals from the SGA parent cohort displayed IGF2R DMR2 hypermethylation. Of these in two families IGF2R DMR2 hypermethylation was detected in the child and one parent. Five individuals in the control cohort displayed IGF2R DMR2 hypermethylation. We conclude that imprinting disorders may still be underdiagnosed and are a relevant differential diagnosis in children born SGA. Hypermethylation in IGF2R DMR2 is not enriched in our patient cohort. Lack of genotype-phenotype correlation in our and previous studies leads to the assumption that IGF2R DMR2 hypermethylation most likely represents an epigenetic polymorphism, however a Mendelian inheritance cannot be excluded from our observations.

P11.121

Determining the role of SIRT6 as an epigenetic regulator of gene expression in hepatocytes

***M. Linke**[1], K. Fischer[2], U. Zechner[1], S. Strand[2];*
[1]Institute of Human Genetics, University Medical Center of the Johannes Gutenberg University Mainz, Mainz, Germany, [2]Department of Internal Medicine I, University Medical Center of the Johannes Gutenberg University Mainz, Mainz, Germany.

The mamalian sirtuin family consists of seven members (SIRT1-7) that target a wide range of cellular proteins in nucleus, cytoplasm, and mitochondria for post-translational modification by deacetylation or ADP-ribosylation. SIRT6 is located in the nucleus and promotes a number of important key functions like DNA repair, genome stabilization and telomere maintenance. In accordance with these functions, Sirt6 knock-out mice show several dramatic symptoms of premature ageing and die within four weeks.

We performed microarray gene expression profiling of hepatocytes from Sirt6-deficient and wildtype mice. This analysis detected a significant upregulation of the imprinted H19, Igf2 and Peg3 genes which was subsequently confirmed by quantitative PCR. Bisulphite pyrosequencing of the imprinting control regions of these three and other imprinted genes did not reveal significant methylation differences between Sirt6-deficient and wildtype hepatocytes. Similarly, DNA methylation analysis of these cells at subtelomeric regions known to exhibit DNA methylation changes associated with increased telomeric recombination in DNA methyltransferase-deficient cells gave normal results. However, using quantification of global DNA methylation with a specific antibody in an ELISA-like reaction, we observed significantly decreased levels of 5-methylcytosine in Sirt6-deficient cells. Bisulphite pyrosequencing excluded that repetitive elements as frequently used indicators of global DNA methylation changes are affected by this demethylation process.

Our results provide further evidence that the epigenetic regulatory role of SIRT6 is more likely associated with higher order chromatin structures and specific histone modifications. Nevertheless, there is an obvious decline in global DNA methylation in Sirt6-deficient cells that needs to be studied in more depth.

Detecting SNP interactions associated with HDL using GPUs

E. M. van Leeuwen[1], F. A. S. Smouter[1], T. Kam-Thong[2], N. Karbalai[2], K. M. Borgwardt[3], C. M. van Duijn[1], L. C. Karssen[1], B. Muller-Myhsok[2];
[1]Erasmus MC, Rotterdam, Rotterdam, Netherlands, [2]Max-Planck-Institute of Psychiatry, Munich, Germany, [3]Max Planck Institutes, Tübingen, Germany.

In recent years many genome-wide association (GWA) studies have been performed. Many of these have been successful in identifying loci associated with complex diseases. Until now, these results failed to fully explain the heritability of many of the diseases.

Searching for interactions between Single Nucleotide Polymorphisms (SNPs) is one of the many possible explanations to the missing heritability. However, the computational time needed for testing all pairs of SNPs is proportional to the square of the number of SNPs, translating into months of CPU time. We therefore evaluated GLIDE [1] which makes use of the computational power of consumer-grade graphics cards (GPUs) to detect interactions via linear regression.

We present our first experiments with GLIDE for which we analysed the HDL levels in 3,000 individuals of the Rotterdam Study. The first results show that GPUs can indeed be used for fast genome-wide analysis of SNP-SNP interactions. We found multiple regions showing genome-wide significant interactions which are currently being investigated. However, occasionally problems occur using imputed data hampering meta-analysis and replication. Further developments are currently ongoing to overcome this issue and will also be presented.

This work is supported by the NVIDIA Academic Partnership Program.

Genetic and functional investigation of the *SOX9* regulatory region in development and disease

C. T. Gordon[1], C. Attanasio[2], D. Kleinjan[3], S. Benko[1], L. Melin[1], M. Ansari[3], V. Abadie[4], K. Temple[5], A. Goldenberg[6], L. Pennachio[2], A. Munnich[1], D. FitzPatrick[3], J. Amiel[1], A. Visel[2], S. Lyonnet[1];
[1]Université Paris Descartes, INSERM U-781, Hôpital Necker-Enfants Malades, Paris, France, [2]Lawrence Berkeley National Laboratory, Berkeley, CA, United States, [3]MRC Human Genetics Unit, University of Edinburgh, Edinburgh, United Kingdom, [4]Centre de Référence Pierre Robin, Hôpital Necker-Enfants Malades, Paris, France, [5]University of Southampton, Southampton, United Kingdom, [6]Hôpital Charles Nicolle, Rouen, France.

Mutations in the coding sequence of *SOX9* cause campomelic dysplasia (CD), a disorder of skeletal development, in association with 46,XY sex reversal, reflecting the essential roles of *SOX9* in chondrogenesis and testis development. Non-coding genomic lesions, including translocations and deletions, within a ~1.4 Mb region upstream of *SOX9* can recapitulate the CD phenotype fully or partially, suggesting the existence of an unusually large cis-regulatory control region. Indeed, studies in transgenic mice have demonstrated that this interval contains several highly conserved non-coding elements that can function as enhancers of tissue-specific transcription, partly recapitulating the *SOX9* expression pattern. Pierre Robin sequence (PRS) is a craniofacial disorder that is typically a component of the CD phenotype, and we have previously reported a locus for isolated PRS at ~1.1-1.4 Mb upstream of *SOX9*. We now report two novel deletions in PRS patients; one partly overlapping the previously identified locus, and the other falling much closer to *SOX9*. In parallel, we performed ChIP-Seq analysis to identify genome-wide binding sites for p300, a marker of active enhancers, in mouse craniofacial tissue. Several binding sites were identified upstream of *SOX9*, and were validated as craniofacial enhancers in transgenic mouse reporter assays. Notably, some of the p300 binding sites fall within the novel PRS deletions, and sequencing of these regions in a large cohort of PRS patients revealed several rare variants. These studies add a further level of complexity to our knowledge of the mechanisms governing transcriptional regulation of *SOX9*.

P11.124

Sex determining region Y (SRY) contributes to normal development by regulation of genes involved in pluripotency and differentiation

S. Ashrafi Kakhki[1,2], R. Favaedi[1], G. H. Salekdeh[3], M. Shahhoseini[1];
[1]Department of Genetics, Reproductive Biomedicine Center, Royan Institute for Reproductive Biomedicin, Tehran, Islamic Republic of Iran, [2]Department of Biology, Science and Research Branch, Islamic Azad University, Tehran, Islamic Republic of Iran, [3]Department of Molecular Systems Biology, Cell Science Research Center, Royan Institute for Stem Cell Biology and Technology, ACECR, Tehran, Islamic Republic of Iran.

Introduction: Members of the SOX (SRY box) family proteins play critical roles in multiple aspects of development.SRY, as a founder member of SOX family, has long been believed to be involved in development of sexual gonads by triggering signaling cascades that lead to formation of testis or ovary from bipotential gonads. However, less is known about whether SRY has role in other developmental procedures. In order to gain further insight into the possible roles of SRY during development, we looked into possible SRY-regulated genes and their levels of expression in a human embryonic carcinoma cell line, named NTera2, before and after induction of differentiation.

Material and methods: For this respect two groups of genes including *OCT4*, *NANOG* and *SOX2* as pluripotency marker genes, and *NESTIN* and *PAX6* as differentiation marker genes were evaluated.Chromatin Immunopercipitation (ChIP) was performed using SRY antibody on chromatin extracted from NTera2 cells before and after neural differentiation and SRY incorporation on the regulatory regions of the aforementioned genes were evaluated quantitatively, using real time-PCR technique.

Results and conclusion: Our results showed that incorporation of SRY in both groups of marker genes was increased after induction of differentiation. Besides, the low expression level of *OCT4*, *SOX2* and *NANOG* and the high expression of *PAX6* and *NESTIN* in the differentiated cells suggest that SRY may act as a transcription repressor for pluripotency-associated genes and as a transcription activator for differentiation -related genes.

Targeted sequencing experiments for rare disease alleles: implications in clinical practice and diagnosis of steroid-resistant nephrotic syndrome

A. Provenzano[1], B. Mazzinghi[2], B. Tesi[2], M. Materassi[3], P. Romagnani[4], S. Giglio[1];
[1]Department of Clinical Pathophysiology, Medical Genetics Unit-Meyer Children's University Hospital, Firenze, Italy, [2]Medical Genetics Unit-Meyer Children's University Hospital, Firenze, Italy, [3]Nephrology Unit-Meyer Children's University Hospital, Firenze, Italy, [4]Department of Clinical Pathophysiology, Nephrology Unit-Meyer Children's University Hospital, Firenze, Italy.

During recent years, several podocyte genes have been implicated in severe forms of steroid-resistant nephrotic syndrome (SRNS) progressing to renal failure. To date, at least 15 genes highly expressed in the podocyte have been associated with the syndrome and different mutations in these genes have been identified; it is now known that the phenotypes associated with mutations in these genes display significant variability, rendering genetic testing and counselling a more complex task. Traditional methods for sequencing genes are often laborious and not easily available and a screening technique that enables the rapid detection of the pathogenetic variants would be very helpful in the clinical practice. The scope of our work is to apply next-generation sequencing (NGS) technology to study patients affected by SRNS, in which the previous analysis of *NPHS2* and *WT1* genes had not shown any mutations. We perform in 8 affected subjects a targeted resequencing of 46 genes including those already known as causative of the disorder and several other genes highly expressed in the podocyte.

We found new heterozygous missense mutations in different genes that occasionally are associated with the disease in childhood (*PLCE1, ACTN4, MYO1E, PODXL)*. We also detected a variation in the *ZHX2* gene, to date never associated with SRNS. This gene encode for a transcriptional factor which regulates the expression of several genes in the podocyte, including *WT1*. This results and further clinical investigations provides an exciting opportunity to reveal more insight into the pathogenic mechanisms that underlie this debilitating disorder.

P11.126

A systems biology approach to linking genotype to phenotype, using celiac disease as an example

***V. Kumar**, H. Westra, J. Gutierrez, B. Hrdlickova, R. Almeida, J. Karjalainen, L. Franke, C. Wijmenga, S. Withoff;*
Department of Genetics, UMCG, Groningen, Netherlands.

Genome-wide association studies (GWAS) have been successful in identifying genes involved in complex diseases. However, the critical challenge is to translate GWAS hits into a biological hypothesis. We have previously identified 57 independent, non-HLA loci to be strongly associated with celiac disease (CeD). Many of these loci harbor multiple genes and for many of these it is difficult to link genotype to phenotype. We therefore undertook a systems biology approach to fill this gap, integrating results from eQTL analysis, network/pathway-based analyses, imputation results, and SNP function annotation. The eQTL mapping, using whole genome gene-expression data and genotyping data from 1,240 samples and replication in an independent set of 229 blood samples, suggested significant eQTLs at 16 CeD SNPs (FDR P < 1.12*10-7 to 1.51*10-137). Pathway analyses using seed genes identified by GWAS and eQTL analysis suggested causative genes at 55 out of 57 CeD loci. Surprisingly, along with enrichment for T-cell, B-cell and neutrophil genes, co-expression network analysis also suggested that 11% of CeD genes are highly expressed in epithelial tissues and are involved in epithelial cell-cell adhesion. We imputed CeD-associated regions using 1000 Genome project and annotated the function of all the susceptibility variants. SNPs with strong eQTLs lay within binding sites of either microRNAs (e.g. for IL18RAP, UBE2L3) or transcription factors (e.g. for MMEL1, CSK). Thus, our study provides a biological hypothesis for almost every CeD susceptibility locus to connect the genotype and CeD phenotype and it implicates the involvement of a novel pathway in CeD pathogenesis.

P11.127

Analisys of MMP-3 gene promoter methylation status in epithelial cells from oral mucosa and gingival tissue cells and genetic expression in smokers and nonsmokers subjects with chronic periodontitis

***G. R. Damm**[1,2], N. F. Oliveira[1,3], A. P. Souza[1];*
[1]FOP - Unicamp, Piracicaba, Brazil, [2]Hospital AC Camargo, São Paulo, Brazil,
[3]Universidade Federal da Paraiba, João Pessoa, Brazil.

The objective was to investigate the methylation status of CpG site at position -686 of MMP-3 gene promoter and the levels of mRNA expression of MMP-3. Subjects were divided into: nonsmokers healthy, non-smokers and smokers with chronic periodontitis. DNA was purified from buccal epithelial cells, that were obtained after oral rinse and DNA and RNA were purified from biopsies gingival cells. The methylation status at -686 of MMP-3 gene promoter was investigated by restriction enzyme sensitive to methylation *HpaII*, the PCR and electrophoresis. Methylated samples showed positive bands after PCR and non-methylated samples showed no bands. The statistical analysis between the methylation status found in this samples in each groups was performed by X^2 test at 5% level. The relative expression of MMP-3 was examined by real time PCR and statistical analysis was performed by Kruskal-Wallis test at 5 % level. There was not difference in the methylation status found in each group. The frequency of the unmethylated status found in the epithelial oral cells was 18,3% in healthy non-smokers, 12,5% in chronic periodontitis smokers and 9,7% non-smokers. And the unmethylated status of gingival cells was higher in all groups: 28% in healthy non-smokers, 38% in smokers with chronic periodontitis and 27% in non-smokers with chronic periodontitis. Also, there was not difference in genetic expression of MMP-3 among these groups. We conclude that there is not association between the methylation status observed at position -686 of MMP3 gene promoter and chronic periodontitis in smokers and non-smokers.

Agilent Technologies SureSelect™ Human All Exon Designs: High Performance Target Enrichment System for Human Exome Sequencing

***D. N. Roberts**, E. Lin, A. Lee, A. Giuffre, C. Pabón-Peña, H. Ravi, B. Novak, M. Visitacion, F. Useche, J. Ong, M. Guadalupe, G. Amparo, S. Happe, E. Leproust;*
Agilent Technologies, Santa Clara, CA, United States.

Next generation sequencing technologies have reduced high-throughput sequencing costs by several orders of magnitude and enabled numerous whole-genome analyses. Nevertheless, the expense and operational capacity necessary for large scale whole genome studies is still prohibitive for many laboratories. Since large portions of the genome consist of repeat elements and regions of unknown phenotypic value, targeted exome capture combined with massively parallel sequencing has become one of the most viable options to gain novel insights into the genetic causes of inherited disorders. By focusing on the protein-coding regions of the human genome, scientists are now able to more efficiently identify both common and rare polymorphisms that are more likely to result in cellular dysfunction and exhibit significant penetrance in disease association studies. This includes Mendelian disorders and complex diseases like cancer or neurological pathologies. Herein we describe our latest SureSelect Human All Exon designs, which incorporate updated exome coordinates from the major databases. Performance and workflow improvements including automation and multiplexed samples are demonstrated with respect to capture efficiency, uniformity, reproducibility of enrichment, and ability to detect SNPs and indels on multiple sequencing platforms. The specificity and accuracy of the human All Exon design ensures coverage of biologically relevant coding regions for small and large scale sequencing operations.

P11.129

Multiplex enrichment of genomic regions using HaloPlex PCR

***H. Johansson**, M. Isaksson, F. Roos, E. Agné, F. Dahl;*
Agilent Technologies, Uppsala, Sweden.

Targeted sequencing methods, in combination with bench top sequencers, enable studies of select regions of large genomes in multiple samples with sufficient coverage.

For a target sequencing to be useful for genetic research as well as for clinical applications it is important that the regions of interest are enriched with high specificity and uniformity to maximize the amount of useful data retrieved from each run. Furthermore it is also important that the protocol is fast to make use of the short turnaround times on bench top sequencers.

The HaloPlex PCR method combines target enrichment and library preparation in a single protocol without the requirement of any dedicated instruments. The protocol associates all targeted fragments with common primer motifs which can then be used to run multiplex PCR using only one primer pair. To make use of the capacity in the sequencing run, up to 96 samples can be enriched, barcoded and pooled on the same flowcell.

We have developed a faster version of the protocol that can be completed in six hours and with improved enrichment uniformity. The key improvements are shortened restriction digestion and hybridization times and consolidation of several of the reaction steps.

The performance of the new protocol was demonstrated by the enrichment of a 400 kb region in ten samples that were subsequently pooled and sequenced on one MiSeq flowcell. All samples were enriched with >95% specificity and 90% of the targeted bases were covered at >10% of average depth.

P11.130

Development of a gene panel for targeted next generation sequencing of twelve thoracic aortic aneurysmal genes

***D. Proost**[1], C. Vrints[2], B. Paelinck[2], J. Saenen[2], B. Loeys[1], L. Van Laer[1];*
[1]Center of Medical Genetics, Faculty of Medicine and Health Sciences, University of Antwerp and Antwerp University Hospital, Antwerp, Belgium, Edegem, Belgium,
[2]Department of Cardiology, Faculty of Medicine and Health Sciences, University of Antwerp and Antwerp University Hospital, Antwerp, Belgium, Edegem, Belgium.

Dissection/rupture of aortic aneurysms represent important causes of death in the Western world. The genetic contribution to thoracic aortic aneurysm (TAA) is significant and a dozen causative genes are known. The molecular confirmation of the clinical diagnosis is important as the identification of the underlying mutation has implications for further patient management and therapy. Because of overlapping phenotypes, the high allelic/locus heterogeneity and large size of the involved genes, the molecular diagnosis for TAA is not always straightforward. Moreover, the consecutive molecular screening of genes using conventional mutation screening methods is expensive and labor intensive. Next generation sequencing (NGS) after hybridization or amplification based enrichment offers an attractive alternative.

Here, we propose a cost- and time-efficient method for simultaneous screening of twelve TAA genes (ACTA2, COL3A1, FBLN4, FBN1, FLNA, MYH11, MYLK, NOTCH1, TGFBR1, TGFBR2 and SLC2A10) based on the Haloplex technology. The latter is an innovative, simple method for specific enrichment of target regions. The protocol simultaneously incorporates the sample identification barcodes (up to 96 different) and the primers for the subsequent NGS run and does not require the acquisition of expensive dedicated equipment. It requires 2 x 150 bp paired-end runs, which we have performed on a Miseq (Illumina). We have obtained an overall coverage "by design" of 99.7% and a "real-life" sequencing coverage of 96.6% of the targeted regions. We are currently optimizing the assay, which includes design improvements and validation in large sample groups.

P11.131

Sample preparation of animal and plant tissues prior to automated nucleic acid purification with Thermo Scientific KingFisher Duo and KingFisher Kits

***M. Suomalainen**, S. Suomalainen, K. Bertula, V. Puro, A. Lamberg;*
Thermo Fisher Scientific, Vantaa, Finland.

Efficient homogenization of animal and plant tissues is an essential step to ensure good DNA and RNA yield and quality. Certain sample types, e.g. harder tissue samples, require strong, either chemical or mechanical treatment for destroying tissue and cell structures before nucleic acid purification process.

Magnetic particle technology enables fast and effective purification of high quality nucleic acids. Thermo Scientific KingFisher Duo uses magnetic particle technology based on the use of magnetic rods with specially designed plastic consumables, BindIt software for protocol development and optimized KingFisher Kits for nucleic acid purification. KingFisher Duo enables purification of 12 samples during one run in working volumes of 30-1000 µl. Running two protocols sequentially without interruption raises throughput up to 24 samples per load. In addition, the instrument gives an option to choose working volumes up to 5 ml.

We tested several different mechanical homogenization methods in addition to chemical lysis to optimize sample preparation before nucleic acid purification in the KingFisher Duo. We analysed performance of homogenization and purification using several different sample materials, including tobacco leaves as well as animal liver and heart samples. The purification process in the KingFisher Duo was performed using three different KingFisher Kits, suitable for cell and tissue DNA or RNA purification. The results indicate high sensitivity of the purification process.

The KingFisher Duo in combination with the KingFisher Kits and new BindIt software 3.2 constitute an exceptional purification system for obtaining excellent yield and purity of nucleic acids.

P11.132

Different Next Generation Sequencing approaches detect mosaic mutations and deep intronic mutations in tuberous sclerosis complex

***K. Mayer**[1], C. Wagner[2], M. Scholz[1], S. Datter[1], I. Vogl[1], I. Rost[1];*
[1]Center for Human Genetics and Laboratory Medicine, Martinsried, Germany, [2]IMGM Laboratories GmbH, Martinsried, Germany.

Tuberous sclerosis complex (TSC) is caused by TSC1 or TSC2 mutations. Current molecular genetic testing combining Sanger sequencing of all 62 and MLPA of 58 coding exons, respectively, identifies a mutation in approximately 80% of the individuals with a definite clinical diagnosis. Possible reasons for this detection gap are mosaicism for a mutation underrepresented in lymphocyte DNA or mutations in regulatory regions.

We reanalyzed patients with the definite clinical diagnosis TSC by resequencing the entire genomic regions of TSC1 and TSC2 applying two Next Generation Sequencing approaches. Firstly, target enrichment with the Agilent SureSelect technology was combined with the Life Technologies SOLiD4 sequencing system. Probe design for 63.885 bp TSC1 and 44.255 bp TSC2 resulted in 43 and 27 genomic regions, respectively. Secondly, 108.140 bp genomic region was amplified by 20 overlapping long-range PCR fragments of 5.000-5.400 bp and subjected to the 454 pyrosequencing technology using the GS FLX Titanium system.

The SureSelect/SOLiD4 technology revealed a bias with an average of 46.68% reads (coverage 612-1332) mapped to TSC1 but only 5.8% (coverage 170-390) to TSC2. Coverage gaps in 17 of the 27 TSC2 regions are obviously due to its high GC content. The long-range PCR/454 GS FLX Titanium approach achieved a more uniform coverage ranging from 697-1719 for TSC1 and 687-3905 for TSC2.

Preliminary results following the two approaches for 10 TSC patient samples uncovered four mosaic mutations composed of two missense and two splice site mutations as well as one true heterozygous deep intronic mutation leading to aberrant splicing.

P11.133

Expression, Purification and Molecular Evolution Studies of Human Tyrosinase

***R. Behzadi**[1], M. Sadeghizadeh[1], A. Mousavi Movahedi[2];*
[1]Tarbiat Modares University, Tehran, Islamic Republic of Iran, [2]Tehran University, Tehran, Islamic Republic of Iran.

Tyrosinase is a copper- containing enzyme that has been isolated and studied from a wide variety of plant, animal and fungal species.Tyrosinases found in different sources such as prokaryotic or eukaryotic microorganism, mammals and plant, differ from each other with respect to the primary structure, size, glycosylation pattern and activation characteristics, but, all tyrosinases, have in common within their active site. In tyrosinase active site, two copper atoms are each coordinated with three histidine residues. Histidine residues are located in two regions named cuA and cuB. A loop containing three residues including M374 connects two copper atoms centers. Therefore this loop is essential for stability and activity of enzyme. M374 is conserved in the phenol oxidase superfamily. A set of mutants were generated previously by replacement of this residue with glycine. In this study, M374 was replaced with asp, Lys, arg, and thr. To carry out mutational characterization of human tyrosinase, an expression plasmid, pHis-tyrosinases, which contain the entire coding sequence of tyrosinase with site directed mutations that mentioned above, were constructed and expressed in p.lysis. The expressed enzymes were purified by an affinity chromatography. Oxidative activity and km values for native and recombinants enzymes were detected respectively. These newly recombinant tyrosinases may have therapeutic potential due to their activity and stability.

GenomeNL variant database; towards a deep genetic encyclopedia of Dutch variation

***P. B. T. Neerincx**[1], F. van Dijk[1], T. Rengaw[1], L. C. Francioli[2], P. I. W. de Bakker[2,3,4], C. Wijmenga[1], M. A. Swertz[1];*
[1]Genomics Coordination Center & Department of Genetics, University Medical Center Groningen, Groningen, Netherlands, [2]Departments of Medical Genetics and Epidemiology, University Medical Center Utrecht, Utrecht, Netherlands, [3]Broad Institute of Harvard and MIT, Cambridge, MA, United States, [4]Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, United States.

Background

The Dutch biobank collaboration BBMRI-NL has initiated the „Genome of the Netherlands" (GoNL) project to produce ~12x whole DNA genetic profiles of 769 Dutch people: 231 trios of a child with its parents, 11 quatros of monozygotic twins and 8 quatros of dizygotic twins. This deep genetic resource will offer unique opportunities for science, which is currently being expedited by an international team of researchers on optimal variant discovery, population genetics and evolution.

Results

Here we present the GoNL variant database, an online encyclopedia of Dutch variation. At submission of this abstract, researchers can already query the GoNL variant database to verify whether variants in their own sample are unique against 25 million SNPs observed in the panel of 500 parents. By April we expect a high quality SNP set based on the full panel and a collection of structural variations using the unique trio structure to filter false positives. We will enrich the database with reference annotations on each variant to disclose a wealth of new information and possible applications the diagnostics.

Methods

The SNP data was produced using Illumina sequencing, BWA alignment, Immunochip for QC, and GATK SNP calling. The data is represented in the database using the Observ-OM standard, developed in collaboration with EU-GEN2PHEN. The software is implemented using the open source MOLGENIS biosoftware toolkit and is freely available for groups to setup their own repositories. The database is accessible via http://www.nlgenome.nl

P11.135

Adhesion Protein VSIG1 Is Required for the Proper Differentiation of Glandular Gastric Epithelia

***G. Nyamsuren**, O. Oidovsambuu, S. Liu, W. Göring, A. Khamit, W. Engel, I. M. Adham;*
Institute of Human Genetics, Göttingen, Germany.

VSIG1, a cell adhesion protein of the immunoglobulin superfamily, is preferentially expressed in stomach, testis, and certain gastric, esophageal and ovarian cancers. Here, we describe the expression patterns of three alternatively spliced isoforms of mouse Vsig1 during pre- and postnatal development of stomach and potential function of Vsig1 in differentiation of gastric epithelia. We show that isoforms Vsig1A and Vsig1B, which differ in the 3' untranslated region, are expressed in the early stages of stomach development. Immunohistochemical analysis revealed that VSIG1 is restricted to the adherens junction of the glandular epithelium. The shorter transcript Vsig1C is restricted to the testis, encodes an N-terminal truncated protein and is presumably regulated by an internal promoter, which is located upstream of exon 1b. To determine the role of VSIG1 during the development of stomach epithelia, an X-linked Vsig1 was inactivated in embryonic stem cells (ESCs). Although Vsig12/Y ESCs were only able to generate low coat color chimeric mice, no male chimeras transmitted the targeted allele to their progeny suggesting that the high contribution of Vsig12/Y cells leads to the lethality of chimeric embryos. Analysis of chimeric stomachs revealed the differentiation of VSIG1-null cells into squamous epithelia inside the glandular region. These results suggest that VSIG1 is required for the establishment of glandular versus squamous epithelia in the stomach. To perform more functional analysis of *Vsig1*, generation of conditional knockout mice is underway.

P11.136

Genotyping Fanconi Anemia Patients by Whole Exome Sequencing

K. Knies[1], *B. Schuster*[1], *T. Bettecken*[2], *R. Friedl*[1], *B. Gottwald*[1], *D. Schindler*[1];
[1]University of Wurzburg, Department of Human Genetics, Wuerzburg, Germany, [2]Max-Planck-Institute of Psychiatry, CAGT Center for Applied Genotyping, Munich, Germany.

The rare genomic instability disorder Fanconi Anemia (FA) is characterized by bone marrow failure, variable malformations and increased predisposition to leukemia and solid tumors. Biallelic mutations in at least 15 genes involved in the FA/BRCA network of DNA interstrand crosslink repair (ICL), are known to be disease causing. FA can be diagnosed in different ways: At cellular level functional assessments like chromosomal breakage analysis or cell cycle testing are state of the art. However, at the molecular level it becomes more difficult, time consuming and expensive to detect mutations the more FA genes are identified. Therefore we performed whole exome sequencing (WES) in four FA patients with previously unknown mutations in order to evaluate the benefit of this method for molecular diagnosis and FA genotyping. To find the best combination between enrichment and sequencing technologies we tested two different pairings: *NimbleGen* enrichment from Roche along with the *Illumina* Next Generation Sequencing (NGS) platform and Agilent *SureSelect* enrichment with the *SOLiD* platform from *Applied Biosystems*. Irrespective of the enrichment method or sequencing platform we were able to detect and confirm the pathogenic mutations in each of our four patients. We found homozygous and heterozygous single base pair substitutions in *FANCJ, -D1, -D2* and *-P* but also an insertion of two base pairs and a splice site mutation. Therefore WES is proposed as a valuable tool for molecular diagnosis of FA which may replace classical genotyping approaches.

P11.137

Alternative Splicing Governs miRNA Biogenesis

Z. Melamed[1], *A. Levy*[1,2,3], *G. Lev-Maor*[1], *G. Ast*[1];
[1]Department of Human Molecular Genetics and Biochemistry, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel, [2]Department of Molecular Genetics, Weizmann Institute of Science, Rehovot, Israel, [3]Rosetta Genomics Ltd., Rehovot, Israel.

MicroRNAs (miRNAs) are noncoding RNAs of 22 nucleotides that induce post-transcriptional gene silencing through base-pairing with their target mRNAs. miRNA primary transcripts contain a local hairpin structure that is cleaved by the Microprocessor complex, consisting of RNAse III Drosha and DGCR8. The processing reaction releases the hairpin-shaped intermediates (pre-miRNAs). The majority of mammalian miRNAs are located in introns. Splicing of the introns in which such miRNAs reside was recently suggested to derive independently from the miRNA processing. We have uncovered a novel regulatory mechanism in which splicing determines the processing of pre-miRNAs. Based on a bioinformatic analysis of predicted transcription units of all miRNAs genes in 18 species, we identified a group of 52 miRNA precursors that share an intriguing genomic location - positioned on exon-intron junctions, these miRNAs are exposed to a regulatory mechanism in which splicing or alternative splicing might determine their biogenesis.

We experimentally demonstrated that in these cases the splicing machinery and the Microprocessor complex compete for processing of the same region on the RNA transcript and therefore, either the spliced mRNA or the pre-miRNA can be produced separately from the shared transcript. We also showed that tissue-specific and embryonic-specific alternative splicing negatively regulates the levels of mature miRNA produced from splice-site overlapping miRNA precursor, and reciprocally, that Drosha and DGCR8 modulate inclusion of alternatively spliced exon that overlaps with the miRNA stem-loop. Our data reveal a potential role for alternative splicing in the regulation of miRNA biogenesis.

P11.138

Pseudogenes: an unsolvable problem in Whole Exome Sequencing?

B. Schuster, *K. Knies, D. Schindler;*
University of Wuerzburg, Department of Human Genetics, Wuerzburg, Germany.

Over the past years Whole Exome Sequencing (WES) became an established tool for the detection of mutations underlying rare human genetic disorders. We performed WES in nine patients and in all cases the same genes consistently caught our attention, because they were overrepresented by heterozygous single nucleotide variants (SNV). One of our patients carried a large number of heterozygous base substitutions in CDC27, even though one allel of this gene was known to be partially deleted. We found three listed pseudogenes of CDC27 which could be responsible for wrong mutation calls by misalignment of short sequence reads. Via selective primer design we were able to specifically resequence the functional gene by Sanger technique. As expected, all variants were identified as false positive calls due to overlap with the pseudogenes. In consequence of this finding, we became more alert concerning alignment artifacts due to paralogous sequences in the other projects as well. But contrary to the general expectation that these misalignments should be detectable because of their increased SNV counts, we also found several isolated SNVs which should have mapped to a related pseudogene. Analysis of the same data with different bioinformatic tools could only partially decrease the error rate. We therefore conclude that pseudogenes cause an enormous amount of false positive SNVs and require careful attention because they cannot be withdrawn as easily as sequencing errors. Mutation validation by Sanger sequencing still seems to be indispensable and the possibility of false negative mutation calls should be regarded as well.

P11.139

Functional characterization of Williams-Beuren syndrome chromosome region 22 protein

K. Õunap[1,2], *A. Kurg*[1], *R. Kurg*[2];
[1]Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia, [2]Institute of Technology, University of Tartu, Tartu, Estonia.

Williams-Beuren syndrome (WBS) is a multisystem disorder associated with the hemizygous deletion of 26-28 genes on chromosome 7q11.23. Typical features of WBS comprise a recognizable pattern of facial dysmorphism, supravalvular aortic stenosis, connective tissue abnormalities, hypercalcemia and distinctive neurobehavioral phenotype. Hemizygosity of elastin gene is associated with supravalvular aortic stenosis; however it is unknown how the deletion of other genes in 7q11.23 contribute to the phenotype. Altered expression level of dosage-sensitive genes within aneuploid segments is the main cause of WBS.

WBSCR22 (protein expressed from Williams-Beuren chromosomal region 22) is a nuclear protein which has a predicted S-adenosylmethionine (SAM) binding motif and it is assumed that WBSCR22 has methyltransferase activity. SAM-dependent MTases represent a diverse class of enzymes which act on protein, small molecule, lipid or nucleic acid methylation and therefore mediate numerous cellular processes. The yeast homolog of WBSCR22, Bud23, sharing 47% similarity on amino acid level, is a ribosomal 18S rRNA methyltransferase required for ribosome biogenesis.

In our laboratory, we investigate the cellular function of WBSCR22. In sucrose gradient ultracentrifugation WBSCR22 cosediments with free ribosome small subunit (40S). WBSCR22 knock-down reduces the level of free 40S and alters 40S/60S ratio. WBSCR22 is involved in processing of 18S rRNA since WBSCR22 knock-down causes the accumulation of 18S-E pre-rRNA in cell nucleus. Our data suggest that WBSCR22 protein is involved in ribosome biogenesis.

X-linked Intellectual Disability (XLID) is a common cause of intellectual impairment in males with an estimated prevalence of ~1:1000. Many studies have been performed for the identification of genes associated with XLID. One approach for the identification of regions that may harbour novel XLID genes is through the detection of copy number changes (CNCs) by array-CGH. The purpose of our study was to screen a European cohort of male XLID patients using a high-resolution oligonucleotide 105K microarray specific for the X chromosome. This custom-designed chromosome X exon-specific microarray provides full coverage not only of the X chromosome itself but complete exome coverage with at least 6 probes for each exon thereby ensuring a robust screen for the identification of CNCs down to the individual exon level. To date, we have screened 153 patients and found CNCs in 11 patients (7.2%). These aberrations consisted of seven deletions and six duplications that ranged in size from 165bp to 7.26Mb. All of the deletions and two of the duplications resided in single genes while the remaining duplications spanned regions that harbored several genes. Follow-up studies including confirmation and segregation analysis with family members are in progress. In addition, the clinical significance of these aberrations and the possible role of these genes as novel XLID loci will be assessed.

Expanding and enhancing access to the Sequence Read Archive (SRA) through a complementary new web-based mirror

***C. Smith**, B. Ganter, E. Worley, B. Xia, A. Sundquist;*
DNAnexus Inc., Mountain View, CA, United States.

Public institutions such as the National Center for Biotechnology Information (NCBI) have made tremendous investments in generating and archiving a wide array of valuable genomic data for use by the research community. Expanding access to these valuable public data and streamlining the ability to integrate them into data management tools and powerful analyses, will further expedite their use and value in medical research, discovery and applications.

Teaming up with Google, DNAnexus has developed a complementary hosted mirror of the NCBI's Sequence Read Archive (SRA) that provides researchers an additional way to access these important datasets. This freely accessible resource provides a new web-based user interface built using the latest "cloud" technologies and genomic data standards. As the most comprehensive archive of publicly available next-generation sequencing data, the SRA is an important resource to researchers around the world. The SRA remains the single best source of useful sequence data from research initiatives such as the 1,000 Genomes Project and institutions like the Broad Institute, Washington University, and the Wellcome Trust Sanger Institute.

Here we discuss our work with the NCBI and Google to create a complementary mirror of the SRA available at sra.dnanexus.com. Through a typical user scenario, we will discuss the underlying data processing pipeline, key features of the new web-based interface that enables researchers to quickly identify and browse datasets of interest, link-outs to PubMed references, and integration of those data into an analysis workflow for hypothesis generation.

P11.142

A nonsense mutation in ATR-X gene responsible for nonsyndromic XLID in MRX77 family

***C. Sismani**[1], M. Syrrou[2], A. Alexandrou[1], F. Abidi[3], C. Skinner[3], M. Friez[3], S. McGee[3], L. Holloway[3], C. E. Schwartz[3], P. C. Patsalis[1];*
[1]Department of Cytogenetics and Genomics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus, [2]Cytogenetics Unit, Laboratory of General Biology, Medical school, Ioannina, Greece, [3]Greenwood Genetic Center,Center for Molecular Studies, JC Self research Institute, Greenwood, SC, United States.

In 2003 we reported a linkage analysis performed on a 3-generation Greek family (MRX77) with seven affected males. Clinical evaluation showed apparently nonsyndromic X-Linked Intellectual Disability (XLID). The affected males have moderate to severe intellectual disability, severe speech problems and aggressive behavior. Two point linkage analysis using 26 polymorphic markers spanning the X chromosome had localized the disease gene to a large interval Xq12- Xq21.33 (flanking markers DXS983 in Xq12 and DXS6799 in Xq21.33) with a maximum lod score of 2.36. In 2010, the affected MRX77 patients were screened using the new full coverage chromosome X exon-specific array designed by our group which showed no copy number changes. In 2011, a proband was screened for mutations in 92 XLID genes using next generation sequencing prior to undertaking a whole X exome sequencing. A nonsense mutation, p.R37X (c,109C>T), was identified in exon 2 of the *ATR-X* gene. Although, the *ATR-X* gene had been sequenced in 2003, this mutation was not detected since this exon was not annotated at that time. Segregation and the skewed X-inactivation pattern in carrier females were consistent with the clinical phenotype of the MRX77 family. This nonsense mutation had previously been observed in the Chudley-Lowry syndrome and another XLID family, both of which had a phenotype less severe than ATRX syndrome. Since our family has nonsyndromic XLID, the finding further confirms that the variability of the phenotype associated with this mutation is likely due to the presence of alternative transcripts which do not contain exon 2.

P11.143

Genome-wide association in 1198 Dutch individuals for 163 serum metabolites

***H. Draisma**[1,2,3], R. Pool[1,4], G. Willemsen[1,2], J. Hottenga[1,2], D. I. Boomsma[1,2,4];*
[1]Department of Biological Psychology, VU University Amsterdam, Amsterdam, Netherlands, [2]The EMGO+ Institute for Health and Care Research, Amsterdam, Netherlands, [3]ENGAGE: European Network of Genomic And Genetic Epidemiology, Amsterdam, Netherlands, [4]BBMRI-NL: Infrastructure for the Application of Metabolomics Technology in Epidemiology (RP4), Amsterdam, Netherlands.

Metabolites, or the small molecules involved in cellular metabolism, are presumed to be directly linked to (patho)physiology. Hence, it is important to gain a deeper understanding of the genetic and environmental contributions to interindividual variation in metabolite levels. As part of our ongoing contributions to the European Network of Genomic and Genetic Epidemiology (ENGAGE) consortium, we carried out a genome-wide association (GWA) study for serum metabolite levels in 1198 unrelated individuals who participated in the Netherlands Twin Register Biobank project. From 2004 until 2008, blood samples were obtained from these individuals (67.2% male, 32.8% female; mean age 52 years [SD, 13]) after overnight fasting. Metabolomics analysis was performed on the serum fractions of these samples, using the Biocrates AbsoluteIDQ p150 kit and electrospray ionization-MS/MS enabling detection of 163 metabolites belonging to five different classes: acylcarnitines (N=41), amino acids (AA, N=14), glycerophospholipids (N=92), sphingolipids (N=15), and a compound measure for hexoses (N=1). Genotyping was performed using various GWA chips. Imputation against HapMap 2 Build 36 Release 24 resulted in data for 3.8M unfiltered single nucleotide polymorphisms (SNPs) for each participant. SNPtest v2.2.0 was used for association analysis, including age, sex and principal component scores for population stratification as covariates. Genome-wide (conservative Bonferroni-corrected p <3.1E-10) significant hits were observed for several metabolites. The associations for 22 glycerophospholipids with SNPs in the fatty acid desaturase (FADS) gene cluster were among the most prominent. In conclusion, we found several clusters of genome-wide significantly associated SNPs for metabolites detected by MS in human serum. Future meta-analyses will combine these data with the results of six ENGAGE partners, to determine whether the results found in our Dutch sample are replicated in other cohorts.

Mutational analysis of RPE65, ABCA4 and RHO genes on Greek patients with Retinitis Pigmentosa, Leber congenital amaurosis and Stargardt's disease

***M. Tsipi**[1], M. Tzetis[1], S. Kitsiou[1], M. M. Moschos[2], E. Kanavakis[1];*
[1]University of Athens, Department of Medical Genetics, Athens, Greece, [2]University of Athens, Department of Ophthalmology, Athens, Greece.

Retinal dystrophies are a clinically and genetically heterogeneous group of disorders which affect more than two million people worldwide. This heterogeneity raises difficulties on genetic testing and counseling for the affected families. Although our knowledge about genetic factors underlying these diseases has recently increased dramatically, a lot of disease causing mutations still remain unknown. Our study deals with identifying the disease-associated variants in Greek families with Stargardt disease, Cone-Rod dystrophy , Retinitis Pigmentosa and Leber Congenital Amaurosis.

We focused our research on the possible role of three genes (ABCA4, RHO and RPE65) in the pathogenesis of hereditary retinal dystrophies in Greek patients. All exons of ABCA4 were sequenced in families with Stargardt Disease, Cone-Rod Dystrophy and Retinitis Pigmentosa. RHO was sequenced in families with Retinitis Pigmentosa and RPE65 in families with Leber Congenital Amaurosis and Retinitis Pigmentosa.

A great number of genetic variants in coding and non-coding regions were found in this study. Most of them were known variations and include disease-causing mutations and known polymorphic variants. Mutations in ABCA4 were found in patients with Stargardt Disease, autosomal recessive Retinitis Pigmentosa and Cone-Rod Dystrophy. Mutation c.272G>A (p.R91Q) in RPE65 was found in a patient with Retinitis Pigmentosa and in his healthy mother. This mutation has been associated with autosomal recessive Retinitis Pigmentosa. We also found novel variants in non- coding sequences which may affect the splicing process. These variants were analyzed with the use of bioinformatic tools. We also attempted possible phenotype/genotype correlations.

Ospedali Galliera, Genoa, Italy.

MDR3 protein translocates phosphatidylcoline (PC) from the inner to the outer leaflet of the hepatocanalicular membrane; its deficiency, related to ABCB4 mutations, favours the formation of "toxic bile". A continuum of hepatobiliary diseases have been associated with ABCB4 mutations but, for most of them, the detrimental effect on the protein is speculative only. The functional relevance of two strategic mutations within the N-terminal Nucleotide-Binding-Domain was examined with stably transfected HUH28-cell-lines expressing wild type and mutant MDR3 proteins by western-blotting, immunocytochemistry and chromatographic quantification of lipids, collected from culture medium after sodium-taurocholate (NaTC) stimulation. As suggested by our three-dimensional model of MDR3 (Degiorgio D et al., 2007), the p.Y403H mutation involves the A-loop while the p.L481R mutation is contained into the Q-loop. Our results show that both MDR3-mutant proteins were expressed in a comparable way to the MDR3-wild-type protein: a molecular mass of 160KDa associated with a green fluorescent signal, intenser and sharper in the plasma membranes, was constantly identified. However, compared to the stably transfected HUH28-cell-line expressing wild-type-MDR3 protein in the presence of NaTC 3mM, the lipid dosage into culture medium has shown (with five indipendent experiments) that
i) the efflux of PC is reduced ($p<0.01$) from cell lines expressing p.Y403H and p.L481R mutant proteins;
ii) the efflux of cholesterol is increased ($p<0.01$) from cell line expressing the p.Y403H mutant protein.
In conclusion, these mutations could promote in vivo formation of toxic bile with reduced amounts of PC (p.L481R) or with reduced amounts of PC and increased level of cholesterol (p.Y403H).

P12.003

New clues on the differential diagnosis between acrodysostosis and pseudohypoparathyroidism type Ia

A. Pereda[1], *O. Rubio-Cabezas*[2,3,4], *S. Berrade*[5], *M. Muñoz-Calvo*[2,3,4], *J. Argente*[2,3,4], *G. Perez de Nanclares*[1];
[1]Molecular (Epi)Genetics Laboratory, Vitoria-Gasteiz, Spain, [2]Endocrinology Service, Hospital Infantil Universitario Niño Jesús, IIS La Princesa, Madrid, Spain, [3]Department of Pediatrics, Universidad Autónoma de Madrid, Madrid, Spain, [4]CIBEROBN, Instituto de Salud Carlos III, Madrid, Spain, [5]Service of Pediatrics, Complejo Hospitalario de Navarra, Pamplona, Spain.

Acrodysostosis is a skeletal dysplasia characterized by short stature, nasal hypoplasia and brachydactyly. When multihormonal resistance is also present (mainly, PTH and TSH), the disorder might be clinically misdiagnosed as pseudohypoparathyroidism type Ia (PHP-Ia). Acrodysostosis with multihormonal resistance is caused by mutations in PRKAR1A, which participates in the Gsα protein signaling pathway.
Patients and methods: PRKAR1A was sequenced in five PHP-Ia patients with negative genetic and epigenetic analysis in GNAS locus.
Results: A heterozygous mutation in PRKAR1A was identified in three of the five patients. Parental testing showed that the mutation arose de novo in the three cases. A detailed analysis of clinical and radiological data revealed the characteristic bone abnormalities of acrodysostosis.

Conclusion: Acrodysostosis is an infradiagnosed disorder that might be confounded with PHP-Ia. An exhaustive radiologic study of patients presenting with short stature and PTH resistance could help clinical diagnosis and genetic testing.

A new form of autosomal recessive syndromal acroosteolysis with recurrent infections, sensory neuropathy and mental retardation.

P. Chiurazzi[1], *F. Pirozzi*[1], *S. Swagemakers*[2], *B. van der Eerden*[3], *G. Neri*[1], *J. P. T. M. van Leeuwen*[3], *P. J. van der Spek*[2];
[1]Istituto di Genetica Medica, Rome, Italy, [2]Department of Bioinformatics, Erasmus MC, Rotterdam, Netherlands, [3]Department of Internal Medicine, Erasmus MC, Rotterdam, Netherlands.

We describe a syndromic form of acroosteolysis characterized by mental retardation, sensory neuropathy and recurrent infections with autosomal recessive inheritance. SNP haplotyping mapped the disease locus to the short arm of chromosome 11. Whole-genome sequencing using unchained base reads on self-assembling DNA nanoarrays allowed identification of a homozygous missense mutation in a gene localized in 11p15 that encodes a SNARE-associated Golgi protein. We show that the gene's mRNA is markedly upregulated in osteoclast cell cultures and patients' osteoclasts (induced by blood mononuclear cells) exhibit a significantly enhanced bone resorption activity. Mutations in the NOTCH2 gene (associated to Hajdu-Cheney syndrome), mapping in 1p12-p11.2, and in the WNK1 gene (associated to hereditary sensory and autonomic neuropathy type IIA), mapping in 12p13.33, have been excluded by both haplotype analysis and whole-genome sequencing.

P12.005

Autosomal Dominant Polycystic Kidney Disease: A comprehensive mutation analysis of the PKD1 and PKD2 genes in Spanish patients

J. Garcia-Planells[1], *M. Garcia-Hoyos*[1], *C. Ruiz*[1], *M. Bermejo*[1], *L. Rausell*[1], *M. Molero*[1], *M. Ballesta*[2], *A. Benavides*[3], *M. Martínez-Atienza*[4], *M. Lopez-Ariztegui*[5], *M. Garcia-Barcina*[6], *M. Perez-Alonso*[1];
[1]Instituto de Medicina Genomica (IMEGEN), Paterna (Valencia), Spain, [2]Unidad de Genética Médica. Hospital Virgen de la Arrixaca, Murcia, Spain, [3]Unidad de Genetica. Hospital Central de Asturias, Oviedo, Spain, [4]Servicio de Genética. Hospital Virgen de las Nieves, Granada, Spain, [5]Unidad de Genética. Hospital de Cruces, Barakaldo (Bilbao), Spain, [6]Servicio de Genética. Hospital de Basurto, Bilbao, Spain.

Autosomal Dominant Polycystic Kidney Disease (ADPKD) is one of the most prevalent inherited disorders, with an incidence of 1:1000. ADPKD is caused by mutations in the *PKD1* (85%) and *PKD2* genes (15%). The genetic diagnosis of this disease has so far been a very complex task because of the presence of 5 pseudogenes with a high identity (98%) with the *PKD1* gene. We have developed a PCR+sequencing based technology that allows a specific and accurate analysis of the *PKD1* sequences, excluding the pseudogenes ones.
In this work we have used this methodology to obtain a genetic diagnosis in a cohort of ADPKD from different Spanish hospitals. Results do not show the presence of prevalent mutations in the Spanish population. We have identified a high percentage of non-previously mutations making difficult their clinical interpretation. In these cases, familial analyses have been performed and results have been supported by *in silico* analyses. The identification of the disease-causing mutations in several Spanish families has allowed to provide a genetic counselling and an accurate genetic diagnosis to the patients and opened the possibility to offer familial testing and prenatal genetic diagnosis.

P12.006

Recurrent agnathia caused by DNA replication slippage in PRRX1 gene

M. J. Dasouki[1], D. Kamnasaran[2], B. Andrews[1], P. Parimi[1];
[1]University of Kansas Medical Center, Kansas City, KS, United States, [2]Laval University, Québec, QC, Canada.

Agnathia-otocephaly is a rare craniofacial malformation which was recently found to be caused by de novo dominant as well as recessive mutations in the PRRX1 gene in two unrelated babies. We studied the PRRX1 gene in a non-consanguineous Indonesian family with a 4 month old daughter who was diagnosed prenatally with severe micrognathia (bilateral Pruzansky III). Her older affected brother died shortly after birth and clinically had agnathia-otocephaly. A frame shift mutation in a poly lysine (poly A) tract in the PRRX1 gene was identified in the proband while her father just had an insertion of one lysine residue . Expression of both mutations in COS7 cells showed loss of function of the frame shift mutation only. SNP analysis coupled with the recurrence of this mutation in this family are consistent with paternally derived germline mosaicism rather than autosomal recessive inheritance. Also, severe micrognathia (bilateral Pruzansky III) and agnathia-otocephaly represent a spectrum of craniofacial malformations in this family.

P12.007

COL4A5 mutational analysis of 51 unrelated Portuguese patients with Alport syndrome - preliminary report

M. J. N. Sá[1,2], S. Alves[1], F. Carvalho[1], J. P. Oliveira[1,2];
[1]Departamento de Genética - Faculdade de Medicina/Universidade do Porto, Porto, Portugal, [2]Unidade de Investigação e Desenvolvimento em Nefrologia - Faculdade de Medicina/Universidade do Porto, Porto, Portugal.

Introduction: Collagen type IV glomerulopathies include Alport syndrome (AS) and thin basement membrane nephropathy (TBMN). X-linked AS (XLAS) is caused by *COL4A5* mutations and the autosomal recessive and dominant forms of AS and TBMN are due to *COL4A3* and/or *COL4A4* mutations. Approximately 80% of AS is X-linked.
Aim: Describe the molecular pathology of XLAS in Portuguese families.
Patients and methods: In the setting of an ongoing national multicenter study, 51 unrelated patients with the clinical diagnosis of AS referred by nephrologists have already been studied. Mutational analysis of *COL4A5* gene was performed by direct PCR sequencing and multiplex ligation-dependent probe amplification (MLPA). Direct PCR sequencing of the *COL4A3* and *COL4A4* genes will be subsequently performed in *COL4A5*-negative cases.
Results: *COL4A5* direct sequencing identified 5 missense mutations [c.4342G>C (p.Gly1448Arg); c.715G>A (p.Gly239Arg); c.1009G>A (p.Gly337Ser); c.1844G>A (p.Gly615Glu); c.2633G>T (p.Gly878Val)], 4 splice site mutations [c.1339+6C>G; c.4297+1G>A; c.4803+1G>A; c.891+83_84insACTT], 3 deletions [c.2423del (p.Gly808fsX818); c.590del (p.Gln197fsX202); c.2510_2554del(45bp)], 2 nonsense mutations [c.4444C>T (p.Gln1482X); c.2815G>T (p.Glu939X)] and one previously reported mutation of unknown significance [c.1992G>T (p.Lys664Asn)]. Four large deletions were detected by MLPA [del ex.1_13 + (del ex.1_2 COL4A6); del ex.2_29; del ex.2_51; del ex.43_45].
Discussion: *COL4A5* mutational analysis confirmed the diagnosis of XLAS in only 19 families (≈37%), allowing the identification of 15 novel mutations, comprising ≈90% of all genetically confirmed AS cases. Two index patients carried the same missense mutation with a similar microsatellite haplotype, suggesting that they may share a common ancestor. The clinical criteria used by nephrologists appear to overestimate the diagnosis of AS.

P12.008

Alport syndrome epidemiology in Greek-Cypriots

L. Papazachariou[1], P. Demosthenous[1], K. Voskarides[1], M. Arsali[2], M. Hadjigavriel[3], C. Stavrou[4], A. Pierides[5], C. Deltas[1];
[1]Molecular Medicine Research Center, University of Cyprus, Nicosia, Cyprus, [2]Department of Nephrology, Limassol General Hospital, Limassol, Cyprus, [3]Department of Nephrology, Larnaca General Hopsital, Larnaca, Cyprus, [4]Department of Nephrology, Evangelismos Hospital, Pafos, Cyprus, [5]Hippocrateon Hospital, Nicosia, Cyprus.

Alport syndrome (AS) is a hereditary hematuric nephritis, associated with sensorineural deafness, eye defects and progression to end stage kidney disease (ESKD) around 20-25 yo. *COL4A5* gene on chromosome Xq22-23 accounts for ~80% of all AS cases (XLAS). *COL4A3/COL4A4* genes on chromosome 2q36-q37 account for the remaining cases (ARAS).
We are studying *COL4A3/COL4A4/COL4A5* genes (in AS and in familial hematuria) for the last 9 years. Depending on inheritance pattern, we screen either *COL4A5* or either *COL4A3/COL4A4* or all three genes (totally ~150 exons). *COL4A5* is analyzed by genomic PCRs and direct re-sequencing. *COL4A3/COL4A4* screening is accomplished by genomic PCR and SURVEYOR endonuclease, followed by targeted DNA re-sequencing. PCR-RFLP is used for detecting more mutation carriers in the AS families.We have DNA samples from all Greek-Cypriot AS families (totally nine) refered to Cyprus' hospitals. Two were studied and published by a French laboratory in 2001 (one homozygous for the COL4A3-c.3533delC mutation and one with the de-novo COL4A5-G618R mutation). In two of them, we found a novel mild mutation, COL4A5-P628L. Two others were found to be compound heterozygous cases [COL4A3-G1334E with COL4A3-G871C (novel); COL4A3-c.2621-2622-delGAinsT with COL4A3-G1077D (novel)]. The remaining three were not studied yet, but the inheritance pattern is obvious (two ARAS, one XLAS). Totally: four XLAS families (45%) with ten living patients (71% of all cases) and five ARAS families (55%) with four living patients (29% of all cases). Although we found more XLAS families than ARAS, the total percentage of XLAS and ARAS cases resembles that in other countries.

P12.009

The p.Gly624Asp mutation in the *COL4A5* gene is the prevalent mutation in the Czech families with X-linked Alport syndrome

P. Plevova[1,2], A. Baxova[3], M. Kubala[4], J. Soukalova[5], J. Zastera[6], E. Silhanova[7,2];

Aim of the study: Alport syndrome is characterized by progressive hereditary nephritis, hearing loss, and ocular anomalies may also be present. The disease is genetically heterogenous, 85% of cases being X-linked caused by *COL4A5* gene mutations. The aim of the study was to detect *COL4A5* gene mutations in patients with hereditary nephritis or hematuria.
Patients and methods: Molecular genetic analysis of the whole coding sequence, i.e. exons 1-51 of the *COL4A5* gene was performed in 61 unrelated patients. Denaturating gradient gel electrophoresis, high resolution melting analysis, direct sequencing, and the MLPA method were used. Besides that, 48 family members of the patients with disclosed mutation were tested for carriership of the familial *COL4A5* mutation. Computer modelling was performed to simulate the impact of some mutations at the protein level.
Results: A pathogenic mutation has been found in twenty-nine of 61 patients (i.e. in 47%). The c.1871G to A / p.Gly624Asp mutation in exon 25 was the prevalent one being found in 12 families (i.e. 41% of pathogenic mutations). This is the only mutation that has been published in the HGMD and ARUP databases. All the other mutations are novel. Thirty-eight of the 48 tested family members were found to carry the familial mutation.
Conclusion: In nearly half of the Czech families with *COL4A5* gene mutations the c.1871G to A / p.Gly624Asp was found suggesting common ancestry.

P12.011

Determination of the exact GGGGCC-hexanucleotide repeat length of C9ORF72 in German and Swedish families with amyotrophic lateral sclerosis and frontotemporal dementia

A. Volk[1], W. Just[1], J. Weishaupt[2], C. Akimoto[3], A. Birve[3], N. Marroquin[1], C. Kubisch[1], A. Ludolph[2], P. M. Andersen[2,3];
[1]Institute of Human Genetics, Ulm, Germany, [2]Department of Neurology, Ulm, Germany, [3]Department of Clinical Neuroscience, Umeå, Sweden.

Amyotrophic lateral sclerosis (ALS) is a progressive, adult-onset neurodegenerative disorder affecting the upper and lower motor neurons. Mutations in 15 genes have been identified in familial cases and mutations in SOD1 have been reported to account for 12-23%% of familial cases. Recently, an intronic GGGGCC-hexanucleotide repeat expansion in C9ORF72 was found to be associated not only with ALS but also with frontotemporal dementia (FTD) and an overlapping phenotype combining ALS and FTD. Indeed, a repeat expansion in C9ORF72 was identified in up to 30% of familial and even 5% of sporadic ALS cases making C9ORF72 the most commonly mutated ALS gene. In most of the studies published so far, molecular testing solely relies on an indirect PCR-based methodology for repeat detection without determining the exact repeat size. Therefore, little is known about the exact size and size range of causative C9ORF72 alleles. Here, we report on a Southern-blot based analysis of the exact repeat length in a cohort of German and Swedish ALS families as well as on possible repeat expansions in seemingly healthy controls. Our study thus broadens the knowledge about the size range of normal and pathological C9ORF72 alleles, which is important e.g. for the identification of genotype-phenotype correlations as well as for improved individualized risk predictions and genetic counseling.

P12.012

The world largest ALS-FTD pedigree is linked to a massive GGGGCC-repeat expansion in the C9ORF72 on 9p21: The Mörtsell Disease.

A. Birve[1], *A. Volk*[2], *W. Just*[2], *C. Akimoto*[1], *J. Bergh*[3], *C. Kubisch*[2], *K. Forsberg*[3], *S. L. Marklund*[3], *T. Brännström*[3], *A. Ludolph*[4], *P. M. Andersen*[1,4];
[1]*Department of Clinical Neuroscience, Umeå, Sweden,* [2]*Institute of Human Genetics, Ulm, Germany,* [3]*Department of Medical Biosciences, Umeå, Sweden,* [4]*Department of Neurology, Ulm, Germany.*

We present a 2200-individual pedigree in 6 countries where individuals either with amyotrophic lateral sclerosis (ALS) or frontotemporal dementia (FTD) in 1999 was found to be linked to 9p21. We now demonstrate that the patients with ALS or FTD share a massive GGGGCC-hexanucleotide expansion in C9ORF72 as a cause of neurodegeneration. The patients have variable degrees of expansion in leucocytes from peripheral blood. Autopsies performed on 6 patients (4 ALS, 2 FTD) show very similar morphological cellular findings but in different cell populations depending on the phenotype of the individual. Remarkably, while no mutations could be detected in the SOD1 in any of the patients, all FTD and ALS patients showed neuronal inclusions that stained positive for highly specific antibodies for misfolded wild-type SOD1. While the disease penetrance for either ALS or FTD is complete in some parts of this huge family, in other parts it is incomplete. Whether this is due to variable size of the hexanucleotide expansion in different cell populations or have other causes is being studied.

P12.013

PAX6 mutations in 93 aniridia Italian cases

A. Franzoni[1], *A. D'Elia*[1], *E. Bregant*[1], *N. Passon*[1], *M. Patrosso*[2], *L. Mauri*[2], *S. Penco*[2], *G. Damante*[1];
[1]*Istituto di Genetica medica, A.O.U.-SMM di Udine, Udine, Italy,* [2]*S.O.S. di Genetica medica, Ospedale Niguarda Ca'Granda, Milano, Italy.*

Aniridia is a rare human congenital malformation of the eye characterized by almost complete absence of the iris and other eye malformations. This disease is a dominantly inherited condition and sequence analysis had established that causative mutations involve *PAX6* gene located in chromosomal region 11p13.

We have investigated the presence of *PAX6* mutations in 93 cases of aniridia come from different Italian regions. We have used molecular techniques such as sequence analysis and MLPA for every case.

Among the 93 cases, 44 are familiar (47%). The causative mutation was identified in 50 subjects (54%). In 19 cases (38%), the mutations was a deletion not identified through MLPA, in 31 remaining cases (62%) by sequence analysis. In two cases with deletion, both *PAX6* and *WT*1 genes are involved. In 10 cases, the deletion regard only *ELP4* gene (located about 35 Kb downstream *PAX6* 3' region), suggesting that the disease is caused by a mutation that affect element controlling gene expression.

Among the identified mutations by sequence analysis, 21 consist in nonsense mutations, 5 in missense mutations, and 5 in site splicing mutations. Several of these mutations are novel, not present in the PAX6 mutation database (http://www.hgu.mrc.ac.uk/Softdata/PAX6/).

These data provide important indications: i) Mutational screening of *PAX6* gene must include techniques such as MLPA, which is able to identified mutations not observed by analysis sequence. ii) In a relevant fraction of patients with aniridia (about 10%), the alteration consist in a deletion of element that play a role in the transcriptional control.

P12.015

PKHD1 mutations in autosomal recessive polycystic kidney disease in Hungary

I. Balogh[1], *T. Szabó*[1], *K. Tory*[2], *C. Bereczki*[3], *E. Marián*[4], *É. Gombos*[1], *I. Máttyus*[2], *É. Ajzner*[4], *J. Kappelmayer*[1];
[1]*University of Debrecen, Debrecen, Hungary,* [2]*Semmelweis University, Budapest, Hungary,* [3]*University of Szeged, Szeged, Hungary,* [4]*Jósa András County Hospital, Nyíregyháza, Hungary.*

Autosomal recessive polycystic kidney disease (ARPKD) is a severe inherited monogenic disease, which is characterized by enlarged polycystic kidneys and congenital hepatic fibrosis. Prognosis of the disease is very poor, 30% of the affected children die within the first year of life. Incidence of ARPKD is 1 in 10.000-40.000. ARPKD is caused by mutations in polycystic kidney and hepatic disease gene 1 (PKHD1) that encodes a large protein called fibrocystin/polyductin. PKHD1 gene consists of 67 exons.

The goal of our study was to establish the mutational spectrum of ARPKD families in Hungary. All exons of the longest open reading frame of PKHD1 gene and their intronic boundaries were amplified in 77 amplicons and sequenced. We have analyzed 18 families with ARPKD. Of the 15 different detected mutations, 8 missense mutations, 5 nonsense mutations and 2 small deletions could be identified. Four novel mutations were found, of which 1 missense, 2 nonsense and 1 small deletion. In 15 families both causative mutations could be identified, in one patient one mutation was found while no genetic alteration could be detected in two patients. Mutation detection rate was 86%. Five mutations, namely c.107C>T (p.T36M), c.3407A>G (p.Y1136C), c.5513 A>G (p.Y1838C), c.6992T>A (p.I2331K) and c.7916C>A (p.S2639X) were detected in more than one patient and are responsible for 58% of PKHD1 disease-causing alleles among Hungarian patients. One of them, c.7916C>A, was found to be surprisingly frequent, being responsible for 22% of all PKHD1 null alleles.

P12.016

Islet1 is a direct transcriptional target of the homeodomain transcription factor Shox2 in the sinoatrial node of the developing heart

S. Puskaric[1], *I. M. Berger*[2], *A. Glaser*[1], *C. Bacon*[1], *L. Li*[3], *K. U. Schneider*[1], *N. Gretz*[3], *H. Steinbeisser*[1], *W. Rottbauer*[2], *S. Just*[2], *G. Rappold*[1];
[1]*Institute of Human Genetics, Heidelberg, Germany,* [2]*Department of Internal Medicine II, Ulm, Germany,* [3]*Medical Research Center, Mannheim, Germany.*

The heart's rhythm is initiated and regulated by a group of specialized cells in the sinoatrial node (SAN), the primary pacemaker of the heart. Abnormalities in the development of the SAN can result in irregular heart rates (arrhythmias). Although several of the critical genes important for SAN formation have been identified, our understanding of the transcriptional network controlling SAN development remains at a relatively early stage. The LIM homeodomain transcription factor Islet1 (Isl1) represents a prominent marker for cardiac progenitor cells of the second heart field and has been proposed, very similar to Shox2, to play an essential early role in the specification and patterning of the SAN.

Here, we compared gene expression levels in the right atria of wildtype and *Shox2*$^{-/-}$ hearts using microarray experiments and identified *Isl1* as one of its putative target genes. The downregulation of *Isl1* expression in *Shox2*$^{-/-}$ hearts was confirmed and the affected region narrowed down to the SAN by whole mount *in situ* hybridization. Using luciferase reporter assays and EMSA studies, we identified two specific SHOX2 binding sites within intron 2 of the *ISL1* locus. We also provide functional evidence for *Isl1* as a transcriptional target of Shox2 by rescuing the *Shox2*-mediated bradycardia phenotype with *Isl1* using zebrafish as a model system.

Our findings demonstrate a novel epistatic relationship between *Shox2* and *Isl1* in the heart with important developmental consequences for SAN formation and heart beat.

P12.017

Genetic screening of plakophillin-2 (PKP2) gene in Russian patients with arrhythmogenic right ventricular dysplasia

A. Shestak[1], *O. Blagova*[2], *V. Rumiantseva*[1], *Y. Frolova*[1], *S. Dzemeshkevich*[1], *E. Zaklyazminskaya*[1];
[1]*Russian Research Center of Surgery RAMS, Moscow, Russian Federation,* [2]*Sechenov Moscow Medical University, Moscow, Russian Federation.*

Background: Arrhythmogenic right ventricular dysplasia (ARVD) is an inherited cardiomyopathy characterized by progressive fibro-fatty replacement of the myocardium, specific ECG-pattern, and high risk of life-threatening ventricular arrhythmias. Disease mainly

affects the right ventricle, but left ventricle, atriums and septum might be involved. Mutations in the desmosome armadillo repeat protein plakophilin-2 are common in patients with ARVD. Methods: A group of 12 unrelated Russian ARVD patients were examined. Clinical and instrumental examination included collecting of personal and family history, physical examination, standard and 24 h-ECG, Echo-CG and cardiac MRI. Genetic analysis of the PKP2 gene was performed by direct Sanger sequencing. Results: Genetic screening of mutations in PKP2 gene in DNA samples of 12 Russian ARVD patients was performed. Two mutations p.S140F and P.W538X were found in two unrelated families. Female patient (35 y.o.) carried heterozygous p.S140F variant had thinning of anterior wall infarction of the right ventricle and the presence of epicardial fat. Male patient (71 y.o.) carried heterozygous nonsense PW538X had sustained ventricular tachycardia since 41 y.o., ventricular fibrillation, AVB(I) and hypertrophy and dilation of RV. ICD was implanted, patient had repeated appropriate shocks. Those two variants were previously described as disease-causing mutations. Three additional variants without apparent clinical significance were detected in 3 patients. Conclusion: We identified two mutations in PKP2 gene in 2 of 12 Russian unrelated ARVD patients (16%). This prevalence matches with the prevalence of ARVD9 (MIM*609040). Genetic analysis of family members and genotype-phenotype correlation is in progress now.

P12.018

Asphyxiating Thoracic Dysplasia: clinical and molecular review of 42 families

G. Baujat[1], *C. Huber*[1], *R. Caumes*[1], *C. Do Ngoc Thanh*[2], *A. Coeslier-Dieux*[3], *A. David*[4], *B. Estournet*[2], *C. Francannet*[5], *H. Kayirangwa*[1], *S. Sigaudy*[6], *M. Le Merrer*[1], *K. Le Quan Sang*[1], *A. Munnich*[1], *V. Cormier-Daire*[1];
[1]Hôpital Necker-Enfants Malades, Paris, France, [2]Hôpital Poincaré, Garches, France, [3]Hôpital Jeanne de Flandres, Lille, France, [4]CHU, Nantes, France, [5]CHU Hotel Dieu, Paris, France, [6]Hôpital d'Enfants La Timone, Marseille, France.

Asphyxiating Thoracic Dysplasia (ATD) belongs to the short rib polydactyly group and is characterized by a long and narrow thorax, short long bones and trident acetabular roof. Other features have been reported including polydactyly, retinal, renal and liver involvement. Today, mutations in IFT80, DYNC2H1, TCC21B and WDR19 genes have been reported in ATD. The clinical and molecular heterogeneity lead to difficulties in the evaluation of the long term prognosis.

Through a national grant (PHRC AOM 06031), we investigated 55 ATD cases from 42 families, and including 29 fetuses. They benefited from a combined approach of deep phenotyping, and IFT80 and DYNC2H1 molecular screening. The series included 26 postnatal cases, ranging in age from 6 months to 36 years. Significant pulmonary insufficiency was noted in 46% of cases, with tracheotomy requirement in 4 cases. Renal and liver diseases occurred in 16% of cases; whereas retinal alteration was present in 40 % cases aged more than 2 years (6/15). The molecular screening allowed the identification of DYNC2H1 mutations in 63% and IFT80 mutations in 6%. In 6 cases, only one heterozygote mutation in either IFT80 or DYNC2H1 was identified. Finally, the two genes were excluded in 31% cases.

These results emphasize that DYNC2H1 is the major gene responsible for ATD. The presence of only one mutation in 38% of mutated cases may suggest a digenic diallelic inheritance. The pulmonary prognosis is probably less pejorative and retinal involvement more frequent than previously thought. Follow up guidelines are proposed.

P12.019

Novel G2 micronucleus test allows detection of defects in homologous recombination and G2/M cell cycle control in a patient with adult ataxia telangiectasia (A-T) and parents

K. B. M. Claes[1], *P. Schietecatte*[1], *J. Depuydt*[2], *A. Baert*[2], *B. Poppe*[1], *V. Vandersickel*[2], *M. D'Hooghe*[3], *K. De Leeneer*[1], *A. Vral*[2];
[1]Center for Medical Genetics, Ghent University Hospital, Gent, Belgium, [2]Department of Basic Medical Sciences, Ghent University, Gent, Belgium, [3]Department of Neurology, AZ Sint-Jan, Brugge, Belgium.

We report here a patient (aged 23 years) with dystonic dyskinetic cerebral palsy and elevated serum alpha fetoprotein levels. The clinical diagnosis of adult A-T was confirmed by the identification of two heterozygous ATM mutations. The patient inherited a previously reported missense mutation, c.8122G>A (p.Asp2708Asn), from her father and a novel splice site mutation, c.8851-1G>T, from her mother.

AT patients are known to display enhanced chromosomal radiosensitivity. With the G0 micronucleus test, whereby the cells are irradiated in G0 phase of the cell cycle, 3-5X enhanced radiosensitivity is observed in typical AT patients compared to control persons. However, in this adult A-T patient, we only found a 1.7X increased radiosensitivity and no enhanced radiosensitivity in the parents. As ATM is involved in homologous recombination and G2/M cell cycle checkpoint, we developed a novel test, evaluating the number of micronuclei in lymphocytes irradiated in G2 phase of the cell cycle. This test showed about 3.5X enhanced radiosensitivity for the A-T patient compared to controls. For the heterozygous parents values were lower than for the proband, but significantly higher than for controls.

This novel G2 micronucleus test showed the potential to distinguish bi-allelic and mono-allelic ATM mutation carriers from controls. We will evaluate if this test allows determination of radiosensitivity in carriers of germline mutations in other genes involved in G2/M checkpoint and associated with an increased risk for breast cancer (BRCA1&2, Chek2, etc.). This could be an interesting approach to identify patients who would benefit from mutation testing of these genes.

P12.020

Atrichia with papular lesions: a recurrent missense mutation with novel phenotype

A. Azhar[1], *M. Tariq*[1], *T. Naeem*[1,2], *J. Klar*[2], *N. Dahl*[2], *S. Baig*[1];
[1]Human Molecular Genetics Laboratory, National Institute for Biotechnology and Genetic Engineering (NIBGE), Faisalabad, Pakistan, [2]Department of Immunology, Genetics and Pathology, Uppsala University Hospital, Uppsala, Sweden.

Atrichia with papular lesions (APL) is a rare autosomal recessive disorder, characterized clinically by occurrence of universal congenital alopecia and the development of papular lesions of keratin-filled cysts over extensive areas of the body. Hair loss in APL is irreversible and the histology is consistent with an absence of mature hair follicles. In this study we ascertained a family AP7 from northern part of Pakistan. We used candidate gene approach by selecting four genes like *HR*, *P2RY5*, *LIPH*, and *DSG4*. Linkage analysis and direct sequencing of the PCR products carried out. A recurrent missense mutation (c.1859G>A) in exon 6 of the hairless gene (*HR*) is identified. This mutation has already been reported in a large family of Irish Travellers. Phenotypic appearance of affected individuals in this family was marked by complete absence of hair on the eyebrows, eyelashes and scalp. Cystic lesions were present on the elbows of affected individuals with no other abnormalities. This mutation found in the Pakistani population that segregates with APL in homozygous form in affected individuals. Phenotypes of the affected members of family AP7 are different from the already reported phenotypic descriptions. Hypotrichosis and nail dysplasia are observed in this family which is not reported before with this mutation in *HR* gene. Papular lesions are present in affected individuals. This research will help in the establishment of carrier screening test for prevention of above disease and to understand the molecular basis involved in the gene function.

P12.021

Inherited and *de novo* SHANK2 variants associated with autism spectrum disorder impair neuronal morphogenesis and physiology

S. Berkel[1], *W. Tang*[2], *M. Trevino*[2], *M. Vogt*[3], *H. A. Obenhaus*[2], *P. Gass*[3], *S. W. Scherer*[4], *R. Sprengel*[2], *G. Schratt*[5], *G. A. Rappold*[1];
[1]Institute of Human Genetics, Heidelberg, Germany, [2]Max Planck Institute for Medical Research, Heidelberg, Germany, [3]Central Institute of Mental Health, Mannheim, Germany, [4]University of Toronto, Toronto, ON, Canada, [5]Institute of physiological chemistry, Marburg, Germany.

Mutations in the postsynaptic scaffolding gene *SHANK2* have recently been identified in individuals with autism spectrum disorder (ASD) and intellectual disability (ID). However, the cellular and physiological consequences of these mutations in neurons remain unknown. We have analyzed the functional impact caused by two inherited and one *de novo SHANK2* mutations from ASD individuals (L1008_P1009dup, T1127M, R462X). Although all three variants affect spine volume and have smaller SHANK2 cluster sizes, T1127M additionally fails to rescue spine volume in Shank2 knock-down neurons. R462X is not able to rescue spine volume and dendritic branching and lacks postsynaptic clustering, indicating the most severe dysfunction. To demonstrate that R462X when expressed in mouse can be linked to physiological effects, we analyzed synaptic transmission and behavior. Principal neurons of mice expressing rAAV transduced SHANK2-R462X present a specific, long lasting reduction in miniature postsynaptic AMPA receptor currents. This dominant negative effect translates into dose-dependent altered cognitive behavior of SHANK2-R462X expressing mice, with an impact on the penetrance of ASD.

P12.022

Evaluation of adRP microarray (Asper Biotech) for the diagnosis of autosomal dominant macular dystrophies

P. F. San Jose[1], *F. Blanco-Kelly*[1,2], *M. Corton*[1,2], *R. Riveiro-Alvarez*[1,2], *A. Giménez*[1], *A. Avila-Fernandez*[1,2], *I. Hernan*[3], *M. Carballo*[3], *C. Ayuso*[1,2];
[1]Department of Genetics, IIS-Fundación Jiménez Díaz, Madrid, Spain, [2]Centre for Biomedical Network Research on Rare Diseases (CIBERER), ISCII, Madrid, Spain, [3]Department of Genetics, Hospital de Terrasa, Barcelona, Spain.

Purpose: autosomal dominant macular dystrophies (adMD) are a group of diseases clinically and genetically heterogeneous. Currently there is no specific tool for genetic diagnosis. AdRP Microarray (Asper Biotech), which includes genes responsible for adMD, has recently demonstrated to be a cost-efficient tool for autosomal dominant retinitis pigmentosa diagnosis (1). We aim to test the AdRP Microarray for its potential use in adMD diagnosis.

Methods: 54 unrelated Spanish adMD patients affected were tested with adRP microarray. All mutations found were confirmed by sequencing. Peripherin 2(PRPH2), the most frequently mutated gene responsible for adMD, was sequenced in all negative samples for the microarray. The rate of false negatives (real mutations in PRPH2 gene represented but not detected by the array) and false positives (microarray results not confirmed by sequencing) were established.

Results: adRP microarray detected the mutation in 10 of the studied patients (diagnostic accuracy: 18.5%). Nine patients presented a mutation in PRPH2 gene, one in RHO gene. All mutations were confirmed by sequencing. Sequencing of PRPH2 of non-characterized families allowed the identification of one false negative. These results show a high level of analytical both sensitivity (91%) and specificity (100%).

Conclusions: adRP microarray shows high levels of analytical specificity and

sensitivity but sequencing of PRPH2 gene seems to be a more cost-efficient tool for adMD diagnostic than the adRP microarray.

P12.023
Identification of genetic defects in Iranian GJB2-heterozygous deaf individuals

A. Kashef[1,2,3], *N. Nikzat*[1], *N. Bazzazadegan*[1], *S. Arzhangi*[1], *Z. Fattahi*[1], *F. Sabagh*[2], *F. Pourfatemi*[3], *H. Najmabadi*[1], *K. Kahrizi*[1];
[1]*GRC (Genetic Research Center) , University of Social Welfare & Rehabilitation Sciences, Tehran, Islamic Republic of Iran,* [2]*Kerman Welfare Organization, Kerman, Islamic Republic of Iran,* [3]*Mazandaran Welfare Organization, Mazandaran, Islamic Republic of Iran.*

Hereditary hearing loss (HHL) is one of the most common sensorineural problems, affecting approximately one in 500 children. Although significant genetic heterogeneity exists as the cause of sensorineural HL, one locus, DFNB1, comprising the GJB2 and GJB6 genes, is responsible for up to 20-50% of cases with congenital non-syndromic HL in many populations. Homozygous or compound heterozygous mutations in GJB2 are detected in most cases with DFNB1-relatedHL. Interestingly, in some studies10-42% of deaf subjects showed recessive pattern of inheritance and withGJB2 mutations, carried only one mutant allele.
In this study, using direct sequencing; second mutant allele of GJB2 which leads to deaf phenotype was screened for possible mutations. One hundred patients with autosomal recessive non-syndromic hearing loss(ARNSHL) through Iranian population bearing first mutation in their coding exon (exon-2) of GJB2, were assessed for any other mutations in non-coding exon of GJB2 (exon-1)as well as promoter region of the gene.
We have identified the second mutant allele in splice site of exon-1 of GJB2 which known as -3170G to A in 14 probands (14%). No mutation in promoter region of GJB2 was found. Furthermore, Real-time PCR has been set up in order to check four known deletions which encompass both GJB2 and GJB6, for remainder probands.

P12.024
A novel ILDR1 gene mutation in two Iranian families with autosomal recessive non-syndromic hearing loss

E. Sohrabi, *M. Babanejad, N. Bazzazadegan, K. Jalalvand, S. Arzhangi, K. Kahrizi, H. Najmabadi;*
Genetic Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran.

Hearing loss (HL) is the most common sensory deficit in human. It affects approximately 10 percent of the world population. Genetic causes of HL are estimated to account about 68% of newborns and 55% of cases by the age of four. Autosomal recessive non-syndromic hearing loss (ARNSHL) is the most common type of inherited hearing impairment. Due to the wealthy gene pool, Iran is a valuable source to identify the genes involved in different conditions.To date, several genes have been studied in Iranian deaf population.
DFNB42, one of the related loci in ARNSHL, was first identified in a Pakistani family. Another study on more Pakistani and Iranian families, led to the identification of 10 different mutations in the related gene, *ILDR1*.
To estimate the contribution of this gene in Iranian deaf population, we have set out to perform homozygosity mapping with flanking STR markers on 140 Iranian deaf families.
Mutation detection, using conventional sequencing, for three out of 140 families showing linkage to DFNB42 locus, led to identification of one splice site mutation (c.379+1G>A) in two of the families.
Our data shows that *ILDR1* gene has the prevalence of about 2.14% in Iranian deaf population, that comparing to other loci seems to have a small proportion of the ARNSHL causes in Iran.
Keywords:Autosomal recessive non-syndromic hearing loss, *ILDR1*, sequencing, Iran.

P12.025
A novel PJVK gene mutation in Iranian family with autosomal recessive non-syndromic hearing loss

Z. Fattahi[1], *M. Babanejad*[1], *N. Bazzazadegan*[1], *N. Nikzat*[1], *S. Arzhangi*[1], *K. Jalalvand*[1], *K. Kahrizi*[1], *H. Najmabadi*[1,2];
[1]*Genetics Research Centre, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran,* [2]*Kariminejad Najmabadi Pathology & Genetics Center, Tehran, Islamic Republic of Iran.*

Hearing impairment is one of the common sensory disorders in world and affects about 1 of every 1000 newborns. In developed countries at least 50% of the cases are due to genetic defects resulting in non-syndromic deafness (70%), of which autosomal recessive inheritance predominates (80%). Hereditary hearing loss is very heterogeneous, so that nearly 95 loci and 40 genes have been identified as the causes of autosomal recessive non-syndromic hearing loss (ARNSHL) to date.
DFNB59 is one of the contributing loci in ARNSHL. Several studies showed mutations in PJVK as the cause of deafness in this locus. PJVK is considered as the first human gene implicated in non-syndromic deafness due to a neuronal defect. To date, several mutations have been reported in Iranian families from different studies and also some reports in Moroccan and Turkish populations as well.
In order to have more comprehensive look into PJVK gene in Iranian population, 144 ARNSHL families with two or more affected individuals from different Iranian ethnic groups were selected for this study.
Homozygosity mapping with flanking STR markers following conventional sequencing of the gene, revealed 2 mutations in 2 families, in which one of them is a novel nonsense mutation(c.274C > T or p.Arg92X) in exon 3. This data shows a prevalence of less than 2% in Iranian population for PJVK mutations. Although, mutations in this gene had been reported in different studies in Iranian deaf families but our data shows that this gene is not as prevalent as it seems.

P12.026
Molecular approach in Spanish families affected by Bardet-Biedl Syndrome

T. Piñeiro-Gallego, *D. Valverde;*
Departamento de Bioquímica, Xenética e Inmunoloxía. Facultade de Bioloxía. Universidade de Vigo, Vigo, Spain.

Bardet-Biedl Syndrome (BBS, OMIM 209900) is a rare autosomal recessive ciliopathy associated with several features including obesity, retinopathy, polydactyly, mental retardation, hypogonadism, and renal defects. Until now 16 genes (*BBS1-BBS16)* have been involved in ~70% of the families.
We selected 36 individuals from 30 families from a Spanish population previously screened for mutations on *BBS* gene using a genotyping microarray (Asper Biotech Ltd) and with negative results. We performed direct sequencing of *BBS10* gene in these 36 patients. This gene accounts for more than 20% of the mutational load in our population. Without taking into consideration the recurrent mutations (*BBS1*-M390R, *BBS10*-C91LfsX95), *BBS10* gen carried the largest mutational load in our population.
Sequencing of *BBS10* gene revealed compound heterozygous mutations p.L533fsX554/ p.V331A (novel mutation) in one affected individual and a single heterozygous novel mutation p.Y197del in another patient. Our work led to the identification of mutations in two families (4.2%)/3 alleles.
In conclusion, two novel heterozygous mutations in *BBS10* gene were found. Our study shows the important of testing preferably *BBS10* gene when *BBS* genotyping microarray is negative in the diagnosis of Bardet-Biedl syndrome. Since we could not detect any mutations in 28 families, sequencing of next gene carrying the largest mutational load (*BBS1*) is convenient.

P12.027
Mutations in *RIPK4* that encodes Receptor-Interacting Serine/Threonine Kinase Protein 4 cause the Autosomal Recessive Form of Popliteal Pterygium syndrome

E. Kalay[1], *O. Sezgin*[2], *V. Chellappa*[3], *M. Mutlu*[4], *H. Morsy*[5], *H. Kayserili*[6], *E. Kreiger*[7], *A. Cansu*[8], *B. Toraman*[1], *E. Abdalla*[5], *Y. Aslan*[4], *S. Pillai*[3], *N. A. Akarsu*[9];
[1]*Department of Medical Biology, Karadeniz Technical University Faculty of Medicine, Trabzon, Turkey,* [2]*Department of Medical Biology, Karadeniz Technical University Institute of Health Sciences, Trabzon, Turkey,* [3]*Cancer Center, Massachusetts General Hospital, Harvard Medical School, Boston, MA, United States,* [4]*Department of Pediatrics, Karadeniz Technical University Faculty of Medicine, Trabzon, Turkey,* [5]*Department of Human Genetics, Alexandria University Medical Research Institute, Alexandria, Egypt,* [6]*Medical Genetics Department, Istanbul Medical Faculty, Istanbul University, Istanbul, Turkey,* [7]*Center for Molecular and Biomolecular Informatics, Radboud University Nijmegen Medical Center, Nijmegen, Netherlands,* [8]*Department of Radiology, Karadeniz Technical University Faculty of Medicine, Trabzon, Turkey,* [9]*Gene Mapping Laboratory, Department of Medical Genetics, Hacettepe University Faculty of Medicine, Ankara, Turkey.*

The autosomal recessive form of popliteal pterygium syndrome, also known as Bartsocas-Papas syndrome (BPS), is a rare, but frequently lethal disorder characterized by marked popliteal pterygium associated with multiple congenital malformations. Using a genome-wide SNP homozygosity mapping strategy for this malformation syndrome in a Turkish family we identified a homozygous segment co-segregating with disease on chromosomal region 21q22.3. Since the phenotype of the deficiency of mouse ortholog of *RIPK4* consistent with anomalies seen in BPS, *RIPK4* was selected as candidate gene from the critical interval. Sequencing of the *RIPK4* showed a homozygous missense mutation p.Ile121Asn (c.362T>A) in the kinase domain of the protein. Screening of additional two BPS families showed a homozygous missense mutation p.Thr184Ile (c.551C>T) and a homozygous one base-pair insertion c.777_778insA (p.Arg260Thr*fs*X14) within the kinase domain of the protein. Molecular modeling and Luciferase reporter assays showed that both Ile121 and Thr184 positions are critical for the stability and catalytic activity of RIPK4. RIPK4 mediates activation of the nuclear factor-kB (NF-kB) signaling pathway that is required for keratinocyte differentiation and craniofacial and limb development. The abnormalities observed in presented individuals were similar, but less severe than those seen in Cocoon syndrome as a result of CHUK (IKKα) deficiency which is another component of NF-κB signaling pathway. In conclusion, our results showed that recessive mutations in *RIPK4* cause autosomal recessive form of multiple pterygium syndrome and RIPK4 and CHUK may function in closely related pathways to promote keratinocyte differentiation and epithelial growth.

P12.028

An identical *PRRT2* mutation underlies benign familial infantile epilepsy with and without paroxysmal dyskinesia

A. K. Anttonen[1,2,3]*, E. Liukkonen*[4]*, E. Gaily*[4]*, A. Sirén*[5,6]*, K. Mattila*[7,3]*, A. Polvi*[7,3]*, A. E. Lehesjoki*[7,3]*;*
[1]*Department of Medical Genetics, University of Helsinki, Helsinki, Finland,* [2]*Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland,* [3]*Folkhälsan Institute of Genetics, Helsinki, Finland,* [4]*Epilepsy Unit, Pediatric Neurology, Helsinki University Central Hospital, Helsinki, Finland,* [5]*Unit of Pediatric Neurology, Department of Pediatrics, Tampere University Hospital, Tampere, Finland,* [6]*Outpatient Clinic for Persons with Intellectual Disabilities, Tampere University Hospital, Tampere, Finland,* [7]*Neuroscience Center, University of Helsinki, Helsinki, Finland.*

Benign familial infantile epilepsy (BFIE) and paroxysmal dyskinesias are clinically and genetically heterogeneous paroxysmal neurological disorders. The ICCA syndrome is a phenotype combining both BFIE and paroxysmal kinesigenic dyskinesia (PKD). BFIE, PKD, and the ICCA syndrome have been linked to the pericentromeric region of chromosome 16. Recently, heterozygous mutations in the *PRRT2* gene on 16p11.2 were described as the cause of BFIE and paroxysmal dyskinesias. *PRRT2* encodes the proline-rich transmembrane protein 2 implicated to have a role in synaptic function. In this study we clinically and genetically characterized patients in three large Finnish families, which presented with either BFIE alone or in combination with a movement disorder with different types of triggers. Linkage analysis in two large ICCA families showed evidence for linkage to chromosome 16p12-p11.2 and a significant two-point LOD score of 5.55 was obtained at marker *D16S3022* (θ = 0.000). In the third family sharing a haplotype over the region on 16p12-p11.2 the clinical presentation was BFIE. After sequencing several positional candidate genes, the *PRRT2* gene was sequenced. Patients in all three families were heterozygous for the c.649dupC duplication mutation, the most frequently encountered *PRRT2* mutation. These data give further support for the association of *PRRT2* mutations to both epilepsy and movement disorders of both kinesigenic and non-kinesigenic type. The association of a single mutation with a variety of phenotypes highlights the contribution of modifying genetic and/or environmental factors to the clinical presentation.

P12.029

Two novel putative beta-globin gene mutations leading beta thalassemia intermedia phenotype

T. Bilgen[1]*, O. Altiok Clark*[2]*, Z. Ozturk*[3]*, M. A. Yesilipek*[3]*, I. Keser*[1]*;*
[1]*Akdeniz University, School of Medicine, Department of Medical Biology and Genetics, Antalya, Turkey,* [2]*Akdeniz University, School of Medicine, Department of Medical Genetics, Antalya, Turkey,* [3]*Akdeniz University, School of Medicine, Department of Pediatric Hematology and Oncology, Antalya, Turkey.*

There have been described approximately 800 different genomic alterations in the beta globin gene reported in the HbVar database and novel mutations are still rarely being reported. In this study, we aimed to identify two novel putative mutations in 3' un-translated region (3'-UTR) of the beta globin gene and to describe their clinical reflections. Four patients from two unrelated families referred with diverse set of hematological and clinical findings associated to beta thalassemia were included in this study. Molecular diagnosis of the beta globin gene mutations was performed by direct sequencing of the beta globin gene. A novel mutation HBB:c.*+108 A>G was found in combination with IVS-I-110 G>A mutation caused intermedia phenotype in two brothers and one sister with mild splenomegaly and occasional transfusion history in the first family. The second novel mutation named as HBB:c.*+132 C>T was found in combination with IVS-I-1 G>A in a 7 years old male diagnosed as beta thalassemia intermedia with irregular transfusion history in family 2. Based on beta thalassemia intermedia phenotypes despite of clinical diversity observed in our patients and taking into account the accompanying mutations, it would be concluded that these novel beta globin gene 3' UTR mutations are associated with mild phenotype of beta thalassemia.

P12.030

Novel indel mutation in CDMP1 gene is associated with brachydactyly type C in a four generation Turkish family

O. Z. UYGUNER[1]*, M. Kocaoglu*[2]*, G. Toksoy*[1]*, S. Basaran*[1]*, H. Kayserili*[1]*;*
[1]*Department of Medical Genetics, Istanbul Medical Faculty, Istanbul University, Istanbul, Turkey,* [2]*Orthopedics Department, Istanbul Medical Faculty, Istanbul University, Istanbul, Turkey.*

The cartilage derived morphogenetic protein-1 (CDMP1), also referred as the growth/differentiation factor 5 (GDF5) gene, has been shown to be a key regulator in the bone morphogenic protein pathway (BMP) during skeletal and joint development. Heterozygous loss-of-function mutations reported to cause hypoplasia/aplasia of certain skeletal elements (brachydactyly), heterozygous gain-of-function mutations, occurring either on the gene itself or through the loss of its inhibitor noggin, result in joint fusion (symphalangism). Furthermore, homozygous mutations, predominantly affecting the limbs have been described; Grebe type dysplasia, Du Pan Syndrome, Acromesomelic Dysplasia-Hunter Thompson type. Also reported is homozygous missense mutation presenting with brachydactyly, formulating phenotype-genotype correlations by type and domain inconceivable, likely due to the influence of other factors impacting the developmental pathway. Presently, 34 mutations dispersed throughout propeptide and chain domains of CDMP1, associated with eight different OMIM entries, have been described.
We ascertain here two affecteds, one female and one male, with brachdactyly type C (MIM# 113100) presenting with disproportionate shortness of the 2nd and 3rd fingers and hypersegmentation of the proximal and middle 2nd and 3rd phalanges. These cases are from a family that reports an additional 8 affected members spanning across four generations. CDMP1 analysis revealed a novel heterozygous in frame indel mutation (c.803_827del25ins25) in the propeptide domain (p.cys268_ser276delCPSGRQPASinsLLSALLDVN). This is the second indel mutation ascribed to the CDMP1. The previously published indel mutation was of the out-of-frame type in homozygous state, in the chain motif, associated with Du Pan Syndrome. Our novel mutation further emphasizes the allelic heterogeneity of CDMP1.

P12.031

Altered Genomic DNA Binding Profile of a HOXD13 Mutant in a Novel Type of Brachydactyly

D. Ibrahim[1,2]*, P. Hansen*[1]*, A. Stiege*[2]*, S. Dölken*[1]*, M. Schmidt-von Kegler*[1]*, F. Wagner*[3]*, B. Timmermann*[2]*, P. Krawitz*[1]*, D. Horn*[1]*, P. Seemann*[1]*, P. Robinson*[1]*, S. Mundlos*[1,2]*,* ***J. Hecht***[1,2]*;*
[1]*Charité - Universitätsmedizin Berlin, Berlin, Germany,* [2]*Max-Planck Institut für molekulare Genetik, Berlin, Germany,* [3]*Atlas Biolabs GmbH, Berlin, Germany.*

Mutations in HOXD13 have previously been associated with synpolydactlyly. Here we describe a patient with brachydactyly and a novel mutation (Q317K) in the DNA binding homeodomain of HOXD13. Anomalies of hands and feet are characterized by shortness of fingers and toes, oligodactyly, and aplasia of some terminal phalanges. Functional analysis was performed by retroviral overexpression of FLAG-tagged HOXD13 wt and mutant in chicken micromass cultures, a well established model of chondrocyte differentiation. Targets of HOXD13 were identified by chromatin immunoprecipitation followed by next-generation sequencing (ChIP-seq). Bioinformatic analysis of precipitated sequences showed an altered DNA binding motif of the mutant protein. The inferred motif of HOXD13^{Q317K} showed similarity to that of PITX1. The mutant lysine at position 317 corresponds also to a conserved lysine at the analogous position of bicoid type homeodomain proteins such as PITX1. Thus we compared the binding pattern of HOXD13^{wt}, HOXD13^{Q317K}, and PITX1 using ChIP-seq and found a shift of HOXD13^{Q317K} towards a PITX1-like binding pattern. Furthermore the expression profile in HOXD13^{Q317K} overexpressing micromass cultures also shifted towards a PITX1 overexpression profile. Injection of HOXD13^{Q317K} into developing wing buds of chicken embryos showed a PITX1-like phenotype as well. Our results demonstrate how ChIP-seq can be used to characterize genome-wide binding profiles of mutant transcription factors. The mutation results in a partial conversion of HOXD13 into PITX1 and thus ectopic activation of PITX1 targets.

P12.032

New genes involved in metabolic disorders: Diseased states due to errors in the enzymatic regulation of the mammalian branched-chain α-keto acid dehydrogenase complex

A. Oyarzabal[1]*, B. Merinero*[1]*, P. Sanz*[1]*, R. Navarrete*[1]*, M. Ecay*[1]*, C. Robles*[2]*, M. Martínez-Pardo*[3]*, M. Ugarte*[1]*, P. Rodríguez-Pombo*[1]*;*
[1]*CEDEM, CBMSO, CIBERER, IDIPAZ, Univ. Autonoma de Madrid, Madrid, Spain,* [2]*Servicio*

de Pediatría, Hospital San Cecilio, Granada, Spain, [3]Servicio de Pediatría, Hospital Universitario Ramón y Cajal, Madrid, Spain.

Mammalian branched-chain α-keto acid dehydrogenase complex (BCKDc) is a mitochondrial macromolecular multienzymatic complex consisting of three catalytic components that catalyzes the rate-limiting step in the oxidation of branched-chain α-keto acids. BCKDc deficiency leads to the autosomal inborn error of metabolism -maple syrup urine disease (MSUD)-. Activity of the complex is regulated by a specific kinase (BCKDK) which causes inactivation, and the protein phosphatase 2Cm (PP2Cm) which causes activation. Up to now, the 150 described MSUD-causing mutations have been only found on the genes encoding for the E1α, E1β and E2 catalytic subunits, but not much is known regarding diseased states that could arise due to errors in the enzymatic regulation of BCKDc. We present here the first two patients with a defective regulation of BCKDc. The first one corresponds to a MSUD patient with a mild variant phenotype. The second one is a patient with neurological abnormalities, showing a decreased amount of branched-chain amino acids levels in physiological fluids. The Sanger sequencing of BCKD related genes in both patients evidenced: a homozygous null mutation change c.417_418delTA (p.His139fs) in the *PPM1K* gene, which encodes for PP2Cm for the MSUD patient, and that was proved to be pathogenic by genetic complementation in patient's fibroblasts using the pT-REX-DEST30/*PPM1K*wt vector, and a homozygous c.1166T>C (p.Leu389Pro) nucleotide variation in the *BCKDK* gene, undetected in 300 control alleles, for the second one. The disease phenotype of these two patients demonstrates the importance of tight regulation of oxidative disposal of BCAA for normal growth and neurological functions.

P12.033

Application of RNA analysis for evaluation of unclassified variants in routine genetic diagnosis of breast cancer and neurofibromatosis 1

***S. Preisler-Adams**, J. Horvath, P. Wieacker;*
University Clinics Muenster, Muenster, Germany.

A frequent problem in molecular genetic diagnosis is the assessment of unclassified variants (UCVs). Exonic missense or silent variants and intronic variants outside the invariably exon-flanking dinucleotides are ambiguous and *in silico* analysis has its limits in being theoretical. Expression analysis via RNA from blood lymphocytes can help to discriminate between variants that influence correct splicing and those that don`t. A precondition for this approach is the expression of the corresponding gene in blood cells as is the case for e.g. BRCA1, BRCA2, RAD51C and NF1. Using reverse transcription, RT-PCR and sequence analysis of the resulting product(s) we were able to show a splice effect for the BRCA1 variants p.G1366S, IVS19-12A>G, the RAD51C variant p.C135F and the NF1-variants IVS16del-6_3, IVS3+6T>G and p.L1569V. Conversely, a splice effect could be excluded for the BRCA1 variants p.D120N, p.T1548T and p.Q1604Q, the BRCA2 variants IVS9-11T>C and IVS22-7_4del, the RAD51C variant p.G3R and the NF1 variants p.K724K, L549Q, p.F1289F, p.R1375H and p.L1957L.

Preparing RNA from blood and performing cDNA analysis is usually not part of the routine molecular diagnosis. In our laboratory practice - if a possible splice mutation was identified - we recommend to take a second blood sample in the context of the subsequent genetic counselling in order to perform RNA analysis. In view of the potential benefit by solving the question of pathogenicity, this turns out to be a feasible effort.

P12.034

New mutation in SNTA1 gene in Russian Brugada Syndrome patient - a new causative gene?

***E. Zaklyazminskaya**, M. Polyak, M. Noskova, S. Dzemeshkevich;*
Petrovsky Russian Research Centre of Surgery, Moscow, Russian Federation.

Brugada syndrome (BrS) is inherited cardiac arrhythmic disorder characterized by ST-segment elevation in right precordial leads, pseudo right bundle branch block, T-wave inversion and high risk of cardiac sudden death due to polymorphic ventricular tachycardia (PVT). The SCN5A gene was identified as causative in 1998 and has been only one known for BrS for many years. Mutations in this gene account 15%-30% of all cases. Starting from 2007 the list of genetic variants was increased up to eight. But all those genes seem to be much less prevalent and does not explain vast majority of BrS cases.

Clinical, instrumental and familial data, informed consent and blood samples were obtained from 20 unrelated SCN5A-negative Russian BrS patients. The PCR-based Senger sequencing of full coding and adjacent intronic areas of SCN5A, and few additional known and new candidate genes including SNT1A gene was performed.

We did find a new rare missense variant c.R106Q in SNT1A gene in patient with spontaneous BrS1-type ECG, registered episodes of PVT, and numerous appropriate shocks after ICD implantation. Quinidine was ineffective in decreasing VT frequency. This genetic variant had not been found in a control group.

New rare genetic variant in SNT1A gene had been found in Russian SCN5A-negative BrS patient. Syntrophin 1A is a protein interacting with Nav1.5 channel and can be considered as a candidate gene for BrS. It might influence on cardiomyocyte repolarization via altering sodium channel function. To elucidate possible causative role of c.R106Q in SNTA1 gene further functional investigations are required.

P12.035

Reliable and sensitive SCN5A high resolution melting curve analysis as a primary gene scanning assay for genetic diagnosis of Brugada syndrome

***S. J. Van Dooren**[1], L. Peirsman[1], I. Timmermans[1], U. Ullmann[1], M. Biervliet[1], P. Brugada[2], M. Bonduelle[1];*
[1]Centre for Medical Genetics, UZ Brussel, VUB, Brussels, Belgium, [2]Heart Rhythm Management Institute, UZBrussel, VUB, Brussels, Belgium.

Brugada syndrome (BrS) is an autosomal dominant inherited primary cardiac arrhythmia in a structurally normal heart, with a propensity to sudden cardiac death. Genetic defects have mainly been attributed to mutations in the alpha-subunit of the sodium channel gene (SCN5A), which account for approximately 20% of cases. The clinical diagnosis is based on an anamnesis of the patient and a baseline and/or infusion electrocardiogram, which should be confirmed genetically by the mutation analysis of the SCN5A gene. To allow a convenient and cost-effective diagnostic genetic testing for BrS a primary indirect gene scanning assay by high resolution melting curve analysis (HRMCA) of the SCN5A gene was developed.To assess the sensitivity and specificity of the HRMCA assay over 100 clinically diagnosed BrS patients were analyzed in parallel by bidirectional cycle sequencing of the 28 SCN5A exons and by HRMCA analysis of 24 exons. Sensitivity of the HRMCA could be increased by using spike-DNA completely homozygous in the amplified regions and by discriminatory analysis of melting patterns with dual melting domains. All of the Sanger sequencing confirmed mutations and SNPs could be detected through HRMCA, with the exception of a deep intronic mutation lying 8 nucleotides downstream of the 3'end of the forward primer. Specificity of the assay met expectations. This study demonstrates that SCN5A HRMCA analysis can be implemented as a cost-effective, high-throughput, user-friendly primary gene scanning method within the framework of the molecular diagnosis of BrS.

P12.036

The imprinted *C15orf2* gene in the Prader-Willi syndrome region encodes a nuclear pore complex associated protein

***L. Neumann**[1], Y. Markaki[2], E. Mladenov[1], D. Hoffmann[3], K. Buiting[1], B. Horsthemke[1];*
[1]Universitaetsklinikum Essen, Essen, Germany, [2]Ludwig-Maximilians-Universitaet München, Martinsried, Germany, [3]Universitaet Duisburg-Essen, Essen, Germany.

The Prader-Willi syndrome (PWS) region in 15q11q13 harbours a cluster of imprinted genes expressed from the paternal chromosome only. Whereas loss of function of the *SNORD116* genes appears to be responsible for the major features of PWS, the role of the other genes is less clear. One of these genes is *C15orf2*, which has no orthologs in rodents but appears to be under strong positive selection in primates.

C15orf2 encodes an 1156 aa protein with six nuclear localisation sequences. To find out more about the function of C15orf2, we used the Phyre software for sequence threading against a structural database and InterProScan for a pattern and profile search. We found a highly significant similarity of the C-terminal part of C15orf2 to the nuclear pore complex (NPC) protein Pom121. Using the Invitrogen Flp-In system we generated a stable cell line that expresses flag-tagged C15orf2 upon doxycycline induction. By immunocytochemistry in expression-induced cells we found C15orf2 located at the nuclear periphery, where it co-localized with NPC and nuclear lamina proteins. Extending these observations to three-dimensional structured illumination fluorescence microscopy (3D-SIM), which achieves an eight-fold improved volumetric resolution over conventional imaging and can resolve single NPCs, we saw that C15orf2 is located at the inner nuclear membrane where it strongly associates with the NPC. Additionally, in nuclear envelope isolation and fractionation experiments C15orf2 co-purified with NPC and nuclear lamina proteins.

These experiments for the first time demonstrate that C15orf2 is part of the NPC or its associated molecular networks.

Whole CYP21A2 gene analysis of congenital adrenal hyperplasia patients due to 21-hydroxylase deficiency

D. Kirac[1], *K. Ulucan*[2], *D. Ergec*[2], *T. Guran*[3], *T. Akcay*[3], *G. Koc*[2], *E. C. Kaspar*[4], *A. Bereket*[3], *T. Isbir*[1], *A. I. Guney*[2];
[1]*Yeditepe University, Faculty of Medicine, Department of Medical Biology, Istanbul, Turkey,* [2]*Marmara University, Faculty of Medicine, Department of Medical Genetics, Istanbul, Turkey,* [3]*Marmara University, Faculty of Medicine, Department of Pediatric Endocrinology, Istanbul, Turkey,* [4]*Yeditepe University, Faculty of Medicine, Department of Biostatistics, Istanbul, Turkey.*

Introduction: Congenital adrenal hyperplasia (CAH) is an autosomal recessive disorder, caused by mainly 21-hydroxylase deficiency. Females with severe 21 hydroxylase deficiency are exposed to excess androgens prenatally and are born with ambiguous genitalia. Also most patients can not synthesize sufficient aldosterone to maintain sodium balance and may develop potentially fatal "salt wasting" crises if not treated.
Methods: Whole CYP21A2 gene were analyzed in 100 patients and 80 controls. Distinctive primers were selected for the amplification of the functional gene (CYP21A2) as there is a pseudogene (CYP21A1P) with 98% homology. After the isolation of DNA from peripheric blood, functional gene was amplified by PCR. Mutations were detected with direct sequencing. Results were evaluated statistically.
Results: Totally 66 different mutations/polymorphisms were found in which 20 of them cause amino acid changes and 24 of them are novel. Also 12 of them were found statistically significant in patients when compared to controls. Additionally G→A mutation at position 711 (13 %) (novel mutation), A/C→G mutation at position 777 (38 %) and C→G mutation at position 1709 (20 %) were only detected in the patient group and were found statistically significant when compared to controls.
Conclusion: Prenatal diagnosis of CAH has been utilized for over 20 years especially by screening 9 known mutations. In case of obtaining the similar results of G→A mutation at position 711 in different populations, it may be used as a marker for prenatal diagnosis. Therefore, genital ambiguity and salt wasting can be reduced in CAH patients by using prenatal approaches.

P12.038

Targeted next-generation sequencing for the molecular genetic diagnostics of arrhythmogenic cardiac disorders in sudden cardiac death

C. Marschall, *C. Heberle, I. Vogl, H. Klein;*
Center for Human Genetics and Laboratory Medicine, Martinsried, Germany.

Sudden cardiac death (SCD) is the most common cause of death in the young. Ion channel disorders (channelopathies) such as the long QT syndrome (LQTS), catecholaminergic polymorphic ventricular tachycardia (CPVT) and Brugada syndrome (BrS) may account for more than 30% of unclear SCD cases lacking cardiac structural abnormalities. Other frequent causes of SCD are hypertrophic cardiomyopathy (HCM) affecting 1 of 500 people and arrhythmogenic right ventricular dysplasia (ARVD). As HCM and ARVD may present with only little structural symptoms, the differential diagnosis of these arrhythmogenic disorders may be difficult. Stepwise analysis of various genes with traditional Sanger sequencing is elaborate, time-consuming and expensive. Although clearly superior to Sanger sequencing, NGS has little impact on clinical testing to date. Sequence capture target enrichment followed by re-sequencing on the Roche Genome Sequencer FLX (GS FLX) system could be useful for novel mutation detection. A Roche-NimbleGen and an Agilent SureSelect in solution target enrichment assay was designed for the capture of coding regions including splice sites of 40 SCD genes known to be associated with SCD. Both enrichment assays were validated with two samples with known mutations in duplicates. Additional clinical SCD samples with unknown genotype were analyzed with a minimum coverage of 30-fold. Data analysis was performed with the CLC Genomic Workbench software. Potentially disease causing variants and regions with an insufficient coverage were re-analyzed with Sanger sequencing.

P12.039

The mutation makes the difference - Analysis of *RMRP* transcript levels in Cartilage-hair hypoplasia

K. Reicherter[1], *E. Lausch*[1], *P. Hermanns*[2], *R. Keppler*[1], *C. Steinwender*[1], *T. J. M. Welting*[3], *B. Zabel*[1];
[1]*University of Freiburg, Centre for Pediatrics and Adolescent Medicine, Freiburg, Germany,* [2]*Medical Centre of the Johannes Gutenberg University Mainz, Centre for Pediatrics and Adolescent Medicine, Mainz, Germany,* [3]*Maastricht University Medical Center, Department of Orthopaedic Surgery, Maastricht, Netherlands.*

Cartilage-hair hypoplasia (CHH) is an autosomal recessive disorder characterized by short stature and metaphyseal dysplasia. Variable extraskeletal features include sparse hair, immunodeficiency, and predisposition to malignancy. CHH is caused by mutations in the *RMRP* gene, which encodes the RNA component of the RNase MRP complex. RNase MRP is involved in the endoribonucleolytic processing of specific RNA substrates (viperin and cyclin B2), RNA primers for mitochondrial DNA replication, and pre-5.8S rRNA. The *RMRP* RNA also forms complexes with TERT, the telomerase protein component.
When reanalyzing the *Rmrp* expression in heterozygous *Rmrp* 70A>G knock-in mice, we exclusively detected the wildtype allele in all tested tissues. We hypothesized that the instability of the mutated transcript had increased after neo-cassette removal and decided to analyse the expression of mutated *RMRP* transcripts in CHH patients. Our qPCR data show clearly reduced *RMRP* transcript levels in all patients and mild reductions in parents carrying one mutated allele. Then we compared the transcript ratios of both alleles by sequencing. Confirming our mouse data, the mutated transcript was nearly absent in heterozygous parents. Interestingly, we also observed shifted transcript ratios in compound heterozygous CHH patients.
Our results indicate that *RMRP* mutations lead to reduced *RMRP* transcript levels, probably due to instability of mutated transcripts. Furthermore, the transcript instability depends on the individual *RMRP* mutation. The different stabilities and resulting variable residual *RMRP* transcript levels might explain the diverse clinical presentation of CHH patients, as, e.g., the degree of telomerase dysfunction observed in CHH patients may be dosage-dependent.

P12.040

Identification of novel CAV3 gene alterations

M. Svingou[1], *K. Kekou*[1], *H. Fryssira*[1], *P. Manta*[2], *D. Petychakis*[1], *E. Kanavakis*[1];
[1]*Department of Medical Genetics, University of Athens, „Aghia Sophia Children's Hospital", Athens, Greece,* [2]*Department of Neurology, University of Athens, Eginition Hospital, Athens, Greece.*

The human CAV3 gene, mapping to chromosome 3p25, encodes for caveolin-3 muscle-specific protein, which is the principal integral membrane component of caveolae. Caveolin-3 is localized to the muscle cell plasma membrane, where it forms a complex with dystrophin and associated-proteins. This suggests that the small vesicular invaginations of the plasma membrane (caveolae), involved in cell signaling and trafficking, might play an important role in muscle membrane physiology. In vitro and in vivo experimental models indicate that the maintenance of normal levels of caveolin-3 is essential for normal skeletal muscle development and postnatal function. Mutations in the coding sequence of CAV3 cause dominant limb-girdle muscular dystrophy (LGMD-1C). In this survey 121 Greek individuals, comprised of 119 normal controls and 2 patients presenting with increased serum creatine kinase (CK) levels, muscle weakness and a compatible with caveolinopathy muscle biopsy were screened for mutations along CAV3 gene. Two causative mutations in exons 1 and 2, respectively where disclosed in the 2 patients. Twenty three heterozygous polymorphic alterations were identified in the control group, including 3 missense mutations- one of which is novel, and two previously reported - a novel a microdeletion in 3'UTR and 19 silence mutations. As different alterations were detected between the control group and the patients, interpretation of gene defects will help towards the understanding of LGMD-1C pathogenesis.

P12.041

Genotype-phenotype correlations in cerebral cavernous malformations

Cerebral cavernous malformations (CCM) are prevalent cerebrovascular lesions predisposing to chronic headaches, epilepsy, and hemorrhagic stroke. Individuals carrying an autosomal dominantly inherited mutation in *CCM3/PDCD10* have been reported to have a higher risk for cerebral hemorrhage during childhood when compared to *CCM1/KRIT1* and *CCM2/OSM* mutation carriers. Most recently, it has also been suggested that CCM3 function may be distinct from CCM1 and CCM2 and that CCM3 acts in different molecular pathways.

Genomic DNA sequencing and MLPA analyses allowed us to identify 38 additional CCM probands harbouring a loss-of-function mutation in one of the three CCM genes (21 in *CCM1*, 5 in *CCM2*, 12 in *CCM3*) over the past three years. Notably, the proportion of *CCM3* mutation carriers (32%) was significantly higher than previously reported. The mean age at referral was 17 years for index patients with a *CCM3* mutation (ranging from 1 to 51) while the mean age at referral was 36 years for *CCM1* probands (ranging from 6 to 79) and 43 years for *CCM2* probands (ranging from 17 to 72). We are currently inquiring for more details about disease manifestations and disease processes. However, our data already suggest a tendency towards earlier disease presentation in *CCM3* mutation carriers.

The atypical Rett-syndrome protein CDKL5 promotes excitatory synapse formation by strengthening the interaction between NGL-1 and the postsynaptic scaffold protein PSD95

M. Hambrock[1]*, S. Ricciardi*[2]*, F. Ungaro*[2]*, N. Rademacher*[1]*, G. Stefanelli*[2]*, U. Fischer*[1]*, A. Grimme*[1]*, D. Brambilla*[3]*, A. Sessa*[2]*, C. Magagnotti*[2]*, A. Bachi*[2]*, C. Kilstrup-Nielsen*[4]*, V. M. Kalscheuer*[1]*, V. Broccoli*[2]*;*

[1]*Max Planck Institute for Molecular Genetics, Berlin, Germany,* [2]*San Raffaele Scientific Institute, Milan, Italy,* [3]*University of Milan Medical School, Milan, Italy,* [4]*University of Insubria, Busto Arsizio VA, Italy.*

Mutations in the X-linked gene cyclin-dependent kinase like 5 (CDKL5) cause a severe neurodevelopmental disorder with clinical features that are closely related to Rett syndrome (RTT), including intellectual disability, early onset intractable epilepsy and autism. However, very little is currently known about the biological role of CDKL5. We here show that Cdkl5 localizes at excitatory synapses and contributes to correct spine morphology and synaptic activity. Since we previously found that a balanced chromosome translocation in the Netrin-G1 gene (NTNG1) also caused atypical RTT with early onset seizures, we hypothesized that the two genes play a role in common pathogenetic processes. Immunofluorescence and immunoprecipitation experiments revealed that Cdkl5 interacts with the Netrin G1 ligand NGL-1, a postsynaptic neuronal adhesion protein. In addition, we could show that NGL-1 is phosphorylated and that this phosphorylation is mediated by CDKL5, in vitro. Using fibroblasts from a patient who carried a truncation of the CDKL5 gene, we obtained further evidence that CDKL5 phosphorylates NGL-1. Moreover, we have found that this phosphorylation is necessary for promoting a stable association between NGL-1 and PSD95, a scaffold protein of the post-synaptic density. Accordingly, phospho-mutant NGL-1 lacked the ability to induce synaptic contacts, while its phospho-mimetic form bound PSD95 more efficiently and partially rescued the CDKL5-specific spine defects. In conclusion, we provide novel mechanistic insights into how CDKL5 mutations can impact on neuronal function in atypical RTT.

P12.043

Further contributions towards the molecular analysis of NIPBL and SMC1A genes in a cohort of patients with Cornelia de Lange Syndrome

E. Pinto da Costa[1]*, J. Oliveira*[1]*, J. Silva*[2]*, R. Santos*[1]*;*

[1]*Unidade de Investigação e desenvolvimento, Centro de Genética Médica Dr. Jacinto Magalhães - INSA, Porto, Portugal,* [2]*Unidade de Consulta, Centro de Genética Médica Dr. Jacinto Magalhães - INSA, Porto, Porto, Portugal.*

Cornelia de Lange Syndrome [CdLS (MIM#122470)] is a rare multisystemic disorder, characterized by a typical phenotype that includes distinctive facial dysmorphism, hirsutism, growth and psychomotor developmental delay, abnormalities of the upper extremities, and relatively frequent gastrointestinal and congenital heart defects. CdLS is essentially caused by mutations in the *NIPBL* and *SMC1A* genes (~50% and 5% of cases, respectively), but mutations have been also described in other genes (*PDS5A*, *PDS5B*, *SMC3*) (http://www.lovd.nl/CDLS). This genetic heterogeneity in CdLS can however be explained by a close functional relationship at the cellular level, since all these proteins are involved in chromatid cohesion.

The molecular and clinical characterization of 42 Portuguese CdLS patients has been previously described (Oliveira *et al*., 2010). In this work we conducted the molecular analysis of *NIPBL* gene and more recently expanded this study to other 20 patients. Subsequently, all the molecularly unresolved patients were screened for large deletions and duplications in *NIPBL* by MLPA, and point mutations in *SMC1A* by high resolution melting curve analysis and sequencing.

Preliminary results allowed us to identify 4 previously known mutations (including a case with somatic mosaicism), 3 novel mutations (c.3316C>T, c.6983C>G and c.7307C>T) and 2 large deletions in the *NIPBL* gene. Mutation screening in *SMC1A* is still ongoing.

Our results, at least for *NIPBL* gene analysis, suggest that the use of several different techniques is essential for attaining a high mutation detection rate. CdLS cases with somatic mosaicism are probably underestimated in the literature and may explain some degree of phenotypical variability.

P12.045

CHD7 is involved in a multi-protein complex together with CHD8 and FAM124B

T. Batsukh[1]*, Y. Schulz*[1]*, H. Urlaub*[2]*, T. Oellerich*[2]*, S. Pauli*[1]*;*

[1]*Institute of Human Genetics, Göttingen, Germany,* [2]*Max Planck Institute for Biophysical Chemistry, Göttingen, Germany.*

Mutations in the *CHD7* gene are in approximately 2/3 of cases the underlying cause of CHARGE syndrome. To identify candidate genes involved in the pathogenesis of this disease, we searched for CHD7 interacting partners. We could previously demonstrate that a part of CHD7 interacts with a part of CHD8. Because CHD8 is a known component of the WDR5-ASH2L-RBBP5 (WAR) complex, we asking the question if CHD7 is also a member of this complex. Additionally, we search for new CHD7-CHD8 interacting partners by using the SILAC (***s***table ***i***sotope ***l***abelling with ***a***mino acids in ***c***ell culture) method in combination with mass spectrometry.

We identified FAM124B as a potential interacting partner of CHD7 and CHD8. We confirmed the result by co-immunoprecipitation. Furthermore, we studied the direct interaction between the CHD7 part, the CHD8 part and FAM124B by using the method of direct yeast two hybrid. We could demonstrate that the CHD8 part directly interacts with FAM124B, while the CHD7 part is not interacting. This result leads to the suggestion that CHD7 is together with CHD8 and FAM124B a component of the same complex, with direct contact to CHD8 and no direct interaction with FAM124B. Using the Duolink Pla II method we could demonstrate that CHD7 is also in near proximity with the WAR-complex members, leading to the suggestion that CHD7 is also involved in this complex.

The characterisation of CHD7 containing complexes and the identification of interaction partners will help to understand the pathogenesis of CHARGE syndrome.

P12.046

Targeted High-Throughput Sequencing for Diagnosis of Genetically Heterogeneous Diseases: Fast and Efficient Mutation Detection in Bardet-Biedl Syndrome, Alström Syndrome, and in clinically overlapping ciliopathies

C. Redin[1]*, S. Le Gras*[1]*, O. Mhamdi*[2]*, V. Geoffroy*[1]*, C. Stoetzel*[3]*, M. Vincent*[4]*, B. Jost*[1]*, H. B. Chaabouni*[2]*, H. Dollfus*[3,5]*, J. Mandel*[1,4,6]*,* ***J. Muller***[1,4]*;*

[1]*IGBMC, Illkirch Graffenstaden, France,* [2]*Laboratory of Human Genetics, University of Medicine of Tunis, Tunis, Tunisia,* [3]*Laboratoire de Génétique Médicale EA3949, Faculté de Médecine/Université de Strasbourg, Strasbourg, France,* [4]*Laboratoire de Diagnostic Génétique, Hôpitaux Universitaires de Strasbourg, Strasbourg, France,* [5]*Service de Génétique Médicale, CARGO, Hôpitaux Universitaires de Strasbourg, Strasbourg, France,* [6]*Chaire de Génétique Humaine, Collège de France, Illkirch, France.*

Bardet-Biedl syndrome (BBS) is a pleiotropic recessive disorder that belongs to the rapidly growing family of ciliopathies. It shares phenotypic traits with other ciliopathies such as Alström syndrome (ALMS), nephronophthisis (NPHP) or Joubert syndromes. BBS mutations have been detected in 16 genes and no clear genotype-to-phenotype correlation could be observed. This extensive genetic heterogeneity is a major problem for molecular diagnosis and genetic counseling. While various strategies have been proposed in order to optimize mutation detection they either fail to detect mutations in a majority of patients or are time-consuming and costly. We tested a targeted exon-capture strategy coupled with multiplexing and high-throughput sequencing on a total of 52 patients: 14 with known mutations as proof-of-principle, 38 with no previously detected mutations. Thirty genes were targeted in total, including the 16 BBS genes, the 12 known NPHP genes and the single ALMS gene. This strategy allowed the reliable detection of causative mutations (including homozygous/ heterozygous exon deletions) in 68% of BBS patients with no previous molecular diagnosis and in all proof-of-principle samples. Three probands were found to carry truncating mutations in ALMS1 confirming the phenotypic overlap between both disorders. The overall efficiency of detecting mutations in patients was positively correlated with their compliance to classical BBS phenotype suggesting that only a few true BBS genes remain to be identified. We will illustrate some interpretation problems one may encounter in diagnostic settings due to the multiplicity of variants detected. Targeted capture strategy appears highly efficient and cost-effective for genetically heterogeneous diseases.

P12.047

Whole exome sequencing in prenatal and postnatal investigations identifies the causative mutations associated with complex phenotypes

***C. Pangalos**, B. Hagnefelt, S. Sevastidou, K. Pispili, C. Konialis;*
InterGenetics-Diagnostic Genetic Center, Athens, Greece.

By combining Next Generation Sequencing (NGS) with human whole exome capture, it is now feasible to identify, in a single step, inherited or somatic pathological mutations residing in coding regions of all known human genes. We applied whole exome capture and NGS in 2 complex clinical cases, involving: (1) an 18yr old male patient, exhibiting multiple abnormalities of the kidneys coupled to progressive visual impairment, and (2) a chorionic villus sample following termination of pregnancy, of a male fetus with skeletal and genital anomalies. Exome enrichment was achieved using Roche NimbleGen v2 capture, followed by NGS on an Illumina GAIIx at >50x coverage. Sequence data was analyzed and variants were filtered, identified and evaluated utilizing NextGENe v2.1 sequence analysis software (SoftGenetics) and various publicly available tools and databases. In the first case, a known or novel pathological heterozygous mutation was identified in each of 4 different genes (NPHP4, RPGRIP1L, CC2D2A, AVIL), consistent with a diagnosis of multi-allelic cilliopathy with retinal degeneration. In the second case, a predicted pathological hemizygous mutation c.194A>G (p.N65S) within the NSDHL gene on Xq28 was identified, and its presence was confirmed in the carrier mother. The presence of this novel mutation in the male fetus is most likely associated with malformation syndromes caused by dysfunction in cholesterol biosynthesis, in agreement with the clinical findings. In both cases, our findings provide new and important insights into the genetic causes of complex phenotypes and highlight the value of this new technology when applied in a clinical setting.

P12.048

Exhaustive molecular analysis and accurate estimation of type V collagen mutations in classic EDS

***D. Syx**, S. Symoens, F. Malfait, P. Coucke, A. De Paepe;*
Center for Medical Genetics, Ghent, Belgium.

Classic Ehlers-Danlos syndrome (EDS) is characterized by hyperextensible skin, atrophic scarring, easy bruising and generalised jointhypermobility. Mutations in *COL5A1* and *COL5A2*, encoding type V collagen, have been reported, but the proportion of classic EDS that result from defects in these genes remains unresolved. We studied 126 patients with a clinically established or suspected diagnosis of classic EDS. Of these, 102 patients fulfilled all major diagnostic criteria for classic EDS (Villefranche nosology) (group 1). We also included 24 patients in whom the diagnosis of classic EDS could not unequivocally be established, as they presented jointhypermobility and soft, mildly hyperextensible skin but no typical dystrophic scarring (group 2). Inclusion of this cohort allowed evaluating the most indicative clinical features for the presence of a type V collagen defect. In total, a type V collagen defect was identified in 93/102 patients in group 1, among which 49 novel mutations. Approximately half of these defects caused *COL5A1*-haploinsufficiency, whereas one-third were structural mutations in *COL5A1* or *COL5A2*. In 9/102 patients no type V collagen defect was detected. No obvious genotype-phenotype correlation was observed. In contrast, none of the patients of group 2 harboured a *COL5A1*/*COL5A2* mutation. Our data show that >90% of patients fulfilling all classic EDS Villefranche criteria harbour a type V collagen defect. Biochemical and molecular analysis in the mutation-negative patients from group 1 and 2 excluded the involvement of other fibrillar collagens and *TNXB*, which implies that type V collagen is the major, if not the only, protein involved in classic EDS.

P12.049

TRPV4 mutations in a selected CMT2 Norwegian patient cohort

***T. Fagerheim**, R. Glad, K. Abeler, J. Tajsic, N. Kuklina, C. Wahl;*
University Hospital of North Norway, Tromsoe, Norway.

Mutations in the ankyrin domain of the TRPV4 (Transient receptor potential vanilloid) protein have been shown in patients with congenital distal spinal muscular atrophy (SMA), scapuloperoneal SMA and Charcot-Marie-Tooth (CMT) 2C. We aimed at identifying *TRPV4* mutations by sequencing exon 5 and 6 of the gene in a cohort of Norwegian patients with clinical and electrophysical findings suspicious of CMT type 2. We identified twenty two patients who were previously tested normal for the common CMT2 genes (*GJB1*, *MFN2*, *MPZ*, *GDAP1* and *NEFL*), and identified two patients heterozygous for the mutations p.Arg315Trp and p.Arg316Cys in the *TRPV4* gene. This suggests that *TRPV4* mutations might represent a relatively common cause of CMT2 in the Norwegian population and testing of the *TRPV4* gene should be considered where genetic testing of the common genes is inconclusive.

The patient harbouring the sequence variant c.946C>T (p.Arg316Cys) was referred at age 6 with clinical symptoms of muscular dystrophy. Investigation including FSHD genetic testing and muscle biopsy was inconclusive. On re-evaluation at age 13, electromyography, clinical and radiological investigations raised suspicion of scapuloperoneal SMA. Further genetic testing was negative regarding SMA and CMT2. He has a younger brother that also reports some overlapping clinical symptoms. A clinical re-examination and segregation analysis of the family will be presented and compared with patients previously reported with this *TRPV4* mutation.

P12.050

Cockayne Syndrome testing at BGL- a new service and case study

***M. Greenslade**[1], L. Yarram[1], P. Lunt[2], A. Lehmann[3], H. Fawcett[3], M. Williams[1];*
[1]Bristol Genetics Laboratory, Bristol, United Kingdom, [2]St. Michael's Hospital, Bristol, United Kingdom, [3]Genome Damage and Stability Centre, Brighton, United Kingdom.

Cockayne Syndrome (CS) is a recessive multisystem disorder characterised by early onset microcephaly, mental retardation, cachectic growth failure, photosensitivity and progressive neurological deterioration usually leading to death in childhood or early adulthood.

CS is associated with mutations in *ERCC6* (OMIM:609413) and *ERCC8* (OMIM:216400). 75% of CS mutations are in *ERCC6* and 25% in *ERCC8*. The proteins encoded by *ERCC6* and *ERCC8* both play important roles in transcription-coupled nucleotide excision repair.

We present an urgent prenatal case of a mother presenting at 10+ weeks, her 17 month old son having a definite clinical diagnosis of CS but no molecular or cellular confirmation. Time pressures precluded obtaining a molecular test result in European service/research laboratories, and cellular UV sensitivity studies requiring cultured skin biopsy typically taking 6-8 weeks. Sanger sequencing assays for *ERCC6* and *ERCC8* were designed and validated in ten working days and the proband identified as homozygous for an *ERCC6* pathogenic variant c.3052dupA. This facilitated prenatal testing by sequence analysis with results available in three days, confirmed by UV-test 5-6 weeks later.

Rapid reporting of sequencing assays recommends DNA testing as the first line approach in suspected CS cases meeting clinical criteria, complemented by the cellular UV sensitivity studies when variants of unknown significance (VUS) are detected. DNA testing avoids an invasive skin biopsy, and may reduce the number of additional tests undertaken upstream e.g. microarray CGH.

An accredited diagnostic genetics service for CS is now available for the UK and Europe, we present an audit of referrals to date.

P12.051

Mutations in Swi/SNF chromatin remodeling complex gene ARID1B cause Coffin-Siris syndrome

***G. W. E. Santen**[1], E. Aten[1], Y. Sun[1], R. Almomani[1], C. Gilissen[2], M. Nielsen[1], S. G. Kant[1], Y. Hilhorst-Hofstee[1], N. S. den Hollander[1], M. W. Wessels[3], M. van Belzen[1], C. A. L. Ruivenkamp[1], G. B. van Ommen[1], M. H. Breuning[1], J. T. den Dunnen[1], A. van Haeringen[1], M. Kriek[1];*
[1]Leiden University Medical Center, Leiden, Netherlands, [2]Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, [3]Erasmus Medical Center, Rotterdam, Netherlands.

Coffin-Siris syndrome (CSS) is characterized by intellectual disability, speech impairment, coarse facial features, hypoplasia of the fifth digits and/or fingernails and callosal agenesis. Since several sibships with CSS have been described autosomal recessive inheritance was considered a likely possibility. We selected three unrelated patients with CSS and the parents of one patient for exome sequencing. Filtering using public databases rendered recessive inheritance unlikely, as there was no gene with two heterozygous or one homozygous variant in all three patients. Focusing on autosomal dominant inheritance instead, only one gene with a variant in all three patients remained after filtering inherited and homozygous variants. Three truncating mutations in *ARID1B* were identified which were confirmed and shown to be *de novo* by Sanger sequencing. Array-based CNV analysis in 2000 patients with intellectual disability revealed deletions encompassing *ARID1B* in three patients with partially overlapping phenotypes. They share facial features, intellectual disability and severe speech delay with the CSS patients. Interestingly, they lack the typical CSS abnormalities and CSS was considered in only one if these patients as a diagnosis. Several patients with *ARID1B* haploinsufficiency have been described in literature with a very similar phenotype and often with agenesis of the corpus callosum. Therefore we conclude that haploinsufficiency of *ARID1B*, which encodes a (epigenetic) modifier of chromatin structure, emerges as an important cause of CSS and a potential common cause of intellectual disability and speech impairment. By screening additional groups of patients for *ARID1B* we have identified several new mutations.

P12.052

Genetic abnormalities in Coffin-Siris syndrome

N. Matsumoto*;*
Yokohama City University, Yokohama, Japan.

Coffin-Siris syndrome (CSS; MIM 135900) is a rare congenital anomaly syndrome characterized by growth deficiency, intellectual disability, microcephaly, coarse facial features and hypoplastic nail of the fifth finger and/or toe. The majority of patients are sporadic, being compatible with autosomal dominant inheritance. The genetic cause has not been elucidated.

To reveal the genetic basis of CSS, we performed whole exome sequencing of five typical subjects. Based on our scheme assuming that an abnormality of a particular gene would be shared in two or more patients, 51 variants remained as candidates. All the variants were checked by Sanger sequencing of PCR products amplified using genomic DNA from the five patients and their parents. Nine were false-positives (errors), 40 were inherited from either the father or mother, and two *de novo* heterozygous mutations were found in two patients.

Using this information, we carefully analyzed 23 CSS patients and found that at least 20 of them are genetically explained. Detailed information will be presented.

The following doctors are highly appreciated: Tsurusaki Y, Okamoto N, Ohashi H, Kosho T, Imai Y, Hibi-Ko Y, Kaname T, Naritomi K, Kawame H, Wakui K, Fukushima Y, Homma T, Kato M, Hiraki Y, Yamagata T, Yano S, Mizuno S, Sakazume S, Ishii T, Nagai T, Shiina M, Ogata T, Ohta T, Niikawa N, Miyatake S, Okada I, Mizuguchi T, Doi H, Saitsu H, Miyake N.

P12.053

A novel COL1A1 mutation in a family with infantile cortical hyperostosis (ICH, Caffey disease, OMIM#114000)

A. Baumer[1]*, H. Auricchio*[2]*, D. Bartholdi*[1]*, A. Rauch*[1]*;*
[1]*Institute of Medical Genetics, Schwerzenbach, Switzerland,* [2]*Ospedale Civico, Lugano, Switzerland.*

Infantile cortical hyperostosis is a rare autosomal dominant disorder characterized by subperiosteal hyperosteogenesis manifesting in the prenatal period or in early infancy. It often affects the mandible, the clavicles, the ribs and the long bones. Typical clinical symptoms include painful swelling of the bones and fever. ICH is a self limiting disease which usually resolves spontaneously by 2 years of age.

A single mutation in the COL1A1 gene has been reported to date in ICH patients of different ethnic origins, namely the missense mutation p.Arg836Cys. The mutation was shown to lead to abnormal disulfide bonds and abnormal structures of the alpha 1 chain dimers.(1)

COL1A1 gene mutations, detected throughout the gene, are responsible for further connective tissue disorders such as: osteogenesis imperfecta and Ehlers-Danlos syndrome type III. Typical for these disorders is fragility of the bones and laxity of the skin/connective tissue, respectively.

We report here on the molecular findings obtained for a young girl with typical clinical manifestation of ICH. After having excluded the presence of the COL1A1 mutation p.Arg836Cys we sequenced all coding exons of the gene. The sequencing analysis revealed a heterozygous mutation, p.Arg918Cys, in the patient and her father, who also had typical features of the disorder. The mutation was not present in the patient's mother and 200 control alleles.

We suggest that ICH may not only be caused by the recurrent p.Arg836Cys mutation, but also by the novel p.Arg918Cys mutation.

A Loss of Function Mutation in the COL9A3 Gene Cause Autosomal Recessive Stickler Syndrome

F. Faletra[1]*, I. Bruno*[1]*, A. P. D'Adamo*[2]*, E. Athanasakis*[1]*, S. Biskup*[3]*, L. Esposito*[4]*, P. Gasparini*[2]*;*
[1]*Institute for Maternal and Child Health - IRCCS "Burlo Garofolo", Trieste, Italy,* [2]*Institute for Maternal and Child Health - IRCCS "Burlo Garofolo" – Trieste, University of Trieste, Italy, Trieste, Italy,* [3]*CeGaT GmbH, Tübingen, Germany,* [4]*CBM S.c.r.l. Area Science Park - Basovizza, Trieste, Italy.*

Stickler syndrome is a clinically variable and genetically heterogeneous syndrome characterized by ophthalmic, articular, orofacial, and auditory manifestations. Until now, it has been described with both autosomal dominant and recessive inheritance. The dominant form is caused by mutations in COL2A1 (STL 1, MIM 108300) , COLA11A1 (STL 2, MIM 604841), and COL11A2 (STL 3, MIM 184840) genes, while recessive forms have been associated with mutations of COL9A1 (MIM 120210) and COL9A2 (MIM 120260) genes. Here, we describe the first autosomal recessive Stickler family due to loss of function mutations (c.1176_1198del, p.P392fsX25) of COL9A3 gene. This findings further extend the role of collagen genes family in the pathogenesis of the disease.

P12.055

Consanguinity as a means to identify pathogenic recessive mutations

Consanguinity and inbreeding increase the sharing of alleles among individuals. We have initiated a project to collect samples from families with recessive phenotypes in consanguineous families, in order to identify the functional genomic variation responsible for the disease. Any phenotype and family history compatible with autosomal recessive inheritance (and unknown molecular defect) is candidate for participation in the study. Forty two families of different ethnic background have already been collected. From each family, blood DNA from the patient(s), all unaffected siblings, and the parents is extracted. Samples from one or more of the affected individuals per family are first analyzed by array-CGH 400K for the detection of homozygous deletions. Then the samples of all family members are genotyped with a dense SNP array in order to identify Runs of Homozygosity (ROH), allowing the definition of chromosomal regions likely to contain the responsible genes. Finally exome sequencing is performed in one affected individual per family. Variants are called using publically available tools and filtered according to polymorphic SNVs deposited in public databases and predicted pathogenicity. We have so far analyzed twelve families using this approach. Causative variations of known disease genes have been identified in two families (VLDLR gene, causing disequilibrium syndrome and FKTN gene causing Fukuyama muscular dystrophy). In 5 additional families candidate genes have been identified. Consanguineous families provide an opportunity to identify pathogenic variants in known genes as well as candidate genes responsible for recessive phenotypes and rapidly fill in the space of genotype phenotype links.

P12.056

Molecular analysis of *TSC2/PKD1* contiguous gene deletion syndrome

J. Nevado[1,2]*, R. Peces*[3]*, M. Palomares*[1,2]*, E. Vallespin*[1,2]*, C. Peces*[4]*, E. Cuesta-Lopez*[3]*, P. Gonzalez*[3]*, M. Picazo*[3]*, C. Vega-Cabrera*[3]*, R. Selgas*[3]*, P. Lapunzina*[1,2]*;*
[1]*INGEMM- IDIPAZ (HULP), Madrid, Spain,* [2]*CIBERER, Madrid, Spain,* [3]*IDIPAZ (HULP), Madrid, Spain,* [4]*Area de Tecnologia de la Informacion (SESCAM), Toledo, Spain.*

The *TSC2/PKD1* contiguous gene syndrome (PKDTS, MIM#600273) results in disruption of both the *TSC2* and *PKD1* genes. PKDTS is characterized by severe juvenile polycystic disease, combined with variable phenotypic expression of tuberous sclerosis (TSC2). This extensive renal damage by cysts usually results in end-stage renal disease (ESRD), often before the second decade of life. Currently, the mechanism for PKDTS is nearly unknown.

Previous findings suggest that PKDTS damage is associated exclusively with the severity of kidney symptoms, and not with the severity of other ones, such as TSC, liver cysts, and intracranial aneurysms. To our best knowledge, no whole studies including; clinical, renal imaging studies, nor histopathological and neither molecular biological analysis with new technologies (such as MLPA and aCGH), have been performed on the *TSC2/PKD1* contiguous gene syndrome patients.

The main aim of this work is to examine the genotype-phenotype correlations in this disease including previously reported patients with clarified breakpoints of the large deletions. To end this, we report herein 7 new patients with the *TSC2/PKD1* contiguous gene syndrome deletions in different extent, by means of MLPA and a custom design aCGH within 16p13.3 locus. The extent of the deletion concerning *TSC2* and *PKD1* genes, and the nature of the deleterious event are determined and discussed concerning clinical consequences and pathogenic molecular mechanisms.

P12.057
Familial recurrence and modifier genes in CDLS families with NIPBL mutations.

S. Russo[1], *M. Masciadri*[1], *C. Piccinelli*[1], *A. Ficcadenti*[2], *P. Finelli*[1,3], *L. Larizza*[1,3];
[1]*Istituto Auxologico Italiano, Milano, Italy,* [2]*Clinica Pediatrica dell'Ospedale Salesi, Ancona, Italy,* [3]*University of Milano, Milano, Italy.*

Cornelia de Lange syndrome (CdLS; OMIM #122470) is a rare multisystem disease characterized by mental and growth retardation, typical facies, and limb reduction. Mutations in three genes encoding a regulator (NIPBL) and two structural subunits of the multifunctional cohesin complex (SMC1A and SMC3) , account for up to 60% of CdLS cases, with >50% due to NIPBL. Although germinal mosaicism has been reported, inherited NIPBL mutation have been rarely described.

We report on two familial cases out of a cohort of 90 NIPBL-mutated patients. In the first family, a mother with a very mild facial phenotype and her two CdLS sibs were carriers of c.5329-15A/G splicing mutation, leading to c.5328[TGTTTGCTTGGCAG]5329ins transcript that predicts the truncated p.Ile1777Cys fs22X protein. In the second family the p.Leu1238Phe change was transmitted by the mother, with a psychiatric phenotype, to the CdLS proband and to her brother affected with learning disability. The variant has not been found in either 800 control chromosomes or LOVD . Array-CGH has been performed to investigate whether CNVs acting as modifier factors could modulate the intrafamilial phenotypic variability.

A duplication containing the entire PIAS3 gene and a *de novo* duplication exiting in the whole duplication of RPAI1 gene were detected in the two sibs of the first family and the CdLS proband of the second family both involved in genomic stability.

Quantitative real-time-PCR is in progress These data, suggest a putative concurrent effect of rare CNVs and NIPBL mutation in the CdLS expression of clinical signs.

P12.058
Differential allelic expression of SMC1A gene in Cornelia de Lange female patients

C. Gervasini[1], *I. Parenti*[1], *J. Azzollini*[1], *C. Picinelli*[2], *M. Masciadri*[3], *A. Cereda*[4], *P. Finelli*[5,2], *S. Sirchia*[1], *L. Garavelli*[6], *S. Russo*[2], *A. Selicorni*[4], *L. Larizza*[1];
[1]*Medical Genetics University of Milan, Milano, Italy,* [2]*Istituto Auxologico Italiano, Cusano Milanino, Milano, Italy,* [3]*Istituo Auxologico Italiano, Cusano Milanino, Milano, Italy,* [4]*MBBM Foundation, San Gerardo Hospital, Monza, Italy,* [5]*Biology and Genetics for Medical Sciences, Milano, Italy,* [6]*Clinical Genetics, Santa Maria Nuova Hospital, Reggio Emilia, Italy.*

Cornelia de Lange syndrome (CdLS OMIM #122470, #300590, #610759) is a rare multisystem disorder characterized by facial dysmorphisms, upper limb abnormalities, growth and cognitive retardation. Mutations of NIPBL (5p13.2) and SMC1A (Xp11.22) genes, encoding a regulator and a structural subunit of the cohesin complex, account for about 60% and 6% of CdLS cases. The SMC1A gene escapes X chromosome inactivation, although uncompletely, with a variable expression of the allele located on the inactive X. This finding may contribute to the clinical variability of SMC1A-mutated female patients.

Four female patients carriers of different mutations of SMC1A gene and 8 controls have been tested by Pyrosequencing to assess the reciprocal level of allelic expression, discriminated by the heterozygous mutation in the patients and heterozygous coding SNP rs1264011 in the controls.

The analysis of the two alleles showed a 53/47 ratio in the controls group and a 67/33 ratio favouring the wild type allele in the patients. In particular the patient with the highest wild type expression (73/27=wt/mut) presents a borderline phenotype with mild dysmorphisms and cognitive deficits, at difference of the other patients (65/35=wt/mut) showing a moderate to severe clinical phenotype.

According to the proposed dominant negative mechanism of mutated SMC1A protein in females CdLS patients, the preferential, but variable expression of the wild type allele may influence the clinical phenotype. The overall findings, expanded to further cases and corroborated by quantitative expression data, enhance our understanding of the variable clinical spectrum of X-linked CdLS and highlight the occurrence of overlooked cases.

P12.060
Expanding the mutational spectrum of CRLF1 in Crisponi Syndrome.

R. Piras[1,2], *F. Chiappe*[1], *M. Pitzalis*[1,3], *G. Crisponi*[4], *F. Benedicenti*[5], *B. Kamien*[6], *M. Ali Akin*[7], *F. Tuba Eminoglu*[8], *N. Uzunalic*[8], *O. Assy*[9], *P. Lapunzina*[10], *F. Cucca*[1,3], *F. Rutsch*[11], *L. Crisponi*[1];
[1]*Istituto di Ricerca Genetica e Biomedica, Consiglio Nazionale delle Ricerche, Cagliari, Italy,* [2]*Dipartimento di Scienze Biomediche e Biotecnologie, Università degli Studi di Cagliari, Cagliari, Italy,* [3]*Dipartimento di Scienze Biomediche, Università degli studi di Sassari, Sassari, Italy,* [4]*Casa di Cura Sant'Anna, Cagliari, Italy,* [5]*Genetic Counseling Service, Department of Pediatrics, Regional Hospital of Bolzano, Bolzano, Italy,* [6]*Queensland Health Pathology, Royal Brisbane Hospital, Herston, Australia,* [7]*Erciyes University, Medical Faculty, Department of Pediatrics, Kayseri, Turkey,* [8]*Sami Ulus Maternity and Children Training Hospital, Ankara, Turkey,* [9]*Al Hada Military Hospital, Taif, Saudi Arabia,* [10]*INGEMM, Hospital Universitario La Paz, Madrid, Spain,* [11]*Department of General Pediatrics, Münster University Children's Hospital, Münster, Germany.*

Crisponi syndrome (CS) and cold-induced sweating syndrome type 1 (CISS1) represent manifestations of the same autosomal recessive disorder with different degrees of severity, caused by mutations in CRLF1. The two syndromes share clinical characteristics, such as dysmorphic features, muscle contractions, scoliosis and cold-induced sweating, with CS patients showing a severe clinical course in infancy involving hyperthermia, associated with death in most cases in the first years of life. We suggested recently to rename the two genetic entities with the broader term of Sohar-Crisponi syndrome. We expanded the mutational spectrum of CRLF1 in the syndrome and carried out a meta-analysis of the literature for all the mutations described so far. In conclusion we found 9 new mutations in addition to the 29 already described. The higher prevalence is registered in Sardinia, Turkey and Spain. In Sardinia, where the syndrome seems to be more common than in the rest of Italy, due to 2 founder mutations, we performed a pilot screening to evaluate the carrier frequency. In details we found 16 carriers on 1,100 Sardinian control individuals from 4 different provinces, with an estimated prevalence of 1:20,000. A more detailed analysis (detection of heterozygous CRLF1 deletions by Quantitative Real Time PCR, CLCF1 and CNTFRα testing, exome sequencing) is ongoing to find the genetic cause in those patients with a clinical phenotype suggestive of Sohar-Crisponi syndrome, but with no evident mutations in CRLF1. This will help in better understanding the pathogenesis of the disease and the molecular pathways involved in the phenotype.

Further molecular characterization of PYCR1-related cutis laxa

B. Fischer[1], *T. Gardeitchik*[2], *A. Dimopoulou*[1], *D. Kouwenberg*[2], *S. Sprenger*[1], *C. Schlack*[1], *B. Fauler*[3], *S. Mundlos*[1,3], *L. Nijtmans*[2], *H. Kayserili*[4], *B. Wollnik*[5], *E. Morava*[2], **U. Kornak**[1];
[1]*Institut fuer Medizinische Genetik und Humangenetik, Berlin, Germany,* [2]*Radboud University Nijmegen Medical Center, Nijmegen, Netherlands,* [3]*Max Planck Institute for Molecular Genetics, Berlin, Germany,* [4]*Istanbul Medical Faculty, Istanbul University, Istanbul, Turkey,* [5]*University Medical Faculty, University of Cologne, Cologne, Germany.*

Autosomal recessive cutis laxa (ARCL) sydromes are a group of overlapping disorders with progeroid features, but without lung and vascular involvement (ARCL type 2). In a cohort of patients initially as characterised as wrinkly skin syndrome, gerodermia osteodysplastica or De Barsy syndrome we identified mutations in the PYCR1 gene encoding pyrroline-5-carboxylate reductase 1. PYCR1-related ARCL (ARCL2B; OMIM #612940) is the second most frequent form of ARCL. We give an update on the clinical variability and report novel disease-causing mutations.

The PYCR1 protein is part of the proline-cycle, a conserved pathway described to generate NAD(P)+ in the cytoplasm via synthesis of proline. PYCR1-deficient fibroblasts from ARCL2B patients show decreased mitochondrial membrane potential, a disrupted mitochondrial network, and an increased apoptosis rate upon different kinds of stress. A detailed analysis of the subcellular distribution revealed an exclusive mitochondrial localization of PYCR1. After RNAi-induced loss of PYCR1 in HeLa cells we reproduced the fragmentation of the mitochondrial network and a decreased membrane potential. In addition, alterations of ATP and lactate levels imply mitochondrial dysfunction.

Thus, we conclude a role of PYCR1 in the regulation of the mitochondrial redox state, which influences mitochondrial fusion and possibly also metabolic activity. This combination of defects is likely to be a key event in the pathogenesis of ARCL2B and qualifies ARCL2B as a mitochondrial disorder.

P12.063
Clinical Genetic Analysis of Cystic Fibrosis in Republic of Moldova

N. I. Barbova, *V. V. Egorov*;
State Center of Reproductive Health and Medical Genetics, Chisinau, Republic of Moldova.

Determining the frequency of CFTR mutations which are specific for individual population having a scientific interest.

During the period from 1992 to present we investigated 147 Moldavian patients with CF aged from 1 month to 24 years (70 male and 77 female). We carried out comparison of phenotypic features in CF with type of CFTR mutation. The national distribution of patients was following: Moldavians - 66,2%, Russians - 14,6%, Ukrainians - 7 %, Gagauz - 6,2 %, Bulgarians - 2,3 %, and another nationalities - 3,7%.

To determine 9 mutations (F508del, G542X, N1303K, W1282X, R117H,

G551S, R347P, R334W, R553X) in CFTR gene we are used the method of PCR, in 15 patients was administered DNA diagnosis for 35 - 36 mutations jointly with professionals from Center of Cystic Fibrosis, Bordeaux, France, and Department of Genetics of University Clinic in Hannover, Germany.
CFTR-mutations were identified in 69,72 % investigated chromosomes, were determined 17 mutations. The mutation which have clinical importance in Moldova (> 1%) were: F508del- 58,84%, 2789+5G>A - 1,70 %, G542X - 1,36 % , N1303K- 1,36 %, 2184insA- 1,36 %. All of them are „severe" and are associated with pancreatic insufficiency. The frequencies of other mutations were < 1%. 16 mutations (excluding F508del) were determined in 10,88% studied chromosomes. For patients with non-identified mutations (30,28%) is characteristic high level of pulmonary pathologies (70,0%).
Therefore, the present study discovered fact what in Moldavian patients prevailed rare mutations, and severity of CF correlates with type of mutations in CFTR gene.

P12.064

Whole-exome sequencing identifies a novel nonsense mutation in the TTN gene in a large Dutch family with DCM

R. J. Sinke[1], *J. Zhang*[2], *R. Almomani*[1], *A. Pósafalvi*[1], *K. Y. van Spaendonck-Zwarts*[1], *M. P. van den Berg*[3], *B. Sikkema-Raddatz*[1], *P. van Tintelen*[1], *J. Wang*[2,4], *J. D. Jongbloed*[1];
[1]Department of Genetics, University Medical Centre Groningen, University of Groningen, Groningen, Netherlands, [2]BGI-Shenzhen, Shenzhen, China, [3]Department of Cardiology, University Medical Centre Groningen, University of Groningen, Groningen, Netherlands, [4]Department of Biology, University of Copenhagen, Copenhagen, Denmark.

Dilated cardiomyopathy (DCM) is an etiologically highly heterogeneous disorder, characterized by left ventricular dilation and dysfunction, leading to heart failure and sudden death. Approximately 20-50% of dilated cardiomyopathy cases are familial with significant genetic and phenotypic heterogeneity. In a multigenerational Dutch family with autosomal dominant transmission, we employed whole-exome sequencing in three affected family members. Using the GATK pipeline for whole exome data analysis, we identified between 1431 and1557 novel exonic/splice site variants per individual. Subsequent filtering steps, included filtering for dominant inheritance (heterozygous variants) and for coding regions, revealed a novel shared nonsense variant in the Titin gene (TTN) in all three affected patients. The respective substitution c.59845C>T predicts a premature stop codon (p.Arg19949X) at the protein level, leading to a truncated titin protein. The mutation was confirmed by Sanger sequencing and was shown to co-segregate with disease in all DCM patients in this family. Our results show that mutations in the gene encoding giant muscle filament titin (TTN) can cause DCM and may account for a significant portion of the genetic etiology in familial DCM in the Dutch population.

P12.066

Etiological study of hearing loss: clinical practice guidelines in Brazilian patients

E. L. Sartorato, *P. Z. Ramos, V. C. S. de Moraes, M. C. Svidnicki, A. M. Castilho;*
Universidade Estadual de Campinas, Campinas - SP, Brazil.

Deafness is considered the most prevalent sensory disorder in humans. In Brazil, there are no official data regarding the prevalence and etiology of hearing impairment, but it is known that environmental factors are among the major causes. Although a simultaneous testing approach, including clinical exams, audiological, laboratorial, imaging and genetic expands the etiological diagnostic, overloads the healthcare system due to high costs. Thus, the goal of the present study is to evaluate the effectiveness of imaging and genetics tests and their impact on public health, aiming to increase efficiency and reduce costs of the etiological diagnostic of hearing loss. It was conducted an analysis of 100 patients with sensorineural hearing loss. A detailed investigation was performed in patients, including imaging and genetics analysis. The number of individuals with unknown cause was reduced from 72 to 42 (42% of reduction). Radiologic abnormalities were identified in 29 of the patients, while molecular alterations were found in 31 individuals. The etiology remained unknown in 42% of the patients, was due to environmental factors in 25%, genetics in 19% and inner ear malformations or other defects in 14% of the cases. It was concluded that both imaging and genetic analysis were important to identify the etiology of hearing loss, however, molecular tests contributed mainly for diagnosis of patients with congenital deafness, while radiologic exams had greater contribution for diagnosis of cases with progressive or abrupt hearing loss. The sequential protocol enables an optimization of the etiological diagnosis and cost reduction.

P12.067

Novel GJB2 mutations in Greek patients with sensorineural, non-syndromic deafness

H. Kokotas[1], *M. Grigoriadou*[1], *M. Koutroumpe*[2], *J. Economides*[3], *M. B. Petersen*[1];
[1]Department of Genetics, Institute of Child Health, 'Aghia Sophia' Children's Hospital, Athens, Greece, [2]Department of Pediatrics, 'Aglaia Kyriakou' Children's Hospital, Athens, Greece, [3]Department of Audiology-Neurootology, 'Aghia Sophia' Children's Hospital, Athens, Greece.

Non-syndromic hearing loss is one of the most common hereditary diseases in human, and the disease is a genetically heterogeneous disorder. Connexins (Cxs) are membrane-spanning proteins that co-assemble into intercellular gap junction channels. Gap junction channels mediate electrical and biochemical communication between adjacent cells and play vital roles as mediators of intercellular molecular signaling. Cx-linked deafness highlights the key role of gap junctions in the physiological processes of hearing. Co-localization of Cxs with the gap junction system in the inner ear suggests a role in cochlear electrolyte homeostasis. During auditory transduction, they are proposed to maintain membrane potentials by regulating the flow of potassium ions between the sensory epithelia of the inner ear. Mutations in the GJB2 gene, encoding connexin 26 (Cx26), are a major cause of non-syndromic recessive hearing impairment in many countries and are largely dependent on ethnic groups. Here we describe the clinical and molecular genetic findings in two Greek families presenting with bilateral, sensorineural, non-syndromic deafness. In the first family with hearing parents we detected compound heterozygosity of the c.35delG and the novel c.292C>T (p.R98W) GJB2 mutations in a proband with postlingual hearing loss while in the second family where both parents and the proband suffered from prelingual deafness, we observed homozygosity of the c.35delG GJB2 mutation in the mother and compound heterozygosity of the c.35delG and the novel c.247-249delTTC (p.delF83) GJB2 mutations in the father and the proband.

P12.068

Mutations in the prostaglandin transporter SLCO2A1 cause primary hypertrophic osteoarthropathy with digital clubbing

J. Busch[1], *V. Frank*[1], *N. Bachmann*[1], *A. Otsuka*[2], *V. Oji*[3], *D. Metze*[4], *K. Shah*[5], *S. Danda*[5], *K. Kabashima*[2], *H. Traupe*[3], *H. J. Bolz*[1,6], *C. Bergmann*[1,7];
[1]Bioscientia Center for Human Genetics, Ingelheim, Germany, [2]Department of Dermatology, Kyoto University, Kyoto, Japan, [3]Department of Dermatology, University Hospital Münster, Münster, Germany, [4]Department of Pathology, University Hospital Münster, Münster, Germany, [5]Clinical Genetics Unit, Christian Medical College, Vellore, India, [6]University of Cologne, Cologne, Germany, [7]RWTH University, Aachen, Germany.

Digital clubbing with enlargement of the distal phalanges and overcurvature of the nails frequently occur secondarily as a feature of chronic hypoxia or neoplastic processes. We and others reported mutations in the 15-hydroxyprostaglandin dehydrogenase (*HPGD*) gene encoding the major prostaglandin PGE_2 catabolizing enzyme in patients with digital clubbing and primary hypertrophic osteoarthropathy (PHO). In this study, we hypothesized that PHO can also be caused by mutations in other components of prostaglandin signalling. Extracellular prostaglandins are taken up by a carrier-mediated process across the plasma membrane. For many prostanoids (e. g. PGE_2) this transport is mediated by SLCO2A1, a type IV transmembrane protein that belongs to the solute carrier organic anion transporter family. We performed sequencing of *SLCO2A1* in seven PHO patients previously found to be negative for mutations in *HPGD* and identified pathogenic mutations in all but one individual. All patients were of normal intelligence and height and did not suffer from pulmonary disease or any other interfering disease. All of our mutations in *SLCO2A1* represent truncating alleles or affect residues that are indispensable for prostaglandin transporter activity. To corroborate our data, we constructed molecular models and Ramachandran plots of wild-type and mutated SLCO2A1 proteins to visualize changes of protein folding and structure. We show that *SLCO2A1* is a frequent cause for autosomal recessive PHO confirming the data recently published by Zhang et al. (2012). Although most patients harbour mutations in *HPGD* and *SLCO2A1*, further genetic heterogeneity is likely and candidate approaches targeting other prostaglandin signalling components seem promising.

P12.069

The frequency of short pathogenic repeat expansions in DM2

W. Kress[1], *G. Meng*[1], *B. Schoser*[2];
[1]Institute of Human Genetics, Würzburg, Germany, [2]Friedrich-Baur-Institut, LMU München, München, Germany.

Myotonic Dystrophy type 2 (DM2), in Germany as frequent as DM1, is normally caused by huge CCTG repeat expansions in intron 1 of the zinc finger protein (ZNF9, CNBP) gene on chromosome 3q21. During the last few years we found some symptomatic patients with small CCTG expansions between the normal upper limit of about 26 CCTGs in the population and a putative old lower limit for pathogenic repeat expansions of 75 CCTGs during our routine diagnostic screening process for DM2. Pictures of a Southern blot and TP-PCR (repeat primed PCR) are given. There is good evidence that these „mini expansions“ are pathogenic: there were ribonucleic foci in the patients' muscle biopsies and alternative splicing events in muscle specific genes. From 2004 till now we detected 19 DM2-patients with such a short pathogenic repeat. This is a portion of roughly 2% of all patients with a long expansion (n=960) in this period; the distribution between male and female patients is nearly equal. The short pathogenic repeat expansions may arrise in most cases from a pool of long normal alleles (as suggested in DM1) by a slippage or unequal crosssing over mechanism; on the other side we could find at least one repeat contraction from an effected mother to an affected daughter (full expansion contracting to a mini expansion). The latter case supports the observation of „pathogenic mini expansions“.

P12.070

Clinical, pathological and genetic characterization of manifesting *DMD* carriers: the role of X-chromosome inactivation

*J. Juan-Mateu[1], L. Gonzalez-Quereda[1], M. Rodriguez[2], E. Verdura[2], L. Alias[2], J. Salazar[2], M. Baiget[2], **P. Gallano**[2];*
[1]Hospital Sant Pau-Ciberer, Barcelona, Spain, [2]HOSPITAL SANT PAU-CIBERER, BARCELONA, Spain.

Mutations in *DMD* gene lead to Duchenne muscular dystrophy (DMD), milder Becker muscular dystrophy (BMD) and rare X-linked dilated cardiomyopathy (XL-DCM). Female carriers are mainly asymptomatic, however between 7,8% and 22% manifests some degree of the disease. Several mechanisms have been implicated to cause symptoms among manifesting carriers. These include X-autosomal translocations disrupting *DMD*, compound heterozygous mutations, co-occurrence of *DMD* mutations together with other genetic abnormalities (X-chromosome monosomy, X-chromosome uniparental disomy and male pseudohermaphroditism) and skewed X-chromosome inactivation. Clinical presentation among manifesting carriers are heterogenic and ranges from myalgia to disabling DMD-like forms.

We identified 22 manifesting carriers, ten of them with no family history of D/BMD affected males. We report findings concerning clinical presentation, muscle dystrophin expression, *DMD* mutation spectrum and X-chromosome inactivation (XCI) pattern in blood and muscle. Clinical pictures included: 1) isolated dilated cardiomyopahty (*n*=2, 9%), 2) isolated mental retardation or behavior issues (*n*=3, 14%), 3) myalgia and/or exercise intolerance (*n*=4, 18%) and, 4) mild to severe muscle weakness (*n*=13, 59%) that ranged from mild BMD-like (*n*=6, 27%) to severe BMD-like (*n*=4, 18%) and DMD-like (*n*=3, 14%).

Twenty-one different *DMD* mutations were identified in heterozygous state including: 12 exonic deletions (57%), 3 exonic duplications (14%) and 6 point mutations (29%). The aim of this study was to explore the potential correlation between the severity of the disease and X-chromosome inactivation. We have compared XCI ratios between manifesting carriers, non manifesting carriers and normal female controls.

P12.071

The LGMD2A prevalence among patients diagnosed as DMD in Russia.

***O. P. Ryzhkova**, N. Komarova, A. Polyakov;*
Research Center for Medical Genetics, Moscow, Russian Federation.

Duchenne muscular dystrophy (DMD) is the commonest and best-known of the muscular dystrophies, but other types of muscular dystrophy (MD) like limb-girdle muscular dystrophy type 2A (LGMD2A) may have a similar clinical presentation. LGMD2A is the most frequent autosomal recessive MD.

The molecular defect in *DMD* gene, accounting for approximately 60% of cases of DMD is deletion of one or more exons. The most common molecular defects in *CAPN3* gene in Russia are two missens mutations c.550delA and c.598_612del.

More than thousand DNA samples (1339) of patients diagnosed as DMD have been analyzed for deletions of exons 3, 4, 6, 8, 13, 17, 19, 32, 42-45, 47, 48, 50-53, 60 in *DMD* gene and in 539 of them (40.25%) have been revealed different deletions in *DMD* gene. 800 patients have no these deletions.

DNA samples of 698 patients without deletions in *DMD* gene have been screened for the most frequent mutations in *CAPN3* gene and these mutations were revealed in 34 of them (4.87%). Genotypes was: c.550delA/c.550delA - 14 patients, c.550delA/N - 15 patients, c.550delA/c.598_612del - 2 patients, c.598_612del/N - 3 patients.

From Hardy-Weinberg equilibrium summary the allelic frequency of this two mutations comprised 64%. Using this data we calculated that there have to be 45 patients with LGMD2A among 800 patients without deletions in *DMD* gene. So we found that the frequency of LGMD2A among patients diagnosed as DMD comprise 3.36%.

P12.072

An unusual form of autosomal recessive early onset nephropathy: mapping to chromosome 4.

***Y. Perez**;*
The Morris Kahn Laboratory of Human Genetics and the Genetics Institute, Soroka Medical Center, Ben-Gurion University, Beer Sheva, Israel.

Early onset nephropathy (age of onset less than one year) with features of tubulo-interstitial nephritis, hypertension and tendency for hyperkalemia was diagnosed in 4 individuals of an Israeli Bedouin kindred. None of the affected individuals had rapid deterioration of renal function. Neurological manifestations commensurate with Cogan-type oculomotor apraxia were evident. Molar tooth sign was not seen on neuro-imaging. Association with any of the previously known 12 loci for nephronophthsis was ruled out. Genome wide linkage analysis identified a disease-associated locus on chromosome 4 between 37143147 and 57096602. No mutations were found in the coding sequence of WDR19 (NPHP13). Whole exome sequencing is underway.

P12.073

Identification of novel causal genes for early-onset Alzheimer disease through whole genome sequencing technology

***R. Cacace**[1,2], K. Bettens[1,2], C. Van Cauwenberghe[1,2], C. M. van Duijn[3], K. Sleegers[1,2], C. Van Broeckhoven[1,2];*
[1]Neurodegenerative Brain Diseases Group, VIB Department of Molecular Genetics, Antwerp, Belgium, [2]Laboratory of Neurogenetics, Institute Born-Bunge, University of Antwerp, Antwerp, Belgium, [3]Genetic Epidemiology Laboratory, Department of Epidemiology & Biostatistics, Erasmus University Medical Center, Rotterdam, Netherlands.

Alzheimer disease (AD) is the most common form of late-onset neurodegenerative dementia, that also occurs at young age in 10% of AD patients. In a small percentage of early-onset AD patients the disease is inherited in an autosomal dominant manner. Mutations in the 3 known causal genes (*APP*, *PSEN1* and *PSEN2*) are not explaining all early-onset AD patients.

A previous genome-wide linkage study on a well-documented early-onset AD family has implicated a novel genetic locus of 5.44 Mb at 7q36. Traditional Sanger sequencing of all coding exons of the genes present in the candidate region and array-based comparative genomic hybridization (aCGH) for CNV analysis both failed to reveal evident disease-linked mutations. Yet, the role of non-coding variations remains to be explored. To continue searching for the underlying genetic defect whole genome sequencing (WGS) was performed on 4 distantly related patients from the pedigree. The GenomeComb software tool has been used for filtering on quality and frequency and for variations prioritization. After this procedure, we obtained 93 variations of which 35 were segregating with the disease. These have been tested in the extended control cohort of Flanders-Belgian origin to exclude (common) polymorphisms. Leaving eventually 4 variations shared by the family patients and absent in controls. The screening of these variations in a larger AD population is ongoing to estimate the contribution of the newly identified variations to AD pathogenesis. Next, we will functionally characterize the newly identified variations to better understand their contribution to AD pathology.

P12.074

A RP1 common founder mutation is a major cause of Early-onset Autosomal Recessive Retinitis Pigmentosa in Spanish population

A. Avila-Fernandez[1]*, M. Corton*[1], K. M. Nishiguchi[2], N. Muñoz-Sanz[3], F. Blanco-Kelly[1], R. Riveiro-Alvarez[1], P. F. San Jose[1], B. Garcia-Sandoval[3], C. Rivolta[2], C. Ayuso[1];*
[1]Genetics Department, IIS- Fundación Jiménez Díaz- CIBERER, Madrid, Spain,
[2]Department of Medical Genetics, University of Lausanne, Lausanne, Switzerland,
[3]Ophthalmology Department, IIS- Fundación Jiménez Díaz- CIBERER, Madrid, Spain.

* Both authors have contributed equally to this work

Background. Retinitis pigmentosa (RP) is a clinically and genetically heterogeneous group of retinal degeneration disorders being one of the major causes of genetic blindness. While the RP1 gene is a major gene responsible for autosomal dominant RP (adRP), it also seems to be a rare cause for the autosomal recessive RP (arRP). However, very few studies for *RP1* have been performed in patients affected with arRP so far.

Methods. Homozygosity mapping or exome sequencing analysis were performed in three families segregating arRP. A mutational screening was performed in 241 additional unrelated families for the p.Ser452Stop mutation. Haplotype analysis was also conducted. Individuals who were homozygous, double heterozygotes or carriers of mutations in RP1, underwent an ophthalmic evaluation to establish a genotype-phenotype correlation.

Results. Four novel mutations in RP1 were identified. The new mutation p.Ser542Stop was present in 11/244 (4.5%) of the studied families. All chromosomes harboring this mutation shared the same haplotype. All

patients presented a common phenotype with an early age of onset and a prompt macular degeneration while the heterozygote carriers did not show any signs of RP.
Conclusions. p.Ser542Stop is a single founder mutation and the most prevalent described mutation in the Spanish population. It causes early-onset RP and is responsible for 4.5% of all cases. Our data suggest that the implication of RP1 in arRP could be underestimated.

P12.075
Molecular screening of KRT14 common mutations in Iranian patients affected with Epidermolysis bullosa

M. Mahdavi[1]*, A. Kakavand hamidi*[1]*, H. Dehghan*[1]*, M. Moghaddam*[1]*, N. Hatamnejadian*[2]*, B. Sedaghati khayyat*[1]*, M. Yousefi*[3]*, P. Tousi*[4]*, A. Ebrahimi*[1]*;*
[1]*Parseh Medical Genetic Counseling Center, tehran, Islamic Republic of Iran,* [2]*Shahid Beheshty University Skin Research Center, tehran, Islamic Republic of Iran,* [3]*Shahid beheshti university skin research center, tehran, Islamic Republic of Iran,* [4]*Shahid Beheshti University Skin Research Center, tehran, Islamic Republic of Iran.*

Epidermolysis bullosa (EB) is a heterogenic skin disorder with three classic clinical forms includes Simplex, dystrophic and Junctional which characterized by blisters that follows minor physical trauma .The Simplex form is more common variation which has four subtypes, caused by mutation in KRT5 or KRT14.Although the Skin Biopsy is the first step in EB Testing strategy, it is needed to confirm and localize the mutation by direct molecular methods.We aimed to evaluate the KRT14 hot spot exons as a rapid, noninvasive and cost benefit panel test for first step screening of common mutations in EB affected patients.Methods: About 80 affected patients clinically diagnosed as EB, were collected and classified clinically so all DNA samples evaluated blind for selected exons of KRT14 by direct Sequencing method. Result: Molecular screening for KRT14 hot spots revealed that about 25% of affected probands show mutation in selected exons. It is confirmed that these exons beside the other selected hot spots include KRT5, COL7A1 as a screening panel could exclude about 40% of EB types.Key words: EB, KRT14, Sequencing, KRT5, COL7A1

P12.076
Identification of novel mutations in the amiloride-sensitive epithelial sodium channel in African patients with cystic fibrosis-like disease

L. Mutesa[1,2]*, C. Verhaeghe*[2]*, J. Vanbellinghen*[2]*, D. Veronique*[2]*, D. Veronique*[2]*, V. Bours*[2]*;*
[1]*National University of Rwanda, Butare, Rwanda,* [2]*University of Liege, Liege, Belgium.*

The defect in chloride and sodium transport in cystic fibrosis (CF) patients is a consequence of CFTR loss of function and/or an abnormal interaction between cystic fibrosis transmembrane conductance regulator (CFTR) and amiloride sensitive epithelial sodium channel (ENaC). Apart from the defective chloride secretion, loss of functional CFTR results in increased sodium absorption through the ENaC channel in CF patients.
We investigated whether mutations in the genes that code for the different subunits of ENaC gene might result in CF-like disease in patients in whom only one CFTR gene is mutated, or that carry no mutations at all in the CFTR coding region and its exon/intron junctions. We extensively performed ENaC genes sequencing in these CF-like patients and established the frequency of identified ENaC mutations in a cohort control.
In total, 66 sequence variants in ENaC genes were found in in 60 CF-like patients.
Several novel ENaC gene mutations were identified and some of them were located in highly conserved domains and consistent with a pathophysiological role. Only three novel mutations including p.V348M and p.W423R in SCNN1B subunit and p.R180W in SCNN1G were observed once in our patients, but not in controls. The preliminary functional studies using expression in Xenopus laevi oocytes showed that the p.V348M is a gain of function mutation with a high amounts (2-30%) functional ENaC activity.
Our data suggest that CF-like syndrome in Africa could be associated with ENaC mutations. The combination of ENaC and CFTR mutations may play a hitherto unrecognized role in lung diseases.

P12.078
Improving molecular diagnosis of epilepsy by applying multiple prediction algorithms

M. C. Gonsales*, P. Preto, M. Montenegro, M. M. Guerreiro, I. Lopes-Cendes;*
University of Campinas, Campinas, Brazil.

Mutations in the voltage-gated sodium channel α1-subunit gene (*SCN1A*) have been associated with the spectrum of generalized epilepsy with febrile seizures plus, which includes severe phenotypes such as Dravet and Doose syndromes. However, the prognostic value of these mutations and a possible correlation with the different clinical subtypes remain unclear. Therefore, the aim of this study was to search for mutations in *SCN1A* in patients with Dravet and Doose syndromes, thus establishing genotype-phenotype correlations using predictive algorithms to determine potentially deleterious mutations.
We performed *SCN1A* mutation screening in 15 patients with Dravet syndrome and 13 with Doose syndrome. Eight algorithms were used to analyze the possible impact of the mutations in protein function. In addition, MLPA was used to detect copy number variations within *SCN1A*.
Twelve mutations were identified in patients with Dravet syndrome. All missense mutations were predicted to be deleterious and are mostly located in the pore region or the C-terminal of the protein. Patients with Doose syndrome showed no mutations. Moreover, no copy number variants were identified.
The high frequency of *SCN1A* mutations found in patients with Dravet syndrome (80%) suggests that molecular testing is particularly useful for individuals with this phenotype. In contrast, *SCN1A* testing does not seem to be clinically relevant in Doose syndrome. Our strategy for predicting deleterious effect of mutations using multiple prediction algorithms provided valuable information, helping clinicians with decision making. Furthermore, our results indicate that missense mutations can cause severe phenotypes depending on its location and the type of amino-acid substitution.

P12.079
Mutations in *PRRT2* cause familial and sporadic cases of Benign Infantile Epilepsy

L. M. Dibbens*;*
University of South Australia, School of Pharmacy and Medical Sciences, Adelaide, Australia.

Objective: Benign familial infantile epilepsy (BFIE) is an autosomal dominant seizure disorder that occurs in infancy. Seizures begin around 6 months of age and cease by 2 years. In some cases a movement disorder, paroxysmal kinesigenic choreoathetosis (PKC), follows in childhood or adolescence: this combined disorder is known as infantile convulsions and paroxysmal choreoathetosis (ICCA) syndrome. We have recently shown that the familial disorders BFIE, PKC and ICCA are allelic, caused by mutations in *PRRT2*. We sought to determine if *de novo PRRT2* mutations cause sporadic benign infantile epilepsy and whether the phenotypic spectrum of *PRRT2* was broader than initially recognized.
Methods: 44 probands with infantile-onset seizures, infantile convulsions with mild gastroenteritis and benign neonatal seizures underwent phenotyping and *PRRT2* sequencing. The segregation of mutations identified in probands was studied.
Results: The recurrent *PRRT2* mutation c.649-650insC (p.R217fsX224) was identified in 11 probands. Nine probands had a family history consistent with BFIE or ICCA. Two probands without a family history of seizures or PKC had *de novo PRRT2* mutations. Febrile seizures with or without afebrile seizures were observed in two families with *PRRT2* mutations.
Conclusions: Mutations in *PRRT2* are an important cause of seizures seen in infancy. Mutations can be either familial or *de novo*. *PRRT2* mutations are present in >80% of BFIE and >90% ICCA families, but are not a common cause of other forms of infantile epilepsy. Seizures with fever may occur in BFIE such that it may be difficult to distinguish BFIE from febrile seizures in small families.

P12.080
NGS in molecular diagnostics of epilepsies.

L. Minichová[1]*, E. Decker*[2]*, M. Hikkelová*[1]*, H. Gabriel*[2]*, M. Genčík*[2]*;*
[1]*MedGene, Bratislava, Slovakia,* [2]*diagenos, Osnabrück, Germany.*

The molecular genetic diagnosis of epilepsy particularly in children is essential for precise diagnosis, prognosis and has significant implications for the therapeutic strategy. Until now mutation screening was performed by DGGE, Sanger sequencing and MLPA technique.
Here we report on a new mutation screening protocol for Dravet syndrome & GEFS+ associated genes based on Next-Generation Sequencing (NGS) using the Roche 454J platform. Our current testing panel includes mutation analysis of genes *SCN1A, SCN1B, GABRG2, GABRD* and *PCDH19*.
So far, 22% of the patients suspected for Dravet syndrome / GEFS+ harboured a mutation in the *SCN1A* gene, one patient had a mutation in the *GABRD* gene. The spectrum of identified mutations included small deletions, insertions, indel mutations, truncating and missense mutations, mostly located in the pore and voltage sensitive region of the *SCN1A* protein. We have also detected a deletion of the whole *SCN1A* gene as well as a large duplication by MLPA. Interestingly, in two patients with a severe clinical manifestation a homozygous and two compound heterozygous mutations were identified, respectively.

Genetic diagnostics based on the NGS platform enables the analysis of multiple disease-related genes in parallel, to reduce TAT and the cost of the test as well and therefore outperforms the conventional Sanger sequencing.

P12.081

Mutations of the PCDH19 Gene in 26 Female Patients with Epilepsy

M. Gagliardi[1,2], *M. Sesta*[3], *P. Tarantino*[1], *F. Cavalcanti*[1], *G. Tortorella*[4], *A. Labate*[5], *T. Mirante*[1], *A. Bagala*[1], *A. Quattrone*[5], *A. Gambardella*[1], *G. Annesi*[1];
[1]Institute of Neurological Sciences,National Research Council, Mangone (CS), Italy, [2]University Magna Graecia, Catanzaro, Italy, [3]Departement of Neurosciences, Psychiatry and Anaesthesiolog Department of Neurology, Pediatric Hospital, Bari, Italy, [4]Departement of Neurosciences, Psychiatry and Anaesthesiology University of Messina, Messina, Italy, [5]Institute of Neurology, University Magna Graecia, Catanzaro and Neuroimaging Research Unit, National Research Council, Germaneto (CZ), Italy.

Dravet syndrome (DS), or severe myoclonic epilepsy of infancy (SMEI) is a genetically determined encephalopathy mainly caused by de novo mutations in the SCN1A gene. Recently, Depienne et al identified mutations in the gene encoding protocadherin-19 (PCDH19) in 11 females with epileptic encephalophathy of infancy who were negative for mutations in the SCN1A gene. The PCDH19 gene links to Xq22.1 and this gene contains 6 exons, of which the first is unusually large.

We studied 26 female patients from southern Italy with SMEI that were negative for mutations in SCN1A to investigate the frequency of PCDH19 mutations in our population.

The clinical features of patients are seizures onset before 12 months of age, mild to severe mental retardation with poor language development ,and ataxia. Genomic DNA from the patients was analysed by direct sequencing of the PCDH19 gene on an ABI 3130XL Avant automated sequencer.

In this study, we identified three different heterozygous novel mutations of PCDH19 gene in 26 patients with SMEI (11,5%). The c.1522_1528del/p.Ile508ProfsX59 novel mutation was identified in an isolated female patient. The second novel mutation identified is c.1649G>C/ p.Arg550Pro; the third novel mutation identified is c. 2568C>T/p.Ser856Cys.

The results of this study indicate that PCDH19 mutatinon is a relatively frequent cause of epilepsy in Southern Italy. This frequency (11,5%) is comparable to that reported in previous studies.

In conclusion molecular testing of PCDH19 should be considered in females with early-onset FS and/or epilepsy with or without cognitive impairment and family history.

P12.082

Targeted Next Generation Sequencing as Diagnostic Tool in Epileptic Disorders

J. Lemke[1], *E. Riesch*[2], *T. Dorn*[3], *Y. Weber*[4], *H. Lerche*[4], *D. Böhm*[2], *S. Biskup*[2];
[1]Division of Human Genetics, University Children's Hospital, Inselspital, Bern, Switzerland, [2]CeGaT GmbH, Tübingen, Germany, [3]Swiss Epilepsy Center, Zürich, Switzerland, [4]Department of Neurology, University of Tübingen, Tübingen, Germany.

The epilepsies are a very heterogeneous group of common neurological disorders comprising many individually rare diseases. Thus, genetic diagnosis oft remains difficult. With our approach we aim to reveal the genetic basis of epileptic disorders in so far unresolved cases.

We enriched a panel of 323 epilepsy-associated genes using a custom designed Agilent SureSelect in solution kit and sequenced on a SOLiD 4 platform.

We screened >50 unknown cases with a broad spectrum of epilepsy phenotypes. We detected causative aberrations in commonly mutated ion channel genes (e.g. SCN1A, SCN2A) as well as in rarely affected genes (e.g. STXBP1, MFSD8). Surprisingly, we detected many mutations in extremely uncommon genes (e.g. KCTD7, ARHGEF9, KCNJ10, SMS). We also revealed SCN1A mutations in three patients where conventional testing (Sanger sequencing / HRM) failed to detect the mutations.

We have successfully established a fast and cost efficient genetic screening method for patients with seizure disorders. We were able to uncover the genetic basis of many so far unresolved cases with epilepsy. We detected mutations in patients with both clear and unspecific epilepsy phenotypes. We revealed false negatives in conventional genetic testing methods. Many mutations were detected in genes that only in very rare instances have been associated with epileptic disorders. Thus, many rare epilepsy disorders might perhaps be more common but simply underdiagnosed due to unspecific and diffuse phenotypes. Therefore, our approach may contribute in collecting information on both well-known and unacquainted epilepsy disorders and in revealing their true phenotypic spectrum.

P12.083

Mutation spectrum in the CACNA1A gene in 49 patients with episodic ataxia type 2

C. Sintas[1,2,3], *O. Carreño*[1,2,3], *R. Corominas*[1,3,4], *C. Toma*[1,2,3], *M. Vila*[4], *N. Fernández-Castillo*[1,2,3], *E. Cuenca*[4], *A. Macaya*[4], *B. Cormand*[1,2,3];
[1]Department of Genetics, University of Barcelona, Barcelona, Spain, [2]Institut de Biomedicina de la Universitat de Barcelona (IBUB), Barcelona, Spain, [3]Center for Biomedical Network Research on Rare Diseases (CIBERER)-Institute of Health Carlos III, Barcelona, Spain, [4]Pediatric Neurology Research Group, Vall d'Hebron Research Institute, Universitat Autònoma de Barcelona, Barcelona, Spain.

Episodic ataxia is an autosomal dominant ion channel disorder characterized by episodes of imbalance and incoordination. Episodic ataxia type 2 (EA2) features recurrent episodes of vertigo and cerebellar ataxia, lasting from minutes to a few days, with often interictal nystagmus.

Many EA2 patients harbor mutations in the CACNA1A gene, encoding the α1A subunit of the P/Q-type voltage-gated calcium channel Cav2.1. The vast majority of them are loss-of-function missense or nonsense mutations leading to decreased channel currents. Recently, CACNA1A exonic deletions were reported in EA2 using quantitative approaches, such as multiplex ligation dependent probe amplification (MLPA) and quantitative multiplex PCR of short fluorescent fragments (QMPSF).

We performed a mutational screening of the CACNA1A gene, including the promoter and 3'-UTR regions, in 49 unrelated patients diagnosed with EA2. When point or small indel mutations were not found, we performed MLPA and QMPSF assays to screen for large duplications or deletions. Overall, a mutational screening by PCR amplification and sequencing allowed identification of 9 point mutations (4 nonsense and 5 missense changes) and a 2-bp deletion (predicting a truncated protein), covering 20% of the patients. Subsequently, quantitative analysis identified a deletion of exon 35 as a result of a homologous recombination event between flanking Alu sequences. Our data suggest that these variations are disease-causing, although functional studies are warranted.

P12.084

Does C-terminal deletion in the ALAS2 gene cause x-linked dominant or recessive protoporphyria?

V. Brancaleoni, *E. Di Pierro*, *F. Granata*, *M. D. Cappellini*;
Dipartimento di Medicina Interna-Fondazione IRCCS Ca' Granda-Università degli Studi di Milano, Milano, Italy.

Erythropoietic protoporphyria (EPP) is an inherited disorder caused by over-production of protoporphyrin IX in the final step of heme synthesis. Most patients have autosomal-dominant EPP, which requires coinheritance of a null *FECH* mutation trans to a hypomorphic allele. Recently a new form of X-linked dominant protoporphyria associated to gain of function deletions in *ALAS2* has been described.

In this study we re-examined 7 Italian unrelated *FECH*-negative families for a total of 23 subjects by sequencing of exon 11 of *ALAS2*. In 4 families, 4 males and 5 females carried the deletion c.1706-1709 delAGTG, confirming the role of *ALAS2* in protoporphyria phenotype. Differently from what was previously described (Whatley et al., 2008) we found heterogeneity of phenotypes between females: out of five females with the *ALAS2* deletion, only two showed photosensitivity. Thus X-inactivation (X*i*) were evaluated by analysis of *ZMYM3* gene and HUMARA Assay. The symptomatic females showed extreme skewed X*i* pattern of the wild type allele (95% vs 5%), while the other three showed a balanced or a slightly skewed inactivation of the mutated allele. Our results demonstrate that the disease is transmitted as an X-linked recessive trait and the phenotype depends on the degree of X*i*.

In one family only the proband carried the deletion indicating a possible the novo onset of the mutation that was confirmed by segregation of microsatellites.

The mutations in 3 *FECH*-negative EPP families remain unknown, indicating that new gene targets can offer new opportunities for diagnosis.

P12.085

Whole-exome sequencing in patients with clinical diagnosis of Familial Hypercholesterolaemia

A. C. Alves[1,2], *M. Bourbon*[1,2];
[1]Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisboa, Portugal, [2]Center for Biodiversity, Functional & Integrative Genomics (BioFIG), Lisboa, Portugal.

Familial hypercholesterolemia (FH) is a monogenic condition caused, in most cases, by mutations in LDLR, APOB and PCSK9. From our previous studies only 40% of patients have an identifiable mutation so, other mutations in these genes or other gene defects must exist to explain the cause of hypercholesterolemia in the remaining families.

The main aim of this project was the whole-exome sequencing of 5 index

patients with clinical diagnosis of FH (4 without a detectable mutation and one patient (P1) with a mutation in LDLR but the genotype did not justified the phenotype), in order to identify the genetic cause of the hypercholesterolemia in these patients.
Multiple variants were identified for each patient, more than 15000 per sample. The present analysis only refers to variants occurring only in one sample. A total of 6139 were nonsynonymous single-nucleotide substitutions, 11740 were synonymous, 283 were frameshift alterations and 73 were stopgain or stoploss alterations. A total of 1566 of the nonsynonymous substitutions were not present in dbSNP. The 639 novel nonsynonymous substitutions were distributed among 501 genes. P3 has a nonsynonymous alteration described before in LDLR gene, that was missed before due to technical problem. P1 has a frameshift alteration and P4 has an insertion, both not described before, that are possible causes of hypercholesterolaemia. Family studies are being prepared but functional studies are required to prove pathogenicity.
Exome sequence produces a vast amount of data that needs careful analysis but it can lead to the discovery of new genes for FH.

P12.086
Evaluation of exome sequencing in genes associated with aortic diseases

J. Meienberg[1,2], A. Patrignani[3], M. Okoniewski[3], C. Henggeler[1,2], E. Arnold[1,2], R. Perez[1,2], N. Mahlberg[1,2], N. Amstutz[1,2], H. Burri[2], F. Dutly[4], T. Carrel[5], B. Steinmann[6], ***G. Matyas**[1,2]*;
[1]Center for Cardiovascular Genetics and Gene Diagnostics, Schlieren (Zurich), Switzerland, [2]Institute of Medical Molecular Genetics, Schwerzenbach, Switzerland, [3]Functional Genomics Center Zurich, ETH and University of Zurich, Zurich, Switzerland, [4]Institute for Medical & Molecular Diagnostics Ltd., IMD, Zurich, Switzerland, [5]Clinic for Cardiovascular Surgery, University Hospital, Berne, Switzerland, [6]Division of Metabolism, University Children's Hospital, Zurich, Switzerland.

Exome sequencing is a combination of next generation sequencing (NGS) and the enrichment of all known human protein-coding exons and flanking splice sites. In addition to qualitative analyses, which can detect point mutations and small insertions/deletions, exome sequencing data can also be used for quantitative sequence analysis in order to detect large insertions/deletions. In this study, we have evaluated the qualitative and quantitative properties (i.e. mutation detection rate) of exome sequencing for different mutation types and genes. These genes are associated with syndromic forms of rare aortic diseases, such as Marfan syndrome *(FBN1)*, Loeys-Dietz syndrome *(TGFBR1, TGFBR2)*, and Ehlers-Danlos syndrome vascular type *(COL3A1)*, or with non-syndromic forms such as familial thoracic aortic aneurysms *(ACTA2, MYH11, MYLK)*. For this evaluation, DNA samples with known point mutations and small deletions/duplications detected by Sanger sequencing as well as large deletions/duplications detected by MLPA were used as template in exome sequencing. In a first step, we applied Agilent's in solution sequence capturing of all coding exons and flanking intronic sequences and performed NGS using a SOLiD4 platform. Exome sequencing data visualized by the Integrative Genomics Viewer revealed that the mutation detection rate of the used exome sequencing method was lower than that of Sanger sequencing and MLPA, varying between mutation types and genes. Whereas point mutations were successfully detected in enriched exons with sufficient read-coverage depth, the used exome sequencing protocol needs to be improved for the detection of small deletions and duplications/insertions as well as for the more balanced capturing of exons.

P12.087
Exome sequencing of a consanguineous family affected by a congenital muscular dystrophy with hyperlaxity (CMDH).

***M. Tetreault**[1,2], M. Vanasse[3], B. Brais[1,2]*;
[1]Department of Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, QC, Canada, [2]Laboratoire de neurogénétique de la motricité, Centre d'Excellence en Neuromique de l'Université de Montréal, CRCHUM, Montreal, QC, Canada, [3]Clinique des maladies neuromusculaires, Centre de réadaptation Marie-Enfant, Hôpital Sainte-Justine Hospital, Montreal, QC, Canada.

Over the past two decades, there have been major advances in defining the genetic bases of congenital muscular dystrophies (CMD). Genetic research has allowed the identification of more than 14 genes responsible for various forms of CMDs. Despite the great progress in this field, there are still a significant percentage of cases for which the mutated gene is unknown. This is particularly the case for milder forms. Novel genomic techniques like Next-Generation DNA Sequencing (NGS) open new avenues in the elucidation of genetic defects causing monogenic disorders such as CMD. We recruited a consanguineous French-Canadian family from Southwestern Quebec affected by CMDH. A previous microsatellite genome wide-scan (GWS) has linked this family to 32cM region on chromosome 3p23-21. Most obvious candidate genes have been rule out in this region. A SNPs genome scan (Illumina OmniExpress) have identified six homozygous region shared by the two affected members. Among them, a 17Mb region on chromosome 3p24.3p21.3 was identified. The two affected cases as well as the mother were sent for exome sequencing at Perkin Elmer service lab. The Agilent SureSelect 50Mb kit was used for exons capture and the sequencing was performed on an Illumina HiSeq. A list of candidate genes with rare variants shared by the two cases in a homozygous state and heterozygous in the mother was produced. The uncovering of the genetic bases of muscular dystrophies serve as the essential original building blocks on which successful new therapeutic approaches can be designed.

P12.088
Next-generation sequencing in genome-wide investigations reveals novel candidates in genetic eye disease

***R. V. Jamieson**[1,2], W. Ng[1,2], S. Yousoof[1,2], K. Hana Utami[3], E. Chew[3], F. Collins[4], M. Flaherty[4], J. Grigg[1,5], E. Liu[3], Y. Ruan[3], A. Hillmer[3], G. Peters[4], S. Davila[3], V. Cacheux[3]*;
[1]University of Sydney, Sydney, Australia, [2]Eye & Developmental Genetics Research, Children's Hospital at Westmead & Children's Medical Research Institute, Sydney, Australia, [3]Genome Institute of Singapore, Singapore, Singapore, [4]The Children's Hospital at Westmead, Sydney, Australia, [5]Save Sight Institute, Sydney, Australia.

Many ocular disease including developmental eye conditions such as anterior segment dysgenesis and diseases affecting the retina show marked genetic heterogeneity. The underlying genetic causes are unknown in many cases. An understanding of genotype-phenotype correlations is required to facilitate improved treatment strategies in these conditions. Next-generation sequencing is a key strategy for assessing structural and sequencing variants on a genome-wide scale in personalized medicine. We identified two families with balanced chromosomal rearrangements and eye disease, one *de novo* and one segregating with the disease, indicating pointers to the underlying disease genes. For rapid breakpoint identification, we used a mate-paired-end-tag sequencing approach. Identification of discordant read pairs spanning the breakpoints showed the genomic rearrangements precisely. In the *de novo* case with retinitis pigmentosa, a strong novel candidate disease gene with a role in presynaptic neurotransmitter release was transected by the breakpoint. In the familial case with anterior segment dysgenesis, several candidates were in proximity to the breakpoint and expression results from the patient cells and mouse eye tissues have identified a strong candidate in eye anterior segment development. Exome target enrichment sequencing is being carried out for these and other candidates to screen for mutations in other patients with similar eye phenotypes. Our work emphasises the utility of combined genome-wide structural and exomic analyses in disease gene identification in genetically heterogenous eye disorders.

P12.089
Hemophagocytic lymphohistiocytosis developed in visceral leishmaniasis may have genetic etiology

***G. Balta**[1], F. M. Azik[2], A. Gurgey[1]*;
[1]Hacettepe University, Faculty of Medicine, Department of Pediatrics, Division of Pediatric Hematology, Ankara, Turkey, [2]Ankara Children's Hematology Oncology Hospital, Department of Pediatric Hematology Diskapi, Ankara, Turkey.

Hemophagocytic lymphohistiocytosis (HLH) is an immune dysfunction disorder with various etiologies. Familial HLH (FHL) has genetic basis, while acquired HLH develops secondary to infections, malignancies etc. BMT is the only curative therapy in FHL whereas HLH symptoms in secondary HLH subside by the treatment of main cause. HLH may rarely develop secondary to visceral leishmaniasis (VL). This first study demonstrates that HLH developed in VL may actually have genetic etiology. One-year-old only child of a consanguineous family had abdominal distention and high fever. Leishmania amastigots in BMA led to diagnosis of VL. Liposomal-amphotericin-B therapy resolved symptoms which reappeared subsequently. No amastigots but hemophagocytosis detected in second BMA. She received continuous HLH-2004 protocol therapy since remissions followed by HLH reactivations and/or five CNS relapses until she died at age four. HLA matched donor was unavailable. Haplotype analysis of the family for Perforin, UNC13D, Syntaxin 11 and STXBP2 genes of FHL revealed homozygosity for UNC13D gene. Sequencing identified homozygous 627delT frameshift mutation (Thr209fsX40) in exon 8, resulting in premature termination of translation 40 amino acids downstream. Parents were heterozygous for this pathologic mutation. In conclusion, HLH in this patient did not develop secondary to VL, but FHL, triggered by leishmania infection, most probably emerged at an earlier time. Clinicians must be aware that HLH developed in VL may have genetic etiology and leismaniasis may mask the diagnosis of primary disease, which may eventually lead to loss of the patient due to tardiness in proper therapy and BMT. Supported by TUBITAK (Project No:105S386-SBAG3193).

P12.090

Molecular analysis of *MEFV* gene mutations in Iranian patients with Familial Mediterranean Fever

R. Najafi[1], *M. Azad*[1], *M. Rostami*[1], *H. Imanian*[1], *H. Najmabadi*[1,2];
[1]*Kariminejad-Najmabadi Pathology & Genetics Center, Tehran, Islamic Republic of Iran,* [2]*Research Center, University of Social Welfare & Rehabilitation Sciences, Tehran, Islamic Republic of Iran.*

Familial Mediterranean Fever (FMF) is an autosomal recessive disorder characterized by recurrent attacks of fever and painful inflammatory manifestations in the abdomen, chest or joints. The marenostrin/pyrin-encoding gene (*MEFV*), mapped to 16p13.3, has been proposed as a candidate gene for FMF on the basis of the identification of mutations clustered in 10 exons.

In this study we used reverse-hybridization (FMF StripAssay, ViennaLab Diagnostics, Vienna, Austria) to analyze the following 12 *MEFV* mutations: E148Q, P369S, F479L, M680I (G/C), M680I (G/A), I692del, M694V, M694I, K695R, V726A, A744S and R761H in 331 Iranian patients, who were referred to us based on clinical criteria indicating FMF.

We identified *MEFV* mutations in 33.8% of our patients. Out of these, 66.5% were located in exon 10, while the remaining 33.5% were found in other exons. The most common mutations were p.M694V (20%), followed by p.E148Q (18%), p.V726A (9%), and p.M680I (c.2040G>C) (3%), which suggests a heterozygote advantage of these first three mutations in Iran. In 45.9% of patients we could not identify any mutation that could explain their clinical status; therefore, we plan the comprehensive sequencing of *MEFV* gene to elucidate the cause of their disease. Among these patients, for the first time we report on a novel disease causing compound heterozygote mutation (R202Q) in exon 2 and (c.1588-69 G>A) in IVS-5 of *MEFV* gene in one family which is followed by early onset FMF. As disease-causing mutations these two mutations should be further investigated in more patients in different populations.

P12.091

Homologous recombination - a pool for FA candidate genes

K. Helsper, *B. Schuster, K. Knies, D. Schindler;*
University of Wuerzburg, Department of Human Genetics, Wuerzburg, Germany.

Fanconi anemia (FA) is a rare autosomal or X-linked recessive genetic disorder, characterized by typical physical abnormalities, bone marrow failure and an increased risk for malignancies. Because of a DNA repair defect FA cells show elevated spontaneous and in particular MMC inducible chromosomal instability. To date, fifteen FA genes have been reported. The corresponding proteins are known to be members of the FA/BRCA network that promotes DNA interstrand crosslink repair by homologous recombination (HR).

A small subset of FA patients still cannot be assigned to established complementation groups. Therefore, we screened cell lines from those patients for defects in candidate genes involved in HR. These potential FA genes included MUS81, SFPQ and MMS22L. MUS81 is the structure-specific endonuclease of the MUS81/EME1 heterodimer that interacts directly with the FA protein SLX4 (FANCP). The splicing factor related protein SFPQ cooperates with RAD51D, a paralog of RAD51C (FANCO), and might play a role in homologous recombination. The third candidate gene is MMS22L. In complex with TONSL, it accumulates at stalled replication forks and is required for efficient formation of RAD51 foci after DNA damage.

The screening methods included Sanger sequencing and Western blotting and so far revealed no pathogenic mutations. More unassigned FA cell lines and additional FA candidate genes will be included in our screen, since candidate gene approaches have been successful in the past for the identification of the FA genes BRCA2/FANCD1, PALB2/FANCN and SLX4/FANCP.

P12.093

Evaluation of a Laboratory Developed High Resolution Melt Assay Design for Determination of Methylation Status of the FMR1 Promoter

A. Hamilton, C. L. Sigua, ***D. A. Bost***;
Celera, Alameda, CA, United States.

Fragile X Syndrome (FXS), a common cause of intellectual disability, is inherited via expansion of the trinucleotide (CGG) repeat in the *FMR1* gene. FXS is associated with methylation of the expansion and the neighboring *FMR1* promoter, preventing transcription. Fragile X diagnostic testing incorporating Southern analysis can detect expansion of the repeat region and evaluate methylation using a methylation-sensitive restriction digest, but the process is time-consuming and only queries a small number of CpG sites flanking the expansion. We recently developed and tested a PCR primer pair capable of amplifying both methylated and unmethylated bisulfite-converted DNA, for a region of the *FMR1* promoter incorporating 22 CpG sites. PCR amplification of bisulfite converted DNA with an intercalating dye and High-Resolution Melt analysis can be used in a laboratory developed (LD) protocol to determine the overall methylation status of the *FMR1* promoter. One possible High-Resolution Melt protocol was evaluated in experiments testing the methylation status of 20 clinical samples (4 premutation males, 5 premutation females, 4 full mutation males, and 7 full mutation females) for which the results were compared to methylation values estimated from Southern blot results. Additional clinical and Coriell DNA samples were tested that included normal, premutation and full mutation alleles from both genders. Our results showed qualitative methylation values were in line with those observed by other methods. A PCR-based LD assay for *FMR1* methylation would complement other PCR-based expansion sizing and screening LD tests to allow both expansion and methylation status of patient samples to be rapidly determined.

FMR1 premutation alleles (55-199 CGG repeats) have been associated with primary ovarian insufficiency (POI). More recently some studies have shown that alleles in the intermediate range (45-54 CGG repeats) and in the high end of the normal range (≥35 CGG repeats) are also related with the development of this condition. A group of 31 women with POI from the Basque Country has been analyzed to study the prevalence of alleles in the premutation, intermediate and the high end of the normal range. Considering the 35-54 CGG repeat range, the number of women carrying at least one allele with >35 CGG repeats was statistically higher in patients (16.3% vs. 6.67%). To make a more accurate analysis the patient group was classified into two categories, women with overt POI (19.36%) that presented with amenorrhea for at least four months and FSH levels >10 IU/L and women with occult POI (80.64%) that presented with decreased fecundity and regular menses. When comparing alleles with >35 CGG repeats, the prevalence of these alleles was statistically higher among women with overt POI, but not among women with occult POI. The data of this study suggests that carrying more than 35 CGG repeats in the FMR1 gene might be related with the development of overt POI, but not with occult POI.

P12.095

Mosaicism for a normal allele, a full mutation and a deletion involving the whole CGG repeat in the *FMR1* gene

R. C. Niessen[1], *K. A. Kooi*[1], *K. L. I. van Gassen*[2], *R. J. Sinke*[1], *R. Hordijk*[1];
[1]*Department of Genetics, University Medical Center Groningen, University of Groningen, Groningen, Netherlands,* [2]*Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.*

We report on a 29-year-old female who wants to start a family. She was referred for DNA analysis to see what risk she carries for having offspring with fragile X syndrome, because her mother carried a premutation of 80 CGG units in the *FMR1* gene.

DNA was isolated from lymphocytes. PCR and length analysis on an automated sequencer identified only a normal CGG repeat of 29 CGG units. Further Southern analysis revealed a mosaic pattern, that indicated presence of an *FMR1* allele with a deletion next to a normal allele and alleles with a full mutation. Sequence analysis indeed confirmed presence of a 2475 bp deletion that covered the whole CGG repeat and transcription initiation site until 45 bp proximal of the translation start codon.

Similar deletions have been reported and these result in inactivation of the *FMR1* gene and absence of the FMR1 protein. Our patient therefore has a 50% risk of transmitting either a full mutation allele or the deletion allele, either of which could cause fragile X syndrome in her offspring.

It is important to note that the *FMR1* deletion allele was not detectable with the Amplidex *FMR1* PCR kit (Asuragen, Austin, USA). Since recently, we use this new method as an alternative to Southern analysis in DNA testing for fragile X syndrome. We are now comparing various techniques to decide upon an optimal method that can be offered for prenatal testing.

Fraser syndrome: Implementation and first results of FRAS1 molecular analysis at the University Hospital of Clermont-Ferrand, France

C. Nachury[1], D. Bozon[2], P. Dechelotte[3], C. Francannet[4], ***I. Creveaux****[1,5];*
[1]CHU Clermont-Ferrand, Molecular Biology Laboratory, Clermont-Ferrand, France, [2]CHU Lyon, Centre de Biologie Est, Lyon, France, [3]CHU Clermont-Ferrand, Pathology Laboratory, Clermont-Ferrand, France, [4]CHU Clermont-Ferrand, Medical Genetics, Clermont-Ferrand, France, [5]Université d'Auvergne, GenHotel-Auvergne, Clermont-Ferrand, France.

Fraser syndrome is a rare disease, with autosomal recessive inheritance. It is a malformative syndrome, which most frequent signs are cryptophtalmos and syndactyly. They are associated with other anomalies like craniofacial, genital, urinary or lung malformations. The expression is variable. Clinical diagnosis criteria have been defined by Van Haelst in 2007. Currently, prenatal diagnosis uses ultrasonography during the second quarter of pregnancy and is difficult without family history orientation. Two genes, FRAS1 and FREM2, have been identified as responsible for Fraser syndrome. Only 2 different mutations have been described in FREM2 and 23 in FRAS1.

In this work, our initial goal was to identify, by PCR-sequencing, causative mutations of Fraser syndrome patients from eight families who were diagnosed on clinical criteria. We analyzed FRAS1 in priority.

We found in those patients 4 nonsense mutations, 2 intronic mutations affecting splicing, one 1-bp duplication and finally 4 new sequence variations (intronic and exonic) of unknown significance. We specified the value of these 4 sequence variations using bioinformatic algorithms and functional tests based on transfection of minigene constructs in HeLa cells. Using these tools, a missense mutation was shown to induce exon skipping.

Analysis of FRAS1 gene provides the clinician a molecular confirmation of Fraser syndrome diagnosis in about 40% of cases. This further allows the possibility to offer the parents an early antenatal molecular diagnosis for a future pregnancy. We are now considering the development of the analysis of coding exons of FREM2 gene to increase the coverage rate.

P12.097

Study of FRAXE-MR in intellectually disabled individuals referred for Fragile-X Syndrome testing in Portugal

P. Jorge[1], ***I. Marques****[1], R. L. Gonçalves[2], M. Gonçalves-Rocha[3], R. Santos[1];*
[1]UI&D, Centro de Genética Médica Dr. Jacinto de Magalhães – Porto, Instituto Nacional de Saúde Dr. Ricardo Jorge, INSA I.P., Porto, Portugal, [2]Genética Médica, Hospital de Dona Etefânia-CHLC, EPE, Lisboa, Portugal, [3]UME, Centro de Genética Médica Dr. Jacinto de Magalhães – Porto, Instituto Nacional de Saúde Dr. Ricardo Jorge, INSA I.P., Porto, Portugal.

Among the genetic causes involved in X-linked intellectual disability (XLID), pathogenic variations in *FMR1* (Fragile Mental Retardation 1)*, AFF2 (*AF4/FMR2 family member 2) and *ARX* (Aristaless Related Homeobox) genes emerge as main causes. *FMR1* and *AFF2* genes contain (*polymorphic repetitive regions*) a repeat polymorphism which is susceptible to suffer dynamic mutation, a process that may induce pathogenic expansions. FRAXE-associated mental retardation (FRAXE-MR) is mainly a non-syndromic form of XLID and is due to *AFF2* gene silencing as a consequence of 5'UTR-CCG expansion or gene mutations. A CCG triplet number up to 30 repeats is consider normal, while full expansion (>200 repeats) and hypermethylation of CCG cluster results in FRAXE-MR.

AFF2 variants are not frequently sought. An implementation of a cost-effective strategy (co-amplification with other ID genes) represents an improvement in molecular diagnosis with consequent gains in clinical genetic diagnosis and counseling. Herein we present results of *AFF2* molecular analysis in a subpopulation of 5000 intellectually-disabled individuals with primary referral for FRAXA screening, by a novel multiplex-PCR strategy. This approach accurately detected normal to pre-mutated alleles. A pre-mutated allele with 68 CCG was identified and further characterized by Southern blot analysis in order to exclude methylation and/or repeat number mosaics, as well as PCR failure. Possible phenotype-genotype correlations based on the clinical data of one previously diagnosed family with *AFF2* full expansion, the newly characterized pre-mutation carrier and one case with a new variant of the *AFF2* gene will be investigated and presented.

P12.098

Molecular Combing for the Diagnosis of FSHD

M. Larsen*[1], G. Emmert[1], C. Chaix[2], N. Frankenbach[3], P. Walrafen[3], C. R. Müller[1], S. Rost[1];*
[1]Department of Human Genetics, University of Würzburg, Würzburg, Germany, [2]Département de Génétique Médicale, Hôpital d'Enfants de la Timone, AP-HM, and INSERM UMR_S 910, Université de la Méditerranée, Marseille, France, [3]Genomic Vision, Paris, France.

Facioscapulohumeral muscular dystrophy (FSHD) is the third most common neuromuscular disorder. It is associated with a contraction of D4Z4 macrosatellite repeats on chromosome 4q35. The copy number variation of the D4Z4 repeat varies between 11-100 copies in the normal population and 1-10 in FSHD patients.

Chromosome 10q26 contains a highly homologous repeat array. On both chromosomes, the array can be embedded in two major haplotypes - A and B, but only repeat contractions on the 4qA haplotype are associated with the disease.

The standard method for FSHD diagnostics is Southern blotting, but in about 20% of patients the FSHD genotype remains unclear. Therefore, *GenomicVision* has designed a diagnostic test for FSHD based on Molecular Combing and fluorescence *in situ* hybridisation.

Molecular Combing is a single-molecule analysis that enables direct visualization of multiple whole genomes and the detection of large genome rearrangements. Long DNA molecules are combed onto a solid surface in parallel alignment with uniform stretching allowing direct sizing of fluorescence signals. Probes have been developed to visualize the FSHD-locus as a three-coloured bar code in order to differentiate the repeats and the four haplotypes.

In our diagnostic lab this new technique has been ß-tested for diagnostic purposes. DNA of 30 suspected FSHD patients has been analysed by Molecular Combing, results have been compared to the corresponding Southern blots and show very good accordance.

Molecular Combing provides all molecular data required for the diagnosis of FSHD in a single experiment.

P12.099

Analysis of the Glucocerebrosidase Gene Mutations in 32 Turkish Gaucher Patients

E. Karaca*, S. Kalkan, H. Onay, A. Aykut, M. Coker, O. Cogulu, F. Ozkinay;*
Ege University Faculty of Medicine, Izmir, Turkey.

Gaucher disease (GD) is the most frequent autosomal recessive lysosomal glycolipid storage disease and is caused by acid b-glucosidase (E.C.3.2.1.45) enzyme deficiency. Mutations in the glucocerebrosidase gene (GBA; MIM# 606463; GenBank accession no. J03059.1) cause Gaucher's disease. The GBA (7.5 kb) gene contains 11 exons and 10 introns and is located at chromosome 1q21 locus which consist of several genes. A highly homologous GBA pseudogene is 16 kb downstream from the functional gene. More than 200 mutations such as subtitutions, splicing alterations, partial and total deletions insertions, including complex mutations due to genetic rearrangements between the functional gene and pseudogene have been defined in the GBA gene (2). In this study we report the molecular characterization of 32 unrelated Turkish GD patients having different types of GD. The allelic frequencies of GBA gene mutations in Turkish patients are reported. The most prevalent mutations are N370S and L444P accounting for 50 % and 35.48 % in our GD patient groups respectively. We identified one novel genetic alteration which was a missense change L385R that are associated with the severe phenotype of type II GD. Molecular genetic analysis of the GBA gene in GD is important for genotype phenotype correlation and also will provide reliable genetic counseling in families at high risk for GD.

P12.100

Prevalence of 35delG of the GJB2 gene in hereditary, prelingual, nonsyndromic hearing loss in Mexican population.

R. Rivera-Vega*[1], L. M. Gonzalez-Huerta[1], H. Urueta-Cuellar[1], R. Hernandez-Viquez[1], A. Totomoch[1], S. Cuevas-Covarrubias[2];*
[1]Genetica, Hospital General de Mexico, Mexico, D.F., Mexico, [2]Facultad de Medicina, UNAM, Mexico, D.F., Mexico.

Hearing impairment is the most common sensory disorder. About 1/1000 children is affected by pre-lingual deafness. Several gene mutations have been associated with recessive hearing impairment. The GJB2 gene mutations are the most frequent cause of hereditary, prelingual, non syndromic hearing loss; they present an autosomal recessive inheritance. More than 90 GJB2 mutations affecting Cx26 expression have been reported and linked to hearing loss. Up to 85% of abnormal Cx26 expression may be attributed to the 35delG mutation. This type of mutation showed a high prevalence among Caucasian populations. Prevalence of GJB2 mutations in the Chinese population seems to be different, it appears that 35delC is the most frequent cause of recessive hearing impairment among this population; similarly, Japanese families with bilateral sensorineural hearing loss, also present the 235delC defect, which seems to be the most prevalent mutation affecting Cx26 expression among this population. Previous investigations show ethnic association to other specific GJB2 mutations, per example R143W mutations among African populations or 167delT among Ashkenazi Jews. Objective: To identify the prevalence of 35delC GJB2 mutation in a sample of

Mexican patients. Methods The study included 96 patients from 37 non-related families with hereditary, prelingual-nonsyndromic-hearing-loss, all of them were analyzed through PCR and DNA sequencing from genomic DNA. Results and Discussion: We found in 7 families the presence of 35delC both in heterozygous and homozygous state. We discuss the prevalence of this mutations in the Mexican sample and compare it with the data previously reported in other populations.

P12.101

Identification of a *de novo* splice-site mutation in *SLC2A1* gene causing Glut1 deficiency syndrome in a Turkish patient

I. Karacan[1], *S. Uğur İşeri*[1], *H. Maraş*[2], *Ö. Özdemir*[1], *F. N. Tuncer*[1], *E. Yücesan*[1], *B. Kara*[2], *U. Özbek*[1];
[1]*Department of Genetics, Institute for Experimental Medicine, Istanbul University, Istanbul, Turkey,* [2]*Department of Pediatrics, Faculty of Medicine, Kocaeli University, Kocaeli, Turkey.*

Glucose transporter-1 deficiency syndrome (Glut1-DS) is a metabolic disorder characterized by early onset infantile seizures, movement disorders and a wide range of neurologic abnormalities. Heterozygous mutations in gene *SLC2A1* (*GLUT1*) have been implicated in Glut1-DS, which encodes Glut1-a major glucose transporter in the mammalian blood-brain barrier.

We analyzed *SLC2A1* in a Turkish patient with early onset infantile seizures, microcephaly, intellectual disability, ataxia, dyskinetic cerebral movement disorder and hypoglycorrhachia (cerebrospinal fluid (CSF) glucose concentration:31mg/dl; normal:>40mg/dl and CSF/blood glucose ratio:0.36; normal:>0.45). All exons and exon-intron boundaries of *SLC2A1* were PCR amplified in ten fragments from genomic DNA and screened for mutations by direct DNA sequencing. We detected a novel heterozygous splice site mutation (NM_006516.2:c.680-1G>T) at the last nucleotide of intron 5. Neither the parents nor the 5 healthy sisters of the patient carried this mutation indicating that mutation has arisen *de novo*. This novel mutation analyzed using high resolution melting assay was not detected in a control group of 92 samples selected from the general population. The theoretical consequences of mutation predicted with an *in silico* splice site prediction tool; Human Splicing Finder (HSF). HSF analysis resulted with broken acceptor splice site with 33.57% loss of scoring where scoring decrease >10% was considered predictive of splicing alterations.

We report a novel mutation that possibly creates an altered splice-site. Analysis of relative *SLC2A1* transcript levels by real-time quantitative RT-PCR shows a decreased level in the patient suggesting a pathogenic effect of this mutation on the transcript level, which will further be analyzed.

P12.102

Investigating the functional role of *GPM6A* as a possible intellectual disability gene

A. Gregor[1], *J. M. Kramer*[2], *I. Schanze*[1,3], *A. Reis*[1], *A. Schenck*[2], *C. Zweier*[1];
[1]*Institute of Human Genetics, University Erlangen-Nuremberg, Erlangen, Germany,* [2]*Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands,* [3]*Institute of Human Genetics, University Hospital Magdeburg, Magdeburg, Germany.*

In a patient with mild cognitive impairment/learning disabilities and behavioral anomalies, molecular karyotyping with an Affymetrix 6.0 SNP array revealed a de novo copy number gain of the *GPM6A* gene. Subsequent expression analysis in patient's blood lymphocytes showed increased *GPM6A* expression in the patient compared to healthy controls. Glycoprotein M6a (GPM6A) is a transmembrane protein of the PLP/DM20 protein family whose expression is restricted to neurons. In rats GPM6A has already been implicated in neurite outgrowth, neuronal differentiation and synapse formation. M6a has also been implicated in stress response in different animal models.

We employed Drosophila melanogaster as a model organism to further elucidate its role in stress response, synapse formation and behavior. Using the UAS-Gal4 system we analyzed the function of the Drosophila homologue m6 after tissue specific knockdown and overexpression with different m6 RNAi and m6 overexpressing lines. We found elevated expression levels of m6 in fly brains of L3 larvae and adult flies after heat shock stress treatment, which further increased with heat shock elongation. These findings indicate that m6 expression is also stress responsive in flies. Effects of different m6 levels on survival time upon starvation and oxidative stress are also being studied. Additionally we are currently investigating the role of m6 in synapse formation by dissecting L3 larvae to analyze various parameters of the synapses of neuromuscular junctions and a possible role in complex learning and memory processes by performing the Courtship conditioning assay.

P12.103

Mild haemophilia A in a female patient with an Xq27.3-q28 deletion and a missense mutation in the F8 gene

M. Zimmermann[1], *I. Nanda*[1], *V. Aumann*[2], *J. Oldenburg*[3], *C. R. Müller*[1], ***S. Rost***[1];
[1]*Department of Human Genetics, Würzburg, Germany,* [2]*Magdeburg University Children's Hospital, Magdeburg, Germany,* [3]*Institute of Experimental Haematology and Transfusion Medicine, Bonn, Germany.*

Haemophilia A is an X-linked recessive bleeding disorder which is rarely reported in females. The main reason for the manifestation of haemophilia A in females is due to heterozygous mutations in the F8 gene combined with non-random inactivation of the X chromosome.

Here, we present a 7-year-old girl with mild haemophilia A (FVIII:c 20%) whose brother shows a hemizygous missense mutation (p.Met2164Val) in exon 23 of the F8 gene and suffers also from a mild haemophilia A (FVIII:c 18%).

Direct sequencing of exon 23 in the young girl revealed the same missense mutation as detected in her brother but strikingly it was present in homozygous form. Turner syndrome could be excluded by analyses of polymorphic markers on Xq13, Xq22 and Xq28. Multiplex ligation-dependent probe amplification (MLPA) revealed a large heterozygous deletion involving the whole F8 gene and adjacent control regions. In order to determine the extension of the deletion an analysis for copy number variation was performed on a 300 K Illumina Cyto SNP-12 array. Thereby, a large deletion of approx. 8.9 Mb comprising about 200 genes on Xq27.3-q28 was detected in this girl. Additionally, almost complete inactivation of the X chromosome containing the large deletion could be demonstrated by fragment analysis after methylation sensitive digestion.

Except for the manifestation of haemophilia A the contiguous deletion is supposed to have no or only mild phenotypic consequences for the girl herself in contrast to her potential male offspring: a male fetus carrying this deletion may not be viable.

P12.104

Genetic screening of MYH7 and MYBPC3 genes in Russian HCM patients

N. A. Ogorodnikova, *L. Rizun, U. Frolova, S. Dzemeshkevich, E. Zaklyazminskaya;*
Russian Research Centre of Surgery named by Petrovski, Moscow, Russian Federation.

Background: Primary hypertrophic cardiomyopathy (HCM) is inherited cardiac disorder characterized by clinical and genetic heterogeneity. Mutations in MYBPC3 and MYH7 genes, encoding myosin-binding protein C and myosin heavy chain beta, respectively, account of 40% of HCM cases. Some MYBPC3 and MYH7 mutation carriers have a high risk of sudden cardiac death (SCD).

Methods: By now panel of 30 patients with primary HCM have been formed. We have screened coding and adjacent intronic areas of MYBPC3and MYH7 by direct sequencing in 15 patients. Medical examination: personal and familial history collection, physical examination, standard ECG, 24-h HM and Echo-CG.

Results:We have found 3 mutations (S217G, Q1233ter, V896) in 3 probands inMYBPC3 gene (20% of cohort screened), and 2 HCM-associated polymorphisms (S236G, R326Q). Two mutations (R403W, R249Q) in 2 probands (13,3%) were found in MYH7 gene.

Patient carried heterozygous MYBPC3 variants R326Q and Q1233ter had early manifestation, fast progression and positive SCD familial history. Patient with mild form of HCM had heterozygous S217G mutation in MYBPC3 gene shown previously as leading to dilated cardiomyopathy (DCM) or HCM (with SCD) both. Carrier of heterozygous variants S236G in gene MYBPC3 and R249Q in gene MYH7, 4 y.o., male, had a hypertrophy of left ventricular and interventricular septum. His sister with HCM died suddenly at age of 14 y.o. Mutation carrier R249Q has a high risk of SCD.

Conclusion: Screening of mutations in MYBPC3 and MYH7 genes patients is reasonable and cost-effective in HCM patients.

P12.105

High throughput technologies aimed at the identification of new candidate genes in Italian and Qatari population

g. girotto[1], *M. Alkowari*[2], *K. Abdulhadi*[3], *F. Faletra*[1], *D. Vozzi*[1], *D. Licastro*[4], *R. Siam*[2], *N. Najjar*[2], *R. Badii*[2], ***P. Gasparini***[1];
[1]*Dep.Rep.Sciences,Dev.Pub.Health;IRCCS-Burlo Garofolo-Children Hospital-University of Trieste, Trieste, Italy,* [2]*Molecular Genetics Laboratory, Hamad Medical Corporation, Doha, Qatar, Doha, Qatar,* [3]*ENT Division, Hamad Medical Corporation, Doha, Qatar, Doha, Qatar,* [4]*CBM scrl., Basovizza, Trieste, Italy, Trieste, Italy.*

Hereditary Hearing loss (HLL) is a common disorder accounting for at least 60% of prelingual deafness. Most cases (70%) are non-syndromic (NSHHL) with mutations in GJB2 and GJB6 genes playing a major role worldwide, and

almost no other common genes have been identified. Regarding the Qatari population, a molecular screening for these common genes/mutations clearly demonstrates that they accounts for a minor proportion of NSHHL cases in this population. Thus, these findings strongly suggest that many genes for NSHHL await identification. To increase our knowledge on the molecular bases of HHL in these populations, an extensive use of high throughput technologies such as High Density arrays (i.e for linkage data) and Next Generation Sequencing has been planned.
Six Italian families (dominant inheritance) and 5 Qatari families (recessive inheritance), all negative for the presence of mutations in the most common hearing genes, have been selected. High density SNPs arrays have been utilized to define a minimum number of candidate loci, to be applied in the filtering phase of NGS data. Whole exome sequencing data have been obtained and confirmed by Sanger sequencing. After filtering (dbSNP and in-house database), 2 new candidate genes have been identified in the Qatari population, while data on the Italian samples are still under the validation step. These results will definitely increase our knowledge of new deafness genes, and further confirm the importance of such new technologies for disease gene identification.

P12.106

Different contribution of DFNB loci in Hearing Impaired pedigrees in Iranian population

N. Jalilian[1], *M. A. Tabatabaiefar*[2], *A. Ahmadi*[3], *M. R. Noori-Daloii*[1];
[1]Department of Medical Genetics, School of Medicine, Tehran University of Medical Sciences,, Tehran, Islamic Republic of Iran, [2]Department of Medical Genetics, School of Medicine, Ahvaz Jundishapur University of Medical Sciences,, Ahvaz, Islamic Republic of Iran, [3]Center for Genetic Counseling,Welfare and Rehabilitation Organization,, Birjand, Islamic Republic of Iran.

Hearing loss is the most common sensory disorder. The autosomal recessive non-syndromic form (ARNSHL) accounts for 72% of monogenic HL. DFNB1 is the most common cause of ARNSHL in many populations (50%) including Iran (20%). The fact that many loci are involved together with the heterogeneity of the status, necessitate studying further loci in various Iranian ethnic groups. Fifteen large deaf pedigrees originating from the Southern Khorasan province of Iran were selected. The families analyzed for *GJB2*, exon I & II, mutations and *GJB6* large deletions (D13S1830, D13S1854). Pedigrees negative for GJB2 mutations were then subject to linkage analysis for loci DFNB2, DFNB3, DFNB4, DFNB7/11, DFNB9, DFNB21 & DFNB59. Individuals were genotyped for STR markers using touch-down PCR-PAGE. DFNB4, DFNB3, DFNB21 & DFNB59 have been analyzed and the project is proceeding for other loci. Three out of the 15 families showed *GJB2* mutations. One family carried homozygous c.35delG mutation. The other pedigree carried two different mutations; One patient was heterozygous for c.231G>A while another carried a heterozygous c.380 G>A mutation. The second alleles were not detected. The 3rd pedigree showed heterozygote mutation of p.V27I+E114G/wt . GJB6 deletions were not detected. One family showed linkage to DFNB3 and the remaining did not show linkage to the studied loci. Our results once again emphasize the heterogeneity of HL among different Iranian ethnic groups .These results could provide further insight into the etiology of HL and may lead to better genetic diagnostics & counseling. This study proceeds with more loci and more families.

P12.107

The genetic basis of non-syndromic hearing loss in Cyprus

C. Costi[1], *C. Shammas*[1], *V. Anastasiadou*[1], *G. Tanteles*[1], *E. Spanou*[1], *Y. Kyamides*[2], *V. Neocleous*[1], *L. A. Phylactou*[1];
[1]The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus, [2]Nicosia General Hospital, Nicosia, Cyprus.

Mutations in the *GJB2* (Connexin 26) gene are responsible for more than half of all cases of pre-lingual recessive inherited non-syndromic deafness in Europe. This study presents a mutation analysis of the *GJB2* and *GJB6* genes in 104 Cypriot patients with sensorineural non-syndromic hearing loss compatible with recessive inheritance. Samples from patients were screened for the IVS1+1G splice mutation and the coding exon 2 of the *GJB2* gene including also the deletions del(GJB6-D13S1830) and del(GJB6-D13S1854). Twenty seven patients were verified with *GJB2* mutations in both alleles and with 35delG as the most dominating one, accounting for 76.3% (45 out of 59 mutated alleles), followed by p.R184P (6.9%), p.V37I (1.7%), p.E47stop (1.7%), p.L90P (1.7%), delE120 (1.7%), 167delT (1.7%) and p.V178A (1.7%). Additionally, five patients with severe sensorineural hearing loss were detected only in the heterozygote state. Three of these patients were heterozygous for p.V153I, a fourth was heterozygous for p.V37I and lastly a fifth for the spice site IVS1+1G>A.
Finally, no *GJB6* mutations or the known del*(GJB6-D13S1830)* and del(GJB6-D13S1854) were identified in any of the investigated Cypriot non-syndromic hearing loss patients. This work confirms that the *GJB2* 35delG mutation is an important pathogenic mutation for hearing loss in the Cypriot population and that the underlying molecular basis of autosomal recessive non-syndromic deafness in Cyprus is genetically relatively homogeneous . This finding will be used towards the effective diagnosis of non-syndromic hearing loss, improve genetic counseling and used as a potential therapeutic platform in the future for the affected patients in Cyprus.

P12.108

Nonsense Mutations In SMPX, Encoding A Protein Responsive To Physical Force, Result In X-Chromosomal Hearing Loss

A. K. Huebner[1], *M. Gandia*[2], *P. Frommolt*[3], *A. Maak*[1], *E. M. Wicklein*[4], *H. Thiele*[3], *J. Altmüller*[3], *F. Wagner*[5], *A. Vinuela*[2], *L. A. Aguirre*[2], *F. Moreno*[2], *H. Maier*[6], *I. Rau*[7], *S. Gießelmann*[1], *G. Nürnberg*[3], *A. Gal*[7], *P. Nürnberg*[3], *C. A. Hübner*[1], *I. del Castillo*[2], ***I. Kurth***[8,7];
[1]University Hospital Jena, Institute of Human Genetics, Jena, Germany, [2]Unidad de Genetica Molecular, Hospital Universitario Ramon y Cajal, Madrid, Spain, [3]Cologne Center for Genomics (CCG), University of Cologne, Cologne, Germany, [4]Universitätsklinikum Hamburg-Eppendorf, Klinik für Neurologie, Hamburg, Germany, [5]ATLAS-Biolabs, Berlin, Germany, [6]Medical University Hannover, Department of Otolaryngology, Hannover, Germany, [7]Universitätsklinikum Hamburg-Eppendorf, Institut für Humangenetik, Hamburg, Germany, [8]University Hospital Jena, Institute of Human Genetics, Functional Genetics, Jena, Germany.

Hereditary hearing loss is the most common sensory disorder in humans and is characterized by an extraordinary allelic and nonallelic genetic heterogeneity. X-chromosomal hearing impairment represents only a minor fraction of all cases. In a study of a Spanish family the locus for one of the X-chromosomal forms was assigned to Xp22 (DFNX4). We mapped the disease locus in the same chromosomal region in a large German pedigree with X-chromosomal nonsyndromic hearing impairment by using genome-wide linkage analysis. Males presented with postlingual hearing loss and onset at ages 3-7, whereas onset in female carriers was in the second to third decades. Targeted DNA capture with next-generation sequencing detected a nonsense mutation in the small muscle protein, X-linked (SMPX) of affected individuals. We identified another nonsense mutation in SMPX in patients from the Spanish family who were previously analyzed to map DFNX4. SMPX encodes an 88 amino acid, cytoskeleton-associated protein that is responsive to mechanical stress. The presence of Smpx in hair cells and supporting cells of the murine cochlea indicates its role in the inner ear. The nonsense mutations detected in the two families suggest a loss-of-function mechanism underlying this form of hearing impairment. Results obtained after heterologous overexpression of SMPX proteins were compatible with this assumption. Because responsivity to physical force is a characteristic feature of the protein, we propose that long-term maintenance of mechanically stressed inner-ear cells critically depends on SMPX function.

Transthyretin-related Familial Amyloid Polyneuropathy (TTR-FAP) is a hereditary amyloidosis, caused by amyloid formation and destabilization of the transthyretin tetramer.
The disease is autosomal dominant, caused by mutations in the TTR gene. The majority of the described cases concern small kindred or sporadic patients. The TTR mutation p.Val30Met is the most common one and only this mutation has been reported in large family cases, so far.
We report on 45 TTR-FAP patients from 26 Bulgarian families. The restrictive cardiomyopathy and the progressive polyneuropathy are the most typical clinical findings.
We found endemic region in the south-western part of the country, where 80.7% of the patients carry the mutation c.325G>C; p.Glu89Gln, while the worldwide most common mutation p.Val30Met was detected only once. Interestingly, one patient from this region was compound heterozygous for the mutations p.Val30Met and p.Glu89Gln. The clinical symptoms are typical, although the age of first symptoms is five years earlier in comparison to the average age. On the other hand, one patient was a 62 years old carrier of the mutation p.Glu89Gln without any clinical history.
In summary, FAP encompasses complex phenotype with marked variability within a single family. The screening for mutations in the TTR gene should not be restricted to common mutations, as a second mutation might exist. The detected mutations in pre-symptomatic cases, even well-known ones,

have to be interpreted with caution in respect to their pathological income.

Mutational analysis of *SERPING1* gene in Slovenian patients with hereditary angioedema: four novel mutations

***M. Rijavec**, M. Šilar, P. Korošec, M. Zidarn, M. Košnik;*
University Clinic of Respiratory and Allergic Diseases, Golnik, Slovenia.

Hereditary angioedema (HAE) is a rare autosomal dominant disease characterised by the swellings of the face, lips, tongue, larynx, genitalia or extremities, with abdominal pain caused by intra-abdominal edema. HAE is caused by mutations affecting C1 inhibitor gene, also called *SERPING1*, resulting in low levels of C1 inhibitor (Type I HAE) or by normal levels of ineffective C1 inhibitor (Type II HAE).

We recruited 16 individuals with HAE from 7 unrelated Slovenian families. The diagnosis of HAE was established in the presence clinical and laboratory criteria (low C1 inhibitor antigenic levels and/or function), followed up with positive family history. Genetic studies were carried out by PCR and sequencing for the detection of *SERPING1* mutations, in promoter, noncoding exon 1 and in the 7 coding exons and exon-intron boundaries.

In all patients with HAE a mutation responsible for the disease has been identified. Four mutations were reported for the first time. In HAE type I families one already reported substitution (Gln67Stop, c.265C>T), together with four novel mutations have been identified. The new mutations included two missense substitutions, Ser128Phe (c.449C>T) and Glu429Lys (c.1351G>A), together with two frameshift mutations, indel (c.49G>TT; c.49delGinsTT) and deletion (c.593_594delCT). Both families with HAE type II harboured the two well-known substitutions affecting the arginyl residue at the reactive centre in exon 8, Arg444Cys, c.1396C>T and Arg444His, c.1397G>A, respectively.

Our study identified four novel mutations in the Slovenian HAE population, highlighting the heterogeneity of mutations in the *SERPING1* gene causing C1 inhibitor deficiency and HAE.

The added value of targeted next generation sequencing in patients with cardiomyopathies. Substituting Sanger sequencing as a diagnostic test.

***B. Sikkema-Raddatz**, L. F. Johansson, E. N. de Boer, L. G. Boven, K. Y. van Spaendonck-Zwarts, J. P. van Tintelen, J. D. H. Jongbloed, R. J. Sinke;*
Department of Genetics, University of Groningen, University Medical Centre Groningen, Groningen, Netherlands.

Whole exome sequencing (ES) of a significant number of samples from a wide variety of diseases has become common practice for identifying putative disease linked variants. The advantage of this approach is the possibility of analyzing a large amount of genes in parallel. However, substituting Sanger sequencing with ES for mutation detection in daily diagnostics is yet not applicable due to dramatic differences in coverage within ES experiments, resulting in missing clinically relevant mutations. Targeted enrichment will circumvent this shortcoming by selecting only those genes involved in a particular disease. We developed two kits, based on Illumina's TruSeq™ Custom Enrichment and Agilent Sure Select Target Enrichment, for mutation detection in 48 genes that were proven to be involved in hereditary cardiomyopathies. Eighteen patients were analysed applying both kits and Sanger sequencing for up to six genes. An additional 18 patients were screened using the Agilent Target Enrichment kit only. Sample preparations were performed according to manufacturers protocols. Samples were multiplexed to an amount still permitting a theoretical coverage of 100 reads per targeted sequence/per patient. All samples were sequenced using 151bp-paired end reads on a Illumina MiSeq sequencer and analysed using the MiSeq Reporter pipeline. All (pathogenic) mutations previously detected with Sanger sequencing were identified. In addition, 103 novel putative pathogenic mutations (19 synonymous, 10 splice site and 74 missense) were found, on average three per patient. *In silico* analyses, confirmation by Sanger sequencing and co-segregation analyses are currently performed to identify the causal mutation in each patient/family.

P12.112
Novel mutation in the ENG gene in Russian patients with Hereditary Hemorrhagic Telangiectasia.

*N. S. Averiyanova, V. Y. Kornienco, N. V. Jourkova, O. B. Kondakova, T. A. Prudnicova, Y. V. Kirgizov, A. U. Asanov, **V. G. Pinelis**;*
Scientific center for children's Health, RAMS, Moscow, Russian Federation.

Hereditary hemorrhagic telangiectasia type 1 (HHT 1) or Osler-Weber-Rendu disease (OMIM 187300) is an autosomal dominant disorder. HHT 1 characterized by recurrent epistaxis, telangiectasia, multi-systemic vascular dysplasia and clinical presentation of wide variation. Molecular-genetic analyses of HHT 1 have identified gene ENG on chromosome 9. This gene encoded protein endoglin, which is expressed predominantly on endothelial cells as a heavily glycosylated disulfide-linked dimer that binds TGF-β1 and TGF -β3.

Here, we report genetic analyses of one Russian family with HHT 1 diagnosed by clinical criteria. The proband is a boy 2,5 year old. He was diagnosed as HHT 1 with recurrent epistaxis and arteriovenous malformation (AVM) in the left lung. The history of HHT 1 was found also in his relatives: recurrent epistaxis, arteriovenous malformation in spleen, migraine headache in mother and spontaneous, recurrent epistaxis, telangiectases in maternal grandmother.

Amplicons of 1, 3, 7, 9, 12 exons and introns of ENG gene were directly sequenced. We found a heterozygous single nucleotide (G) deletion in the splice donor site of intron 7 (c.991+1delG or IVS 7+1 del G) that converted the 5' end of intron 7 from GT to TG. This deletion would lead to frame shift and produce unstable mRNA. Found mutation is a novel. Genetic testing of this family confirmed clinical diagnosis in individuals and provided for early detection of AVMs and helps us to prevent the complications of HHT 1 disease in our proband.

P12.113
The mutational spectrum of GDAP 1 gene in hereditary motor and sensory neuropathy patients from Bashkortostan Republic (Russia)

***I. Skachkova**[1], I. Khidiyatova[1], E. Saifullina[2], D. Baizigitov[3], R. Magzhanov[2], E. Khusnutdinova[1];*
[1]Institute of Biochemistry and Genetics, Russian Academy of Sciences, Ufa, Russian Federation, [2]Bashkir State Medical University, Ufa, Russian Federation, [3]Bashkir State University, Ufa, Russian Federation.

Hereditary motor and sensory neuropathy (HMSN) comprises a group of clinically and genetically heterogeneous disorders of the peripheral nervous system. We examined HMSN patients from Bashkortostan Republic (BR) and detected spectrum of specific mutations in the GDAP1 gene using direct sequencing of its coding regions. The GDAP1 gene (8q21.11) codes ganglioside-induced differentiation-associated protein 1 - an important factor in the fission of mitochondria. The GDAP1 gene mutations cause autosomal - recessive disease type 4A. Molecular-genetic investigation of HMSN in 165 unrelated families showed 6 different nucleotide changes in the GDAP1 gene. Two of them haven't been described previously: c.685G>A (p.Glu229Lys), c.934G>A (p.Ala312Thr), and were not detected among healthy family members and controls (n=100), and one previously reported mutation c.715C>T (p. Leu239Phe) wide spread among patients with HMSN 4A type. Its nucleotide changes are supposed to be disease causing mutations. Three revealed nucleotide changes appeared to be gene polymorphic variants: c.102G>A, c.507T>G and c.933G>A. All mutations were heterozygous and revealed in different patients. Taking into consideration an autosomal-recessive type of HMSN, confirmed by genealogical analysis, every patient should carry a second undefined mutation. Perhaps, mutations, which we haven't found, may be located in the GDAP1 promoter region. Thus, it is established that HMSN are caused by the GDAP1 mutations in 2% cases in BR. The received data will contribute to optimization of medical and genetic consulting of HMSN families in our region.

La Fe and CIBER de Enfermedades Neurodegenerativas (CIBERNED), Valencia, Spain.

Inherited peripheral neuropathies that are recurrent and from which affected individuals make full or partial degrees of recovery are unusual. The most prominent disorders that fall into this category are: (i) hereditary neuropathy with liability to pressure palsies (HNPP; MIM 162500) caused by mutations in the *PMP22* gene; (ii) hereditary neuralgic amyotrophy (HNA; MIM 162100) due to mutations in the *SEPT9* gene; and (iii) primary erythromelalgia (MIM 133020) caused by mutations in the *SCN9A* gene. We recruited a large three generation family with eight affected members and the inferred diagnosis of recurrent neuropathy with an autosomal dominant pattern of inheritance. The main clinical manifestations are recurrent episodes of nerve paresis, lumbo-sacral plexopathy, erythromelalgia and migratory sensory neuropathy. In order to characterize the molecular bases which underlie this neuropathy, we first analyzed the candidate genes/loci (*PMP22*, *SEPT9* and *SCN9A*) by Sanger sequencing and/or by segregation analysis. Our findings showed that none of these three genes are involved in the disease. By combining exome sequencing with previous genome-wide linkage analysis, a novel heterozygous mutation was detected in a gene located on chromosome 17, which has not been associated with any neuropathy yet. This mutation co-segregates with the disease and was not observed in 132 unaffected individuals of matched geographical ancestry. We are currently investigating the pathogenicity of this mutation by cellular studies. *This work was supported by the Instituto de Salud Carlos III (Grants number CP08/00053 and PS09/00095) co-funded with FEDER funds.*

Molecular testing for hereditary spastic paraplegia type 4 (SPG4) in a group of Polish patients - preliminary results

E. Elert-Dobkowska*, W. Krysa, M. Rajkiewicz, I. Stepniak, E. Zdzienicka, A. Sulek, J. Zaremba;*
Department of Genetics, Institute of Psychiatry and Neurology, Warsaw, Poland.

BACKGROUND: Mutations in the SPAST gene are responsible for spastic paraplegia type 4 (SPG4), the most common among heterogeneous group termed hereditary spastic paraplegias (HSP).

MATERIAL AND METHODS: A group of 160 patients clinically diagnosed as HSP (90 familial, 70 sporadic cases) were screened for mutations in the SPAST gene. Molecular analysis was performed using multiplex ligation-dependent probe amplification (MLPA) and direct sequencing analysis.

RESULTS: Screening of 160 patients for mutations in the SPAST gene by MLPA enabled us identification of microrearrangements in 12 subjects (7.5%). Among those 11 deletions (9 multiexonic and 2 single exon deletion) and 1 duplication of two exons were found. Sequencing of the SPAST gene, which contains 17 exons, performed so far for 13 exons in 104 patients, revealed 11 different mutations in 12 individuals. Frameshift mutations (c.1215_1219delTATAA, c.1246_1247insG, c.1317delT, c.1418_1431delAGTCTGCTGGAGAT, c.1435_1436delAG, c.1779_1780insA), splice site change (c.1729-2A>G) and missense mutations (c.1079T>C, c.1100T>C, c1378C>T, c.1849T>G) were identified. Out of 11 point mutations 10 are localized in the AAA domain of spastin and one missense mutation in the last TAA STOP codon switched to coding for glutamic acid. Furthermore 5 intronic substitutions and 1 known synonymous variant in exon 6 were detected.

CONCLUSIONS: So far molecular analysis in 160 patients revealed 24 cases of SPG4 (15%). The study results confirm that the majority of point mutations as well as microrearrangements in the SPAST gene are localized in the AAA domain of the spastin protein (19/24 cases).

P12.116

Mutation analysis of SPG4 gene in Bulgarian patients with hereditary spastic paraplegia

[1]*Department of Medical Chemistry and Biochemistry, Molecular Medicine Center, Medical University, Sofia, Bulgaria, Sofia, Bulgaria,* [2]*Clinic of Neurology, University Hospital „Alexandrovska", Department of Neurology, Medical University, Sofia, Bulgaria, Sofia, Bulgaria,* [3]*VIB Department of Molecular Genetics, University of Antwerp, Antwerp, Belgium, Antwerp, Belgium.*

Background: Hereditary spastic paraplegias (HSP) are a group of clinically and genetically heterogeneous neurodegenerative disorders which main features are progressive spasticity and weakness of lower limbs. HSPs are characterized by degeneration of the longest axons in the central nervous system. Prevalence in European population is 3-10 cases per 100 000. All types of inheritance are described in this disorder - autosomal dominant (AD), autosomal recessive (AR) and X-linked. HSP is classified in two big clinical groups - pure and complicated. In about 35% of AD cases with pure form are detected mutations in SPG4 (spastin) gene, but can be found in sporadic cases as a result of de novo mutation.

Materials and methods: We performed a genetic screening for SPG4 mutations by direct sequencing in a cohort of 50 AD and sporadic HSP cases from three different ethnic groups (Bulgarian, Gypsy/Roma and Turkish).

Results and discussion: In this study we identified 9 mutations in SPG4 gene, 4 novel (1 splice site mutation, 2 missence and 1 deletion) and 5 already reported (3 missence, 1 nonsense and 1 deletion). In 6 cases the mutations are found in patients with AD type of inheritance. A novel finding for Bulgarian population are mutations in four sporadic cases confirming the need for SPG4 screening of this HSP group. No mutations were found in Turkish patients.

Conclusions: Our findings contribute to a better understanding the molecular basis of HSP and have implications for diagnostic testing and genetic counseling in Bulgarian population.

P12.117

Studying the molecular basis of hereditary spastic paraplegia in Gypsy/Roma patients from Bulgaria

D. Kancheva[1]*, K. Mihova*[1]*, A. Andreeva*[2]*, N. Ivanova*[1]*, V. Mitev*[1]*, I. Tarnev*[2]*, A. Jordanova*[1,3]*;*
[1]*Department of Medical Chemistry and Biochemistry,Molecular Medicine Center, Medical University, Sofia, Bulgaria,* [2]*Clinic of Neurology, University Hospital „Alexandrovska", Department of Neurology, Medical University, Sofia, Bulgaria,* [3]*VIB Department of Molecular Genetics, University of Antwerp, Antwerp, Belgium.*

Hereditary spastic paraplegias (HSP) are a group of rare heterogeneous neurodegenerative disorders, characterized by progressive spasticity and weakness of lower limbs. All modes of inheritance have been described in HSP - autosomal dominant (AD), autosomal recessive (AR) and X-linked recessive. In order to better tackle the genetic heterogeneity of HSP, we are studying Bulgarian Gypsy/Roma families with this disorder. Gypsies share unique features as an isolated population, like high degree of inbreeding, decreased genetic heterogeneity and higher incidence of rare recessive disorders. So far we have collected 44 Gypsy patients belonging to 24 families (4 AD, 14 AR and 6 sporadic).

The dominant and sporadic families were screened for mutations in the spastin (SPG4) gene, the most common cause of AD-HSP. We identified a novel splice site mutation in one patient. The most frequent AR-HSP gene, paraplegin (SPG7), was screened for the recessive families. In only one of all the tested patients was detected a nonsense mutation.

Two consanguineous recessive families were subjected to genome-wide SNP genotyping followed by homozygosity mapping. In the first pedigree with four affected sibs we identified 4 autozygous regions which contain two known HSP genes, AP4E1 and spartin (SPG20), and their sequencing is ongoing. The homozygosity mapping in the other family with three affected sibs identified only four large homozygous regions that do not contain any known HSP gene, suggesting a novel genetic entity. Exome sequencing is currently underway to indentify the underlying genetic defect.

P12.118

Seven novel genetic mutations within the 5'utr and the housekeeping promoter of HMBS gene responsible for the non-erythroid form of acute intermittent porphyria.

F. Granata*, V. Brancaleoni, D. Tavazzi, M. D. Cappellini, E. Di Pierro;*
Dipartimento di Medicina Interna-Fondazione IRCCS Ca' Granda-Università degli Studi di Milano, Milano, Italy.

Acute intermittent porphyria (AIP) is an autosomal dominant disorder caused by molecular abnormalities in the *HMBS* gene. This gene is transcribed from two promoters to produce ubiquitous and erythroid specific isoforms of porphobilinogen deaminase (PBGD). In the classical form of AIP, both isoforms are deficient, but about 5% of families have the non-erythroid variant in which only the ubiquitous isoform is affected. Only one mutation sited in the housekeeping promoter have been previously reported as causative for this form of AIP. In this study we identified one small deletion and six nucleotide substitutions within the 5'UTR and the housekeeping promoter of *HMBS* gene: c.1-440_-427del14bp; c.1-421G>A; c.1-331C>T; c.1-270G>A; c.1-122T>A; c.1-103C>T; c.1-28A>C.

Using luciferase reporter assays and quantitative PCR experiments we characterized the functional role of these seven novel genetic variants demonstrating that all mutations cause a significant loss of transcriptional activity. Our investigations suggest that these nucleotide substitutions may alter critical binding sites for transcriptional factors and they confirm that these regions represent an important molecular target for pathogenesis of non-erythroid form of Acute Intermittent Porphyria.

Abnormal Responses to Visual Cortex Activation in Early Stage Huntington Disease Patients using 31P-Nuclear Magnetic Resonance Spectroscopy

F. Mochel[1]*, T. Nguyen*[1]*, D. Deelchand*[2]*, D. Rinaldi*[1]*, R. Valabregue*[3]*, C. Wary*[4]*, P. G. Carlier*[4]*, A. Durr*[1]*, P. Henry*[2]*;*
[1]*INSERM UMR S975, Institut du Cerveau et de la Moelle, Paris, France,* [2]*University of Minnesota, Center for Magnetic Resonance Research, Minneapolis, MN, United States,* [3]*CEntre de NeuroImagerie de Recherche, Institut du Cerveau et de la Moelle, Paris, France,* [4]*Institut de Myologie, Laboratoire de RMN, Paris, France.*

Objective: To test the hypothesis that brain energy metabolism is abnormal

in patients at an early stage of Huntington disease (HD).
Background: Energy metabolism has been a major focus of HD research for many years due to several observations in both patients and models of the disease. However, there are currently no in vivo biomarkers of brain energy metabolism in HD.
Methods: We coupled noninvasive 31P-NMR spectroscopy with activation of the occipital cortex in order to measure the levels of ATP, phosphocreatine (PCr) and inorganic phosphate (Pi) before, during and after a visual stimulus. We studied 15 HD patients at an early stage of the disease (mean motor UHDRS= 18 ±9) and 15 age- and sex-matched controls.
Results: In controls, we observed an 11% increase in Pi/PCr ratio (p=0.024) and a 13% increase in Pi/ATP ratio (p=0.016) during brain activation, reflecting increased ATP synthesis and ADP levels. Subsequently, controls had a return to baseline levels during recovery (p=0.012 et 0.022 respectively). In HD patients, both Pi/PCr and Pi/ATP ratios were unchanged during and after visual stimulation, reflecting altered mitochondrial bioenergetics. In addition, in HD patients the ratio of Pi/ATP correlated with the UHDRS score during the activation (p=0.014) and recovery periods (p=0.009), while Pi/PCr ratio correlated with the UHDRS score during recovery (p=0.016), reflecting a correlation between brain energy metabolism and disease severity in HD.
Conclusions: 31Phosphorus nuclear magnetic resonance spectroscopy could provide functional biomarkers of brain energy deficit to monitor therapeutic efficacy in Huntington disease.

Expansion of CAG repeats is a common feature of neurodegenerative disorders like Huntington's disease. We show here that expanded CAG repeats bind to a translation regulatory protein complex that contains MID1, PP2A, and the translation factor S6K. Binding of the MID1-PP2A protein complex increases with repeat size and leads to a stimulation of the translation of the CAG repeat expansion containing mRNA in a MID1, PP2A and mTOR dependent manner. Our data indicate that pathological CAG-repeat expansions upregulate translation leading to an overproduction of aberrant protein and suggest the MID1-complex as a promising therapeutic target for CAG repeat expansion disorders.

Pelizaeus-Merzbacher-Like disease (PMLD) is a hypomyelinating leukodystrophy, a disorder involving aberrant myelin formation presenting with rotatory nystagmus, progressive spastic paraplegia, severe motor impairment and neurological deterioration within the first months of life. The known forms of the disease are caused by homozygous mutations in GJA12 and HSPD1.
Two remotely related Bedouin kindred in southern Israel presented with an autosomal recessive phenotype of PMLD. Homozygosity at the two known loci was ruled out in affected individuals. DNA samples of 5 affected individuals and 7 non-affected obligatory carrier first-degree relatives were analyzed using 250k SNP Affymetrix arrays, and fine mapping was done using microsatellite markers. The phenotype-associated locus was mapped to a 8.94 Mb region on chromosome 4q24 (maximum multipoint LOD score of 4.25). Sequence analysis of 14 candidate genes of the 39 genes in the region unraveled a two-nucleotide (CA) deletion mutation in AIMP1/P43 encoding ARS-Interacting Multifunctional Protein 1. AIMP1 functions as a non-catalytic component of the multi-synthetase complex, catalyzing the ligation of amino acids to their cognate tRNAs. The deletion causes a frameshift mutation resulting in a premature stop codon amputating the 312aa protein after 127 aa, abrogating AIMP1/P43's main catalytic domain .The mutation was not found in 200 control chromosomes.

P12.123

Identification of an Alu-mediated 12.2 kb deletion of the complete LPAR6 (P2RY5) gene in a Turkish family with hypotrichosis and woolly hair

H. Mahmoudi[1], *E. Tug*[2], *A. H. Parlak*[3], *H. I. Atasoy*[4], *M. Ludwig*[5], *M. Polat*[3], *S. M. Pasternack*[1], *R. C. Betz*[1];

Hypotrichosis is a rare form of progressive hair loss characterized by sparse and occasionally woolly hair that is curly and breaks easily. Disease causing mutations in LIPH, LPAR6 and KRT74 have recently been identified. We describe a four generation pedigree from Turkey following an autosomal recessive pattern, in which the four affected members had hypotrichosis and woolly hair. By sequencing LPAR6 and the use of SNP-arrays we revealed a homozygous loss of the entire LPAR6 gene in the affecteds. We hypothesize that the 12 kb deletion resulted from illegitimate recombination secondary to slip-replication. The orientation of three Alu repeats around LPAR6 may have provoked the formation of a 'triple barrel' structure during replication, thereby allowing strand slipping. This first report of complete LPAR6 loss expands the spectrum of known LPAR6 mutations, and suggests a novel mechanism for this gene and for the formation of DNA rearrangements in general.

P12.124

A single amino acid residue deletion, p.Leu3230del, in the brain-specific isoform Dp71 of dystrophin results in intellectual disability without muscular dystrophy

A. P. M. de Brouwer[1], *S. B. Nabuurs*[2], *A. R. Oudakker*[1,3], *R. Hordijk*[4], *H. G. Yntema*[1], *J. M. Hordijk-Hos*[4], *K. Voesenek*[1], *B. B. A. de Vries*[1], *T. van Essen*[4], *H. We have identified a single amino acid residue deletion, p.Leu3230del, in the brain-specific isoform Dp71 of dystrophin in a family with nonspecific X-linked intellectual disability by sequencing of all exons of the X chromosome. Linkage analysis supported causality as the mutation was present in the 7.6 cM linkage interval on Xp22.11-Xp21.1 with a maximum positive LOD score of 2.41. Molecular modeling predicts that the p.Leu3230del deletion results in the destabilization of the C-terminal domain of dystrophin and hence reduces the ability to interact with β-dystroglycan. Subsequent determination of the creatine kinase levels in blood of the index patient indeed showed a mild but significant elevation in serum creatine kinase, which points to impaired dystrophin function. Taken together, these data indicate that we have identified the first *DMD* mutation in Dp71 that results in intellectual disability without muscular dystrophy.

P12.125

Unravelling the genetic causes of syndromic Intellectual Disability in the era of exome sequencing.

Intellectual Disability (ID) represents a large and heterogeneous group of disorders with variable phenotypes and severity, and impaired intellectual abilities as a common feature. Although the number of ID causing genes is increasing rapidly, at present the genetic aetiology remains unexplained for 60% of the ID forms, thus no molecular diagnosis can be made for the majority of the patients. With the aim to identify new genetic causes of ID, we used the exome sequencing approach and focused on syndromic autosomal recessive forms. So far we selected 4 families of Sardinian origin with at least 2 patients affected by Multiple Congenital Anomalies and Intellectual Disability (MCA/ID) associated into a clinically undefined syndrome, and 1 family with 1 patient affected by Filippi syndrome with unknown genetic aetiology. Up to date, 6 samples from 2 families were sequenced with the TruSeq Exome Enrichment Kit (Illumina). On average, 140,000 variants (SNVs and indels) were identified, of which 7% were novel (not yet included in dbSNP 132). Among the novel variants, on average 980 fall in exons and 1,452 in UTR regions, and we are currently searching the potential causative variants related to the diseases by applying a standard step-wise filtering approach. Our study will contribute to the molecular diagnosis of a larger number of subjects by improving the existing map and networks of ID causative genes, and likely to the detection of new syndromes through the so-called “reverse dysmorphology”, ie, using an approach from genotype to phenotype.

Pitfalls of whole exome-sequencing: hidden *DYNC2H1* mutations in patients with Jeune Asphyxiating Thoracic Dystrophy

H. H. Arts[1], *M. Schmidts*[2], *E. M. H. F. Bongers*[1], *M. M. Oud*[1], *L. Duijkers*[1], *Z. Yap*[2], *J. Stalker*[3], *J. L. Yntema*[4], *A. Hoischen*[1], *C. Gilissen*[1], *J. A. Veltman*[1], *A. Kutkowska*[5], *E. Kamsteeg*[1], *P. Scambler*[2], *P. L. Beales*[2], *-. UK10K Consortium*[3], *N. V. A. M. Knoers*[6], *R. Roepman*[1], *H. M. Mitchison*[2];
[1]*Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands,* [2]*Molecular Genetics Molecular Medicine Unit, Institute of Child Health, University College London, London, United Kingdom,* [3]*Wellcome Trust Genome Center, Cambridge, United Kingdom,* [4]*Department of Paediatrics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands,* [5]*Department of Medical Genetics, Institute of Mother and Child, Warsaw, Poland,* [6]*Department of Medical Genetics, University Medical Centre Utrecht, Utrecht, Netherlands.*

In recent years whole-exome sequencing has been developed, a technique by which all exons of the genome (all the protein-coding DNA) can be sequenced at once. Here we show that whole-exome sequencing, using either 35 or 50 Mb Agilent kits for exome capture, was insufficient to detect pathogenic *DYNC2H1* variants in patients with Asphyxiating thoracic dystrophy (ATD; Jeune syndrome). Jeune syndrome is a rare inherited ciliopathy involving chondrodysplasia characterized by shortened ribs and long bones, and polydactyly, progressive kidney and liver disease as well as retinitis pigmentosa. Reduced thoracic capacity causes approximately 60% early lethality. *DYNC2H1* encodes a subunit of the dynein 1B motor that drives tip-to-base ciliary intraflagellar transport, and mutations have previously been associated both with embryonically lethal short rib-polydactyly and the milder, but overlapping Jeune aspyxiating thoracic dystrophy. Although the *DYNC2H1* gene was targeted in our whole-exome experiments many sequence reads were not properly aligned, resulting in 30-70% of the gene not being covered. Only a combination of whole-exome sequencing and a candidate gene approach (i.e. analysis of non-covered *DYNC2H1* exons using Sanger sequencing) enabled us to detect the missing *DYNC2H1* mutations. Whole-exome data analysis of the 90 exon *DYNC2H1* gene is therefore comparable to playing ‘hide and seek’, whereby certain mutations are easier to find than others according to their relative coverage. In conclusion, although whole-exome sequencing has revolutionized the field of human genetics, our findings emphasize that next-generation sequencing also presents significant challenges for gene identification and for implementation of this technique in DNA diagnostics.

P12.127

Molecular analysis of Polish patients with junctional epidermolysis bullosa

J. Sota[1], *K. Wertheim-Tysarowska*[1], *C. Kowalewski*[2], *K. Woźniak*[1], *A. Kutkowska-Kaźmierczak*[1], *A. Sobczyńska-Tomaszewska*[1], *J. Bal*[1];
[1]*Department of Medical Genetics, Institute of Mother and Child, Warsaw, Poland,*
[2]*Department of Dermatology, Medical University of Warsaw, Warsaw, Poland.*

Junctional epidermolysis bullosa (JEB) is a rare, autosomal recessive genodermatosis characterized by spontaneous or mechanically induced blisters formation at the level of lamina lucida of the epidermis-dermis junction. Clinical outcome of the disease varies from generalized, lethal Herlitz subtype, to milder, sometimes localized- non Herlitz JEB.

JEB is mostly caused by mutations in *LAMB3, LAMC2, LAMA3* encoding laminin332 and *COL17A1* encoding collagen type 17 - extrcellular proteins linking hemidesmosomes to extracellular matrix in epidermis-dermis junction.

According to literature data, mutations in *LAMB3* are most frequently found worldwide in JEB patients and some recurrent mutations were identified in this gene in different populations.

The aim of the study was to investigate the mutation spectrum in Polish JEB patients.

11 patients with clinical features of Herlitz-JEB (3 cases) or non-Herlitz JEB (7 patients), and a couple with history of 3 children demised of Herlitz-JEB were enrolled to the study. DNA analysis was performed using direct sequencing.

We established full genotype in 6 cases. The other patients are still under analysis. In 5/6 cases we detected mutations in *LAMB3* gene. 40% of mutated alleles accounted for R635X, in 30% of them we found c.1439_1443del and in 20% novel c.965_966+8del. Our preliminary results indicate that R635X is the commonest mutation in Polish JEB patients, as it is in general population, and that at least 2 other mutations - uncommon in other European countries- are recurrent in Poland. This finding has a practical impact while preparing an algorithm of molecular analysis for Polish JEB patients.

P12.128

Incomplete penetrance of a novel *KCNQ1* mutation in a large family with long QT syndrome

Z. Shinwari, *N. Dzimiri, M. Al-Fayyadh, Z. Al-Hassnan;*
King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia.

Congenital long QT syndrome (LQTS) is an inherited potentially fatal arrhythmogenic disorder that is characterized by prolonged corrected QT (QTc) interval. Mutations in 3 genes (*KCNQ1*, *KCNH2*, *SCN5A*) account for the majority of the cases. However, 10 other genes are now known to be implicated in LQTS. In this work, we describe the clinical and molecular analysis in a large family with LQTS. Screening *KCNQ1*, *KCNH2*, *SCN5A* genes in the proband, who presented with episodes of syncope led to the identification of a novel heterozygous mutation (c.773 A> C; p.H258P) in *KCNQ1*. An extended clinical and genetic screening of the family identified 11 other members who were carriers for this mutation. All identified carriers had prolonged QTc intervals, yet, only two of them were clinically symptomatic. Nevertheless, the electrocardiographic and molecular analysis stratified seven carriers at high-risk of a cardiac event as they had a QTc of ≥ 500 ms and were carriers of a *KCNQ1* mutation. Our work illustrates the importance of extended family screening in LQTS to identify silent carriers and hence adopt the most appropriate therapeutic and preventive intervention.

P12.130

Inherited cystic kidney disease: a molecular screening in Italian patients

A. Aquilano[1,2], *C. Graziano*[3], *O. Baraldi*[2], *E. Sestigiani*[4], *E. Marasco*[1], *A. Prossomariti*[1], *M. Seri*[3], *A. Santoro*[4], *G. La Manna*[2], *S. Stefoni*[2], *V. Mantovani*[1,3];
[1]*Center for Applied Biomedical Research (CRBA), S.Orsola-Malpighi Hospital, Bologna, Italy,* [2]*Department of Internal Medicine, Aging and Kidney Diseases, Bologna University, Bologna, Italy,* [3]*Unit of Medical Genetics, S.Orsola-Malpighi Hospital, Bologna, Italy,* [4]*Unit of Nephrology, Dialysis and Hypertension, S.Orsola-Malpighi Hospital, Bologna, Italy.*

Inherited kidney diseases are a heterogeneous cause of renal failure with great clinical variability. Once ultrasound and urinalysis have excluded polycystic kidney and glomerulonephritis, family history can help to distinguish nephronophthisis (recessive) from dominant nephropathies. Clinical features can also help to define the specific diagnosis, but this is still a demanding task due to phenotypic overlap.

Purpose of this study was to perform a molecular screening of some genes associated with these disorders, in order to validate a diagnostic algorithm related to clinical phenotypes, useful to drive the genetic screening. *NPHP1*, *NPHP5*, *UMOD*, *REN* and *HNF1B* genes were selected for the analysis. DNAs from 12 Italian patients with inherited nephropathies were submitted to direct sequencing. Furthermore, deletion analysis by multiplex PCR for *NPHP1* and MLPA for *HNF1B* were performed.

Three causative mutations were detected: 1) a novel heterozygous p.E48K variant in *REN* found in a patient with cystic nephropathy, hyperuricemia, hyperkalemia and anemia. The mutation lies in a conserved position, cosegregated with affected family members and was absent in 50 chromosomes; 2) a homozygous p.R489X mutation in *NPHP5* gene was detected in a patient with retinitis pigmentosa and recurrent cholangitis, confirming the diagnosis of Senior-Locken Syndrome. This mutation was previously reported in a Pakistani family; 3) a heterozygous pR295C variant in *HNF1B* was identified in a patient with renal failure and diabetes mellitus. This mutation is known to alter the DNA binding domain and was not previously reported in Italy. These preliminary results are promising for defining a diagnostic algorithm.

P12.131
A mutation detected by exome sequencing and phenotypic variability in a family with Lenz microphthalmia syndrome

T. KANAME[1], *K. Yanagi*[1], *Y. Muramatsu*[2], *T. Tohma*[1], *Y. Itagaki*[3], *H. Taniai*[4], *K. Kurosawa*[5], *S. Mizuno*[2], *K. Yoshiura*[6], *K. Naritomi*[1];
[1]University of the Ryukyus, Nishihara-cho, Japan, [2]Central Hospital, Aichi Human Service Center, Nagoya, Japan, [3]Suita Municipal Hospital, Osaka, Japan, [4]Nagoya Child Welfare Center, Nagoya, Japan, [5]Kanagawa Child Medical Center, Yokohama, Japan, [6]Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan.

Lenz microphthalmia syndrome was first described as a type of X-linked microphthalmia in 1955. It is known to exhibit genetic heterogeneity and two loci, Xq27-q28 and Xp11.4, have been mapped to be associated with the syndrome.

We met a large family with syndromic microphthalmia. Bilateral but asymmetric microphthalmos and mental retardation were observed in all the patients and cardiovascular malformations or renal abnormalities were observed in some patients, showing phenotypic variability. All patients were male and the pedigree indicated X-linked recessive inheritance. According to their clinical findings and the form of inheritance, patients were diagnosed with Lenz microphthalmia syndrome.

Whole exome sequencing was performed by using a next-generation sequencer and TruSeq Exome Enrichment system (illumina) to identify a mutation in the family. Pooled DNA with four affected males in the family was used for one exome analysis to enrich hemizygous variations in the patients.

Of 552 called SNPs or indels on X chromosome, 51 were novel (not registered in the SNP131). Four hemizygous (not detected as heterozygous) variations were found in exons. After comparison of exome data between affected and unaffected males, one substitution, c.C254T, was identified and was confirmed by direct Sanger sequencing in all the patients. In addition, we confirmed heterozygous mutation in all female carriers as well.

We concluded that the mutation was responsible for the patients.

P12.132
Three novel mutations in Leptin and Leptin Receptor genes among 3 Egyptian families

M. A. El-Gammal[1], *K. Amr*[1], *M. Abdel-Hamid*[1], *S. Farooqi*[2], *I. Mazen*[1];
[1]National Research Centre, Cairo, Egypt, [2]Cambridge University, Cambridge, United Kingdom.

Background: Congenital leptin deficiency and congenital leptin receptor deficiency are a rare recessive genetic disorder resulting in severe hyperphagia and early onset obesity. It is caused by mutations in the LEP gene encoding leptin and mutations in the congenital leptin receptor gene respectively.

Objective: We report 6 patients from 3 Egyptian families presenting with severe hyperphagia and early onset obesity.

Method: Genomic DNA was extracted from peripheral blood leukocytes of all patients and their family members using a standard method. Direct sequencing of the whole coding region of the leptin gene was carried out in the two families with undetectable serum leptin levels while sequence analysis of the LEPR gene was performed in the third family with high serum leptin levels.

Results: We detect one novel missense mutation in the leptin LEP gene (N103K) and another novel nonsense mutation in the leptin LEP gene (W121X) as well as a missense mutation in the Leptin receptor gene LEPR (P316T).

Conclusion: Although genetic causes of obesity are rare autosomal recessive disorders, high consanguinity rate in our society will lead to the discovery of a high number of monogenic obesity.

P12.134
Transcriptional dysregulation in Hutchinson-Gilford progeria syndrome patients compared to age-matched controls

R. Blatny[1], *Z. Zubacova*[1], *I. Novakova*[2], *L. Jarolimova*[2], *V. Philimonenko*[2], *Z. Halbhuber*[1], *P. Hozak*[2], *V. Krivjansky*[1], *M. Krivjanska*[1];
[1]KRD s.r.o, Prague, Czech Republic, [2]IMG, Prague, Czech Republic.

Hutchinson-Gilford progeria syndrome (HGPS) is a rare genetic condition with symptoms of premature aging manifested at a very early age. Patients born with progeria typically live to their mid teens or early twenties and the most frequent cause of death is myocardial infarction or stroke. HGPS is usually caused by dominant mutations in the lamin A (LMNA) gene. There are 22 known LMNA mutations associated with the development of HGPS that have been published in the literature to date. These mutations can be detected by the classical or next generation sequencing, high resolution melting analysis (HRMA) and denaturing high-performance liquid chromatography. At the subcellular microscopic level, the disease is manifested by morphological abnormalities in nuclear envelope structure. Within the framework of our ongoing effort to integrate technologies (and their results) used to gain the information about genomic mutations (classical or next-gen sequencing, scanning or unlabelled-probe HRMA), gene expression (qPCR, microarray analysis, next-gen sequencing) and its regulation (ChIP-chip, ChIP-qPCR, ChIP-seq) in HGPS patients which could be further used to improve diagnosis, prognosis, treatment and the overall quality of life of the HGPS patients we conducted a pilot experiment on gene expression in fibroblast cell lines from four HGPS patients and four age-matched controls. Our reliminary data on this small group of target and control samples showed that the most affected biological processes are transcription, signal transduction, development and signal transduction. This work was supported by the grant FR-TI3-588 from The Ministry of Industry and Trade of the Czech Republic.

P12.135
Genome-wide SNP analysis to identify genetic modifiers for long QT syndrome in a consanguineous population

Z. N. Al-Hassnan, *S. Tulbah*, *M. Al-Fayyadh*;
King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia.

Congenital long QT syndrome (LQTS) is an inherited potentially fatal arrhythmogenic disorder that is characterized by variable expressivity and incomplete penetrance. Common variants in *KCNQ1*, *KCNE1*, and *NOSA1P* genes have been recently implicated in modifying the risk of life-threatening arrhythmias in LQTS. In our highly consanguineous population, we conducted genome-wide SNP analysis in 15 families with LQTS to identify regions of homozygosity (ROH) that harbor loci known to be associated with either LQTS or risk of sudden cardiac death. In two families with previously known homozygous *KCNQ1* (LQT1) mutations, ROH encompassing *AKAP9* (LQT11) and *SNTA1* (LQT12) that were detected. In a third family, a ROH that harbors *ADRB2* gene, known to be associated with SCD without LQTS, was identified. In the context of consanguinity, our work illustrates the value of homozygosity analysis for detecting genetic modifiers in LQTS. In addition, our approach could also be adopted to detect the presence of digenic inheritance in consanguineous families with LQTS.

P12.136
Towards a better prediction of the age at onset in Spinocerebellar ataxia type 3

T. Schmidt[1], *L. Dengler*[1], *J. Schroeder*[1], *T. Tsoleridis*[1], *J. J. Weber*[1], *T. Karsunke*[1], *H. Pétursson*[1,2], *P. Bauer*[1], *O. Riess*[1];
[1]University of Tuebingen, Medical Genetics, Tuebingen, Germany, [2]Statistics Iceland, Reykjavík, Iceland.

Spinocerebellar ataxia type 3 (SCA3) or Machado-Joseph disease (MJD) is an autosomal-dominantly inherited, neurodegenerative disorder caused by the expansion of a CAG repeat in the *MJD1 gene*.

Statistically, a correlation between the number of CAG repeats and the age at onset of SCA3 patients exists and patients with more CAG repeats have an earlier onset of symptoms. However, this statistical correlation is not perfect and the number of CAG repeats contributes only about 55 % to the age at onset. Therefore, the remaining 45 % are influenced by other factors, which we aim to identify in this study. Aside from the CAG repeat itself, the *MJD1 gene* contains several polymorphisms within the coding region which lead to amino acid changes or even a premature stop in the encoded ataxin-3 protein.

Here, we assume that the amino acid changes within ataxin-3 resulting from these polymorphisms influence the function of normal and expanded ataxin-3 and/or its interaction with other proteins and therefore modify the age at onset, the pathogenesis and disease progression of SCA3 patients. We, therefore, genotyped more than 500 samples of SCA3 patients for these polymorphisms and generated haplotypes comprising the CAG repeat length and the polymorphisms located downstream. Two haplotypes turned out to be most common among SCA3 patients and additional haplotypes have a possible impact on the age at onset in SCA3. We hope that our results will improve the prediction of clinical symptoms and contribute to the understanding of pathogenic processes in SCA3.

P12.137
Applying Next Generation Sequencing to Molecular Diagnosis of Marfan and Loeys-Dietz Syndromes

E. Weis, *M. Willam*, *S. Lechno*, *C. Poarangan*, *D. Galetzka*, *O. Bartsch*, *U. Zechner*;
Institute of Human Genetics, University Medical Center of the Johannes Gutenberg University Mainz, Mainz, Germany.

The Marfan syndrome (MFS) and the phenotypically related Loeys-Dietz syndrome (LDS) are caused by mutations in the genes coding for Fibrillin-1 (FBN1), Transforming Growth Factor Beta Receptor 1 and 2 (TGFBR1 and TGFBR2) and Sma- and Mad-related Protein 3 (SMAD3). Molecular diagnostics of thes two syndromes by PCR sequencing using the Sanger method is time-consuming and expensive, especially for the FBN1 gene with its 65 exons.

As an alternative, we started sequence analysis of these genes using a multiplex PCR approach followed by Next Generation Sequencing (NGS) on the Roche GS Junior System. Plexes were designed in silico considering amplicon length and avoiding potential primer dimer formations using the online tool http://biocompute.bmi.ac.cn/MPprimer/primer_dimer.html. Amplicons that comprise the up to now not extensively studied regulatory regions in the promoter and 5'-UTR areas of the four genes were also included. To distinguish and resolve correct amplification of all multiplex PCR products before NGS analysis, we performed PCR with Cy5-tagged M13 primers and subsequent detection by fragment analysis in a capillary sequencer.

Up to now, we studied genomic DNA samples from 11 patients with previously identified mutations and/or polymorphisms in FBN1, TGFBR1, TGFBR2 and SMAD3 and all known variants were correctly identified. Analyses of samples of 30 patients suspected of having MFS/LDS that have not yet been investigated for mutations in TGFBR1, TGFBR2 and SMAD3 are in progress. Mutation screening using this combined multiplex PCR-NGS approach is suitable to make diagnostics faster and less expensive.

P12.138

A recurrent ALU repeat-mediated deletion within the NFIX gene accounts for a missing part in Marshall-Smith syndrome

D. Schanze[1]*, D. Neubauer*[1]*, V. Cormier-Daire*[2]*, R. C. M. Hennekam*[3]*, M. Delrue*[4]*, D. de Silva*[5]*, T. Hasegawa*[6]*, R. Koenig*[7]*, G. Krueger*[8]*, F. Petit*[9]*, I. Schanze*[1]*, E. Seemanova*[10]*, T. M. Strom*[11,12]*, P. Meinecke*[13]*, A. Reis*[14]*, M. Zenker*[1]*;*

Marshall-Smith syndrome (MSS) is a recognizable entity characterized by moderate to severe developmental delay, skeletal abnormalities, upper airway obstruction, and distinctive facial features. Mutations in the gene NFIX were recently discovered as the cause of MSS (Malan et al. AJHG 2010). In six patients exhibiting the typical phenotype, we identified four novel NFIX frameshift and splice-site mutations by direct sequencing, while two individuals turned out normal. For further evaluation, we set up an MLPA-based screening for exon deletions or duplications. Both patients were found to carry a heterozygous deletion of exons 6 and 7 of the NFIX gene. The same deletion was found in three additional cases of a cohort of 15 MSS patients, of which 9 were previously found to have NFIX point mutations. Breakpoint sequencing revealed the deletion to be mediated by a recombination event between ALU-Y repeats located in introns 5 and 7. Further studies on the mRNA level indicated that the transcript lacking exons 6 and 7 escapes nonsense-mediated mRNA decay, thus suggesting that the deletion leads to the expression of a mutant protein rather than haploinsufficiency of NFIX. We conclude that the recurrent NFIX deletion is specific for MSS, because it mimics the effects of other MSS-associated mutations that are thought to generate mutant proteins able to exert a dominant-negative effect over the wild-type allele. Intronic ALU repeats create predetermined breaking points facilitating *de novo* occurrence of this deletion, a mechanism that accounts for about one quarter of MSS cases in our joint cohort.

P12.139

Accumulation of nonsyndromic hearing loss associated with *Marveld2* gene mutation in Slovak and Hungarian Roma patients

A. Soltysova[1]*, A. Ficek*[1]*, I. Posta-Janicsek*[2]*, K. Komlosi*[2]*, C. Sipeky*[2]*, B. Melegh*[2]*, L. Kadasi*[1,3]*;*

[1]*Comenius University, Faculty of Natural Sciences, Dpt. of molecular biology, Bratislava, Slovakia,* [2]*University of Pecs, Department of Medical Genetics, Pecs, Hungary,* [3]*Slovak Academy of Sciences, Institute of Molecular Physiology and Genetics, Bratislava, Slovakia.*

The wide group of nonsyndromic hearing loss disorders (NSHL) is one of the most common sensory impairment in humans. Approximately 50% of all cases are caused by genetic factors. Among all types of monogenic, Mendelian traits, autosomal recessive form stands for nearly 80% of all NSHL cases. The group of hearing disorders is characterized by tremendously high locus and allele heterogeneity with over hundred genes associated to these disorders. Most frequently analyzed genes in NSHL patients worldwide are *GJB2, GJB6, MYO7A, MYO15A, SLC26A4,* and *TMPRSS3*. In respect to the patient's population origin, mutations in otherwise scarce genes may occur in higher frequencies in some specific populations. Demographic history and population structure of Roma in Europe resulted in occurrence of such population specific mutations which are otherwise very rare or unseen in autochthonous populations in Europe. Studying a large Hungarian family of Roma origin with multiple NSHL patients we identified a founder mutation, IVS4+2T>C of the *MARVELD2* gene, previously identified in Pakistani patients. To test the prevalence of the identified mutation analyzed 167 Hungarian and 300 Slovak NSHL patients regardless the ethnic origin. Random population sample biobanked from unrelated healthy 502 Hungarian and 300 Slovak Roma individuals were also tested. Heterozygous presence of IVS4+2T-C mutation among healthy, control Roma individuals proved the population specific character of this mutation in Hungary and Slovakia. The common origin of the surveyed mutation identified in Hungarian and Slovak Gypsy patients was further analyzed using set of SNP markers located adjacent to the *MARVELD2* gene locus.

P12.140

Screening of a large cohort with UMOD associated kidney disease (UAKD) for mutations in UMOD, HNF1beta and Renin

A. Pannes[1]*, M. T. F. Wolf*[2]*, B. B. Beck*[1]*;*

[1]*Institute of Human Genetics, University of Cologne, Cologne, Germany,* [2]*Pediatric Nephrology, University of Texas Southwestern Medical Center, Dallas, TX, United States.*

A spectrum of slowly progressive autosomal dominant kidney disease characterized by hyperurecaemia, reduced Uromodulin excretion, renal cysts, and endstage renal failure between the third and seventh decade is subsumized under the term UMOD associated kidney disease (UAKD).

The UMOD gene encoding for Uromodulin was the first MCKD gene identified. Mutations often affect a cysteine residue and result in endoplasmatic reticulum retention and subsequent reduced urinary excretion. However the precise pathopyhsiology of tubulointerstitial damage is ill understood.

Next to UMOD, mutations in HNF1beta can result in a similar clinical presentation.

Recently, dominant Renin mutations were shown to result in a UAKD phenotype. Initially recessive mutations in Renin were identified as one cause of renal tubular dysgenesis.

Here we report the results of a stepwise mutational analysis in 71 families compatible with a diagnosis of UAKD.

UMOD mutations were identified in 25, while HNF1beta mutations could be identified in 7 families. On the remaining 39 families complete Renin analysis identified one kindred with a mutation in the signal sequence (p.W10R) affecting four generations. We report the youngest patient showing renal impairment as early as 11 months of age and provide further functional data on signal sequence mutations. Only 4 heterozygous REN mutations all within the signal peptide have been published. For the three previously described mutations, a damaged targeting and cotranslational translocation of preprorenin into the endoplasmatic reticulum had been shown.

This study illustrates that the genetic of cause still remains to be identified in the majority of patients suffering from UAKD.

P12.141

Cellular localization of MCPH1 isoforms and effects of MCPH1 mutations on G2/M checkpoint release

I. Rost*, T. Staab, D. Schindler;*

Department of Human Genetics, Würzburg, Germany.

Biallelic mutations in the human MCPH1 gene are the cause of primary microcephaly associated with a unique cellular phenotype marked by premature chromosome condensation (PCC syndrome) in G2 phase and delayed decondensation post mitosis. MCPH1 encodes a multifunctional protein that was reported to be involved in brain development, DNA damage response and regulation of chromosome condensation.

In previous work of our group, Gavvovidis et al. found that MCPH1 encodes two major transcripts, full-length MCPH1 (MCPH1-FL) and another transcript lacking the six 3' exons (MCPH1Δ9-14). In addition, a splice variant lacking exon 8 (MCPH1Δ8) was detected. Here we re-examined the cellular localization of those isoforms after centrosomal localization of full-length MCPH1 had been reported by several groups. By transfection of human cell lines (U2OS, HeLa) with FLAG-tagged constructs, we were unable to satisfactorily show any of the MCPH1 isoforms colocalizing with centrosomes. We conclude that such localization must be a temporary or cell type-specific phenomenon.

Furthermore, experiments using knockdown of MCPH1 by RNAi or MCPH1-deficient MEFs had previously shown severe effects on the cellular response to DNA damage after irradiation. Here we compared the effect of patient-derived MCPH1 mutations on G2/M checkpoint control. We determined the mitotic index by phospho-histone-H3 flow cytometry after irradiation of cells with 1 Gy. There was no difference in terms of G2/M checkpoint control compared to normal control cells. However, delayed checkpoint release was observed in all of the analyzed MCPH1-deficient cell lines, featuring the way in which DNA damage response to IR is defective.

P12.142

Phenotypical consequences of mild Mecp2 overexpression in the mouse as an experimental approach to estimate gene-dose effects

*C. Bodda[1,2], M. Tantra[3], J. P. Arunachalam[1], K. Can[1], H. Ehrenreich[3,2], **A. U. Mannan**[1,2];*
[1]Instiute of Human Genetics,University Medical Center Goettingen, Göttingen, Germany, [2]DFG-Research Center Molecular Physiology of the Brain, Göttingen, Germany, [3]Division of Clinical Neuroscience, Max Planck Institute of Experimental Medicine, Göttingen, Germany.

Overexpression of MeCP2 as found in the MECP2 duplication syndrome has a detrimental effect in both human and mouse. Thus, any future therapies directed at increasing the levels of MeCP2 in the patient must be considered carefully to avoid further neurological impairments. To estimate gene dose effects and predict the level at which potential non-tolerable side effects might occur, mouse models with mild overexpression are instrumental. We generated Mecp2_WT_EGFP transgenic mouse, in which the total amount of MeCP2 (endogenous plus transgenic) is mildly overexpressed (~1.5X). When Mecp2_WT_EGFP mice were crossed with Mecp2 knockout (KO) mice, our preliminary analysis suggest that major phenotypes of the KO mice were rescued, however further investigation will be necessary to exclude any late stage symptoms. To characterize Mecp2_WT_EGFP mouse model, we performed an extensive test battery which, apart from increased aggressiveness and seizure propensity, revealed essentially unaltered behavior. Evaluation of neuronal parameters both ex vivo and in vivo revealed no major abnormalities. Also, expression analysis of differentially regulated Mecp2 target genes, such as Bdnf, Ddc, Gdf11, Gpr26, Lrp1b, Pygm and Robo1 by quantitative RT-PCR analysis in Mecp2_WT_EGFP mice revealed only minor alteration in the expression of Mecp2 target genes. In contrast, a transgenic mice overexpressing 2X Mecp2 has been reported earlier to have considerable effects on target gene expression. We conclude that quantitative RT-PCR analysis of Mecp2 target genes may be a suitable approach to evaluate in future the success of MeCP2 supplementary therapy.

P12.143

MEFV mutations in patients with Familial Mediterranean Fever from Antalya province, Turkey

***I. Keser**[1], T. Bilgen[1], O. Altiok-Clark[2], R. Artan[3], G. Süleymanlar[4], E. Coban[5];*
[1]Department of Medical Biology and Genetics, Medical Faculty, Antalya, Turkey, [2]Department of Medical Genetics, Medical Faculty, Antalya, Turkey, [3]Department of Pediatric Gastroenterology, Medical Faculty, Antalya, Turkey, [4]Department of Nephrology and Organ Transplantation, Medical Faculty, Antalya, Turkey, [5]Department of Internal Medicine, Medical Faculty, Antalya, Turkey.

Familial Mediterranean Fever (FMF) is mainly autosomal recessive and the most frequent hereditary inflammatory disease characterized by fever, arthritis, serosal inflammation and amyloidosis. FMF affects different ethnic groups and countries including Turkey, connected with the MEFV gene mutations. In this study, we reviewed the data of 2283 FMF suspected patients (1281 female and 1002 male) from May 2003 to December 2011. Automated DNA sequencing was used to identify the mutations in exon 2 and exon 10 of MEFV gene. Of 2283 suspected patients, 1065 (46.64%) had MEFV gene mutation and 52,84% of them were female. Seventeen different mutations (M694V: 67%, E148Q: %14.8, V726A: 11.4, M680I: 9.27%, R761H: 2.19%, K695R: 1.91%, A744S: 1.41%, M694I: %1.2, K695M: 0.14%, E230K: 0.63%, E167D: 0.42%, T267I: 0.014%, and E225D, E251K, L110P, V653I, M680V with 0.07% frequency) were found. Of these mutations, 16 different heterozygote and 10 different homozygote genotype were detected. The most five common mutations were M694V, E148Q, V726A, M680I, and R761H in order. Although the allelic frequency of V726A (9.21%) was found lower than E148Q (14.8%), the frequency of M694V/V726A compound heterozygote was found as higher than M694V/E148Q.

In conclusion, we first time report the mutations of MEFV gene from Antalya province in Southern of Turkey, and found different mutation types and frequencies than previous reported studies in Turkey.

P12.144

SHANK3 Microdeletion in a patient suspected to Rubinstein-taybi syndrome

***j. Malbin**[1], R. Tagi Aliyev[2], Z. Sharifi[3], N. Khazaeii[4], H. Bagerian[4], M. Masodifar[4], M. Falah[4], S. Zeinali[5];*
[1]1. ANAS Genetic Resources Institute ,Baku, Azerbaijan, 3. Genetic Counselling Center, State Welfare Organization, Urmia, Iran, uromieh, Islamic Republic of Iran, [2]anas, baku, Azerbaijan, [3]2. Kawsar Human Genetics Research Center (KHGRC), Tehran, Iran, tehran, Islamic Republic of Iran, [4]Kawsar Human Genetics Research Center (KHGRC), Tehran, Iran, tehran, Islamic Republic of Iran, [5]epartment of Molecular Medicine, Biotech Research Center, Pasteur Institute of Iran, Tehran, Iran, tehran, Islamic Republic of Iran.

Mental retardation (MR) is a heterogeneous disorder with genetic and non-genetic etiology affecting 1 to 3% of the general population. Here we describe a copy number variation in a patient with MR and multiple congenital anomalies (MCA).

A 24 years old man with a history of infantile hypotonia and childhood developmental delay was referred to our clinic. His dysmorphic feature includes short stature, heavy eyebrows, ptosis, speech difficulty and high arched palate. He had convulsion episode due to epilepsy from 5 years old.

Conventional cytogenetic study revealed no abnormal finding. Further investigation was performed using Multiplex Ligation Probe Amplification (MLPA) technique with P245 kit, P070 and P036 kits (SALSA, MLPA Kit, MRC, Holland) to screen microdeletion syndromes and subtelomeric rearrangements. MLPA results were analyzed by Genemaker V1.95.

Micro-deletion was detected in CREBBP gene (16p13.3) and SHANK gene (22q13.33) in P245-kit. A subtelomeric micro-deletion was detected in DECR2 gene in P070 kit.

Patient's phenotype could be explained by this genetic finding as CREBBP gene is a known cause of Rubinstein-Taybi Syndrome (RTS) in most of cases. Nearly 3% of RTS are related to the deletion in EP300 gene (22q113.2) which was not investigated here. However we detected SHANK3 gene deletion that is characterized by severe expressive-language delay and mild mental retardation.

This is the first report of deletion in SHANK3 gene in Rubinstein-Taybi Syndrome that could be confirmed and further characterized by other methods like FISH, array CGH or confirmatory MLPA kit.

P12.145

Primary microcephaly (MCPH): Expanding the phenotype

***K. Müller**[1], K. Seufert[1], C. Korenke[2], G. Uyanik[3], U. Grasshoff[4], B. Albrecht[5], A. Kuechler[5], S. Liu[1], A. Hotz[1], H. Rosenkötter[6], M. Buob[6], M. Nikolaidou[7], E. Rudd[8], A. Kutkowska-Kazmierczak[9], E. Obersztyn[9], D. Bartholdi[10], S. Azzarello-Burri[10], B. Hartmann[1], C. Zeschnigk[1], D. J. Morris-Rosendahl[1];*
[1]Institute of Human Genetics, Freiburg, Germany, [2]Zentrum für Kinder- und Jugendmedizin, Klinikum Oldenburg, Oldenburg, Germany, [3]Institut für Humangenetik, Hamburg-Eppendorf, Germany, [4]Medizinische Genetik, Universitätsklinikum Tübingen, Tübingen, Germany, [5]Institut für Humangenetik, Universitätsklinikum, Essen, Germany, [6]Sozialpädiatrisches Zentrum, Ludwigsburg, Germany, [7]Department of Neuropediatrics, Astrid Lindgrens Childrens Hospital, Stockholm, Sweden, [8]Clinical Genetics, Karolinska University Hospital, Stockholm, Sweden, [9]Department of Medical Genetics, Institute of Mother and Child, Warsaw, Poland, [10]Institut für Medizinische Genetik, Universität Zürich, Zürich, Switzerland.

Primary MCPH (MCPH) defines congenital microcephaly with an occipito-frontal circumference (OFC) two standard deviations (SD) or more below the age- and sex-related mean. It is genetically heterogeneous with at least seven known loci and genes (MCPH1 to 7), for which autosomal recessive inheritance of mutations has been shown in families. Primary MCPH was initially defined as excluding gross structural brain malformations or severe neurological deficits, however additional malformations of cortical development (MCD) are increasingly being recognised. Few patients with primary microcephaly and mutations in the MCPH genes other than ASPM have been described. We have performed mutation analysis in the MCPH1, WDR62, CDK5RAP2, CEP152, ASPM, CENPJ, STIL and PNKP genes using haplotype analysis and direct sequencing in 14 families and 10 sporadic patients. Mutations were found in the ASPM (5 families, 8 patients), WDR62 (5 families, 5 patients), CDK5RAP2 (1 family, 2 patients), STIL (1 family, 1 patient) and PNKP (1 family, 1 patient) genes. Twelve of the 16 different mutations found have not been previously described. All patients had severe developmental delay, with speech development being most severely affected. All patients showed a MCD in addition to severe microcephaly. The mildest brain phenotype was associated with ASPM mutation and a characteristic combination of polymicrogyria and pachygyria was associated with WDR62 mutation. Patients with CDK5RAP2 and PNKP mutation had agenesis of the corpus callosum in addition to simplified gyration. The recognition of specific patterns associated with mutation of each of the MCPH genes will aid targeted diagnosis in the future.

P12.146

A novel locus for autosomal dominant microcephaly

R. Kadir, *T. Harel, S. Shalev, J. Zlotogora, O. S. Birk;*
The Morris Kahn Laboratory of Human Genetics and the Genetics Institute, Soroka Medical Center, Ben-Gurion University, Beer Sheva, Israel.

Autosomal dominant microcephaly with mild to moderate mental retardation with no dysmorphism or other anomalies was diagnosed in eleven individuals of an Arab Israeli family. Craniosynostosis and environmental factors were ruled out per history as possible contributors to the disease, thus verifying the diagnosis of primary microcephaly. Brain CT scan of affected individuals showed no architectural anomalies. Nine living affected individuals were available for clinical and genetic evaluation. Association with all known microcephaly-associated loci were ruled out using polymorphic markers and genome wide linkage analysis data. Genome-wide linkage analysis revealed association of the disease to a region on chromosome 4 with a maximal LOD score of Z = 3.44, at marker D4S1534 (θ=0). Whole exome sequencing is underway.

P12.147

Megalencephalic Leukoencephalopathy with subcortical Cysts type 1 (MLC1) due to a homozygous deep intronic splicing mutation (c.895-226T>G) abrogated by AMO treatment.

C. Mancini[1], *G. Vaula*[2], *L. Scalzitti*[1], *S. Cavalieri*[1,3], *E. Bertini*[4], *C. Aiello*[4], *C. Lucchini*[5], *R. A. Gatti*[6], *A. Brussino*[1], *A. Brusco*[1,3]*;*
[1]*Department of Genetics, Biology and Biochemistry, University of Torino, Torino, Italy,* [2]*Department Neuroscience, AOU. San Giovanni Battista, Torino, Italy, Torino, Italy,* [3]*S.C.D.U. Medical Genetics, AOU. San Giovanni Battista, Torino, Italy, Torino, Italy,* [4]*Laboratory of Molecular Medicine, Ospedale Pediatrico Bambino Gesù, Rome, Italy, Rome, Italy,* [5]*UO Complessa di Neurologia, Ospedale di Ivrea, Italy, Ivrea, Italy,* [6]*Departments of Pathology and Laboratory Medicine, University of California, David Geffen School of Medicine, Los Angeles, 90095-1732, CA, United States.*

Megalencephalic leukoencephalopathy with subcortical cysts is an autosomal recessive disease characterized by early-onset macrocephaly, developmental delay, motor disability in the form of progressive spasticity and ataxia, seizures, cognitive decline and characteristic MRI findings. Mutations in two genes, *MLC1*(22q13.33; 75% of patients) or *HEPACAM* (11q24; 5-10% of patients) are associated with the disease.

We describe an adult MLC patient with moderate clinical symptoms. *MLC1* cDNA analysis from lymphoblasts showed a strong transcript reduction, and identified a 246-bp pseudoexon containing a premature stop codon between exons 10 and 11, due to a homozygous c.895-226T>G deep-intronic mutation. The role of this mutation on splicing was confirmed using a minigene assay, and an antisense morpholinated oligonucleotide (AMO) targeted to the aberrant splice site partially abrogated the mutation *in vitro*.

The mutation c.895-226T>G has a leaky effect on splicing leaving part of the full length transcript and may explain the milder phenotype in our patient. This category of mutations is often overlooked, being outside of canonically sequenced genomic regions, and is particularly important because it can be corrected by antisense oligonucleotides therapy.

P12.148

New deletion in Currarino syndrome

I. Holm[1], *T. Monclair*[2], *T. E. Prescott*[1], *K. L. Eiklid*[1]*;*
[1]*Deparment of medical genetics, Oslo, Norway,* [2]*Deparment of pediatric surgery, Oslo, Norway.*

Currarino syndrome (CS, OMIM#176450) is an autosomally dominant inherited developmental disorder due to incomplete rostral separation of endo- and ectoderm. The condition is characterized by three main findings; a sacral bony abnormality, anal stenosis and a presacral mass. CS is associated with mutations in the *MNX1* gene (previously known as *HLXB9*). Penetrance is reduced and expression is variable within families. Molecular testing can facilitate diagnosis and accurate genetic counseling. *MNX1* mutations were identified by direct Sanger sequencing of the coding regions and intron/exon boundaries of *MNX1* and by multiplex ligation probe amplification (MLPA kit P277-B1 Human Telomere-10) and a specially designed kit with probes within the *MNX1* gene. A total of 23 individuals with CS from nine different families were tested. We found mutations in only three families. In one family four affected individuals had a deletion of a cytosine in exon 1 (c.340delC, p.His114ProfsX111), previously described by Ross et al. (1998) and referred to as DelC, nt 414-17. In the second family, the two affected individuals, harboured a duplication of a guanine in exon 1 (c.336dupG, p.Pro113ArgfsX110), previously described by Köchling et al. (2001) and referred to as 413delG. In the third family, four affected individuals had a microdeletion of *MNX1* detected by MLPA only. The extent of the deletion, which has not been reported previously, is defined. This case underscores the importance of dosage analysis as an adjunct to sequencing in determining the molecular cause of CS.

P12.150

Parallel approach in molecular diagnostics of progressive muscular dystrophies.

Z. Vlckova[1], *P. Stöbe*[2], *M. Gencik*[1,2]*;*
[1]*Praxis fuer Humangenetik Wien, Wien, Austria,* [2]*Diagenos, Osnabrueck, Germany.*

There are two major disease groups to account for the phenotype of a progressive muscular dystrophy: X-linked dystrophinopathies (Duchenne, Bekker) and limb-girdle muscular dystrophies (autosomal dominant/recessive LGMD). Their common features are progressive muscle weakness and atrophy spreading form proximal to distal muscle areas. The particular type of the disease is clinically difficult to distinguish. Pedigree analysis, muscle biopsy and molecular-genetic analysis are used as main diagnostic tools.

In our laboratory, deletion/duplication analysis of the dystrophin gene and direct sequencing of relevant genes constitute the standard testing procedure. Until now our strategy involved a stepwise sequencing analysis starting with genes most frequently harbouring disease causing mutations.The stepwise strategy was selected due to

a) the large size of involved genes
b) high genetic heterogeneity of LGMD and
c) low throughput and high cost of Sanger sequencing method.

All these factors contributed to significantly prolonged testing time per patient. In many cases, the testing was stopped prematurely due to high cost/long duration.

Therefore, we have implemented a high-throughput sequencing platform (GS Junior, Roche), which has enabled us to switch from consecutive to parallel testing strategy. Our muscular dystrophy panel currently contains 14 genes (DMD, MYOT, LMNA, CAV3, CAPN3, DYSF, SGCG, SGCA, SGCB, SGCD, FKRP, POMT1, ANO5, POMT2) and further genes will be added as necessary. We aim to decrease the testing time and cost, increase the mutation detection rate and avoid muscle biopsy where possible.

P12.152

Molecular genetic diagnostics of myotonia congenita and structural analysis of mutations in the *CLCN1* gene

L. Fajkusová[1], *D. Páclová*[2], *J. Sedláčková*[2], *J. Marek*[1]*;*
[1]*Central European Institute of Technology, Brno, Czech Republic,* [2]*Centre of Molecular Biology and Gene Therapy, University Hospital Brno, Brno, Czech Republic.*

Non-dystrophic myotonias are skeletal muscle disorders associated with mutations in the *CLCN1* and *SCN4A* genes. Mutations of *CLCN1* result in autosomal dominant (Thomsen) and/or autosomal recessive (Becker) myotonia congenita (MC). Mutations in *SCN4A* are typically inherited as an autosomal dominant trait. The ClC1 protein is a homodimer with a separate ion pore within each subunit. The varied inheritance pattern of myotonias appears to result from differential effects of a mutation on the channel dimer. Mutations causing recessive myotonia most likely affect properties of mutant monomer leaving the wild type monomer unaffected in the heterodimer. On the other hand, mutations causing dominant myotonia affect properties of both subunits in the wild type/mutant heterodimer. Our study addresses two points: 1) molecular genetic diagnostics of MC by tandem analysis of the *CLCN*1 and *SCN4A* genes, and 2) homology modelling of the dimeric ClC1 channel. In the first part, mutations associated with the disease were identified in 57 probands - 39 carried mutations in *CLCN1* and 18 in *SCN4A*. In the second part, we performed homology modelling of the dimeric ClC1 channel on the basis of known crystallographic structures. From this model, we predicted aminoacids (AA) forming the dimer interface and AA forming the Cl^- ion pathway. Further, we performed search for mutations of AA forming the dimer interface or/and the Cl^- ion pathway in our model which have been found in patients with MC to assess the correlation between the localisation of a mutation and the type of MC.

P12.153

FZD6 encoding the Wnt receptor frizzled 6 is mutated in autosomal-recessive nail dysplasia

S. M. Pasternack[1], *G. Naz*[2], *C. Perrin*[3], *M. Mattheisen*[1,4,5], *M. Refke*[1], *S. Khan*[2], *A. Gul*[2], *M. Simons*[6], *W. Ahmad*[2], *R. C. Betz*[1]*;*
[1]*Institute of Human Genetics, Bonn, Germany,* [2]*Department of Biochemistry, Islamabad, Pakistan,* [3]*Hôpital L Pasteur, Laboratoire Central d'Anatomie Pathologique, Nice, France,* [4]*Institute for Medical Biometry, Informatics and Epidemiology, Bonn, Germany,* [5]*Department of Genomics, Life & Brain Center, Bonn, Germany,* [6]*Center for Biological Systems Analysis (ZBSA), Freiburg, Germany.*

Isolated nail dysplasia is rare and has only been reported in a small number of families. In this report, we describe two Pakistani families with an autosomal-recessive inherited nail dysplasia. Thickening and hyperpigmentation of all finger and toe nails were present at birth, and the nails subsequently became claw-like around puberty. By genomewide linkage analysis, we mapped this genodermatosis to chromosome 8q22.3, and identified a homozygous nonsense mutation c.1750G>T (p.E584X) in the frizzled 6 (FZD6) gene in all affecteds. Expression analyses in nail sections from healthy individuals revealed strong expression of FZD6 in the ventral nail matrix and a less pronounced expression of FZD6 in the nail bed. FZD6 belongs to a family of proteins that serve as receptors in Wnt signaling pathways, and has been shown to act as a negative regulator of the canonical Wnt/β-catenin signaling cascade and a positive regulator of the non-canonical Wnt or planar cell polarity (PCP) pathway. The present results therefore suggest that FZD6 plays a pivotal role in the growth and guidance of the nail plate in humans by acting as a molecular switch between different Wnt pathways. Previous studies have identified mutations in the RSPO4 and LMX1B components of the Wnt pathway in patients with the hypoplastic nail disorders anonychia and nail-patella syndrome, respectively. Only recently, FZD6 mutations were identified in isolated nail dysplasia. The present results emphasize the important role of the Wnt pathways in nail development and increase understanding of Wnt-mediated developmental events in general.

P12.154

Identification and characterization of a rare gene variant in congenital interstitial lung fibrosis and nephrotic syndrome

N. Nicolaou[1], *S. Kevelam*[1], *M. Lilien*[2], *M. Oosterveld*[3], *R. Goldschmeding*[4], *A. van Eerde*[1], *R. Pfundt*[5], *A. Sonnenberg*[6], *P. Terhal*[1], *N. Knoers*[1], *K. Renkema*[1];
[1]*Department of Medical Genetics, University Medical Centre Utrecht, Utrecht, Netherlands,* [2]*Department of Pediatric Nephrology, University Medical Center Utrecht, Utrecht, Netherlands,* [3]*Department of Pediatric Nephrology, Amsterdam Medical Centre, Amsterdam, Netherlands,* [4]*Department of Pathology, University Medical Center Utrecht, Utrecht, Netherlands,* [5]*Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands,* [6]*Division of Cell Biology, The Netherlands Cancer Institute, Amsterdam, Netherlands.*

We saw a patient who presented with severe congenital interstitial lung fibrosis and nephrotic syndrome, characterized by kidney hypoplasia, hydronephrosis, glomerulosclerosis, pulmonary hypoplasia, and alveolar glycogenosis, leading to death 7 months after birth due to respiratory insufficiency. The purpose of this study was to describe the clinicopathologic findings and unravel the underlying genetic cause. Known nephrotic syndrome genes were screened and 250K SNP array analysis was performed. No novel variants were identified in the known nephrotic syndrome genes. A homozygous region of 20 Mb was identified in the patient's DNA. Sequencing of the strongest candidate gene revealed a novel homozygous missense variant that was inherited from the heterozygous unaffected parents and not found in 384 control chromosomes. Striking similarities were seen between the gene knockout mouse and the patient's phenotype. Further in vitro characterization studies demonstrated the effect of the variant on the protein function. Here, we report a novel human gene variant, causing congenital interstitial lung fibrosis and nephrotic syndrome for the first time. The variant leads to an amino acid substitution in a gene essential for basement membrane development, in a domain interacting with extracellular matrix components. This is the first clinical phenotype associated with a mutation in this gene in humans. Our findings have major implications for our understanding how basement membrane morphogenesis is regulated and facilitates the design of genetic screening tests for early diagnosis and genetic counselling for patients and their relatives.

P12.155

Next Generation Sequencing (NGS) in the diagnostics of Nephrotic Syndrome

J. Hoefele[1], *A. Büscher*[2], *C. Heberle*[1], *M. Konrad*[3], *S. Weber*[2], *H. Klein*[1];
[1]*Center for Human Genetics and Laboratory Medicine Dr. Klein & Dr. Rost, Martinsried, Germany,* [2]*University Children's Hospital, Department of Pediatric Nephrology, Essen, Germany,* [3]*University Children's Hospital, Department of Pediatric Nephrology, Muenster, Germany.*

About 10% of children with idiopathic Nephrotic syndrome (NS) are steroid-resistant (SRNS), and develop end-stage renal disease. In the last couple of years, mutations in a number of genes highly expressed in podocytes have been identified causing SRNS.

The focus of this study was to establish a NGS approach for developing a fast and extensive method leading to increased genetic diagnostics of SRNS patients. As positive control 31 patients were analyzed, who had already been sequenced using the Sanger sequencing method following the mutational algorithm. These patients were examined in all thitherto known SRNS relevant genes (*ACTN4*, *CD2AP*, *COQ6*, *INF2*, *LAMB2*, *NPHS1*, *NPHS2*, *PLCE1*, *TRPC6*, *WT1*) using the Roche 454 technology. In 18/31 patients mutations were known, 13 patients did not show mutations in the already examined genes (Sanger detection rate 58%).

In 16/18 genetically diagnosed patients mutations were confirmed using NGS. Two mutations localized within homopolymer regions had not been identified. In 4/13 (31%) without mutations so far, mutations in one of the following genes have been identified: *CD2AP* (1 patient), *INF2* (1 patient), and *NPHS1* (2 patients). These genes were not sequenced using Sanger sequencing because they were excluded by the mutation algorithm. Altogether, in 20/31 patients causative mutations have been identified (NGS detection rate 65%).

NGS in the diagnostics of NS seems to be a good option for a rapid and reliable genetic analysis. However, mutations within homopolymer regions can be missed by the Roche 454 technology. These regions should still be analyzed by Sanger sequencing.

P12.156

Mutational analysis of the PLCE1 gene in Greek children with clinical presentation of nephrotic syndrome (NS) and diffuse mesangial sclerosis (DMS) or focal segmental glomerulosclerosis(FSGS)

E. Fylaktou[1], *C. J. Stefanidis*[2], *V. Askiti*[2], *S. Kitsiou-Tzeli*[1], *M. Bitsori*[3], *A. Mitsioni*[2], *E. Kanavakis*[1], *J. Traeger Synodinos*[1];
[1]*Medical Genetics, Athens University, „Aghia Sophia" Children's Hospital, Athens, Greece,* [2]*Department of Pediatric Nephrology, „P. and A. Kyriakou" Children's Hospital, Athens, Greece,* [3]*Department of Paediatrics, University Hospital of Heraklion, Heraklion, Greece.*

Mutations in *PLCE1* encoding phospholipase C epsilon 1(PLCe1) have recently been described in patients with early onset nephrotic syndrome (NS), diffuse mesangial sclerosis (DMS) and focal segmental glomeruloscerosis (FSGS). In 40 NS patients (35 sporadic, 5 familial) with histological findings of DMS or FSGS, 27/31 exons of *PLCE1* were analysed by direct sequencing. Pathological mutations in the *NPHS1, NPHS2* and *WT1* genes had been previously excluded in all patients. Sequencing analysis revealed *PLCE1* mutations in 4/35 patients. Three, homozygous for the previously described p.R1246X, had similar clinical findings (FSGS, age diagnosis 3.7, 2.5 and 3.5 years, respectively; age first dialysis 3.9, 2.6 and 4.5 years, respectively). Additionally, 1 case was found homozygous for a novel mutation, p.A945P. The patient (male) presented at 3months with DMD, initiating dialysis at 9months. *In silico* analysis (SIFT, Polyphen, Pmut and MutationTaster) were applied to evaluate causality of the p.A945P mutation. Pmut and SIFT found the nucleotide change "possibly damaging", while Polyphen and MutationTaster indicated p.A945P to be benign. Resequencing analysis in members of the patients' family (over 3 generations, all unaffected with NS) found only heterozygotes for p.A945P (according to expected phase). Further studies are required to conclude the pathogenicity of this novel *PLCe1* mutation, in the light of observations that pathogenicity of *PLCe1* gene mutations may be ambiguous (Boyer et al, J Med Genet, 2010). Overall our findings are consistent with previous conclusions that *PLCe1* mutations are not uncommon in childhood NS patients in whom mutations in other NS-gene have been excluded.

P12.157

Analysis of VANGL2 in 164 patients with neural tube defects reveals no mutations

I. Kirmes, *U. Zechner*, *O. Bartsch*;
Institute of Human Genetics, University Medical Center of the Johannes Gutenberg University Mainz, Mainz, Germany.

Van Gogh-like (Vangl2) is a protein of the non-canonical Wnt signalling pathway regulating polarized cell movements during embryonic development such as neurulation. Mutations of the Vangl2 gene have been shown to cause neural tube defects (NTDs) in loop-tail (Lp) mice and have become strong candidates for causing NTDs in humans. Mutations in the VANGL1 gene, which is homologous to VANGL2, were described to be associated with NTDs in 1-2% of cases. To examine the contribution of VANGL2 sequence variants to human NTDs, we studied lymphocyte DNA from peripheral blood of 164 patients with clinically relevant NTDs for VANGL2 gene mutations using PCR sequencing.

We identified no mutations, but 14 single nucleotide polymorphisms (SNPs) in the VANGL2 gene. Of these, seven were silent SNPs within the coding DNA (exons 3, 4, 6 and 7) and seven were intronic SNPs. Nine SNPs were already reported by the 1000 Genomes Project with similar frequencies, and five SNPs were novel and appeared with low frequencies. In silico testing of the five novels SNPs predicted no deleterious effects (no alteration of splice sites), but further studies remain to be done before final conclusions can be drawn. Furthermore, we performed a methylation analysis by bisulfite pyrosequencing of the potential VANGL2 promoter region to search for possible epimutations causing NTD and identified no methylation differences between patients with NTDs and controls. Other studies reported VANGL2 mutations in about 2% of NTD cases, suggesting that VANGL2 gene mutations are associated with NTDs in a small subset of cases.

P12.158

Neurofibromin (NF1) is required for skeletal muscle development

S. Stricker[1], *N. Kossler*[1], *J. Kim*[2], *J. Kühnisch*[3], *D. A. Stevenson*[4], *T. Braun*[2], *S. Mundlos*[1,3], *M. Kolanczyk*[1,3];
[1]*Max Planck Institute for molecular Genetics, Berlin, Germany,* [2]*Max-Planck-Institute for Heart and Lung Research, Bad Nauheim, Germany,* [3]*Institute for Medical and Human Genetics, Charité, Universitätsmedizin Berlin, Berlin, Germany,* [4]*Division of Medical Genetics, University of Utah, Salt Lake City, UT, United States.*

Neurofibromatosis type I (NF1) is a multi-system disease caused by mutations in the *NF1* gene. *NF1* encodes a RAS-GAP protein, Neurofibromin, which negatively regulates RAS signaling. Besides neuroectodermal malformations and tumours, the skeletal system is often affected in NF1 patients, scoliosis and long bone dysplasias being a main cause of considerable morbidity. Interestingly, a reduction of muscle strength and size has been reported in NF1 patients. However it remained unclear whether the observed muscle weakness was a consequence of the skeletal ramifications developing during puberty and early adulthood or if there was a muscular phenotype before the onset of a bone phenotype. Nf1 gene inactivation in the early mouse limb bud mesenchyme using Prx1-cre ($Nf1^{Prx1}$) resulted in muscle dystrophy characterised by fibrosis, reduced number of muscle fibres, and reduced muscle force. This was caused by an early defect in myogenesis affecting the terminal differentiation of myoblasts between embryonic days (E)12.5 and E14.5. In parallel, the muscle connective tissue cells exhibited increased proliferation at E14.5 and an increase in the amount of connective tissue as early as E16.5. These changes were accompanied by excessive MAPK pathway activation. Satellite cells isolated from $Nf1^{Prx1}$ mice showed normal self-renewal, but their differentiation was impaired as indicated by diminished myotube formation. Our results demonstrate a requirement of Neurofibromin for muscle formation and maintenance. This previously unrecognized function of Neurofibromin may contribute to the musculoskeletal problems in NF1 patients.

P12.159

Mutation screening by Next generation sequencing technology in analysis of Neurofibromatosis type 1- our first experience.

J. Kadlecová[1,2], *S. Dudová*[1,2], *M. Vaňásková*[1], *I. Valášková*[1,2], *R. Gaillyová*[1,2];
[1]*University Hospital Brno, Medical Genetics Dept., Brno, Czech Republic,* [2]*Fakulty of Medicine, Masaryk University, Brno, Czech Republic.*

Neurofibromatosis type 1 (NF1) is autosomal dominant disorders and is caused by mutations in the *NF1* gene. Current approaches of NF1 analyses are complicated molecular diagnostics due to the large size of the *NF1* gene, the presence of pseudogenes, the great variety of possible lesions and high mutation detection rate.

We report our first experience of NF1 gene analysis using the next-generation sequencing (NGS) (Roche GS Junior). 20 patients with clinical symptoms of the disease were included to DNA mutational screening .The PCR of all exons of NF1 gene were performed by the use of primers composed by a gene-specific part and a universal tail. Each primer was labeled by MID tails (Multiplex Identifier Adaptors), which serve to identify specific patient´s DNA sample. Prepared amplicons of NF1gene were analysed using of two runs in the GS JUNIOR system. The generated NGS data were processed with Roche software Amplicon Variant Analyzer version 2.5p1 and acquired sequences were compared to reference genome.

We have detected point mutations within the coding region: deletion, nonsens, missense, splicing and frameshift mutations. All of these sequence variants were confirmed by conventional analysis method (Sanger sequencing). Since the data acquired within our first experiment by the Roche Junior system are in full accordance with results obtained by traditional approach and the process is both time and cost effective , we are involving NGS to our strategy of molecular genetics testing of NF1 patietns in combination with conventional analysis methods as MLPA, Sanger Sequencing of DNA and cDNA

Next-Generation Sequencing in Neurofibromatosis 1

E. Decker[1], *L. Behalova*[2], *M. Hikkelova*[2], *H. Gabriel*[1], *M. Gencik*[1], *A. Gencik*[1];
[1]*diagenos, Osnabrück, Germany,* [2]*MedGene, Bratislava, Slovakia.*

Neurofibromatosis 1 is an autosomal-dominant disease characterized by multiple café-au-lait spots, axillary and inguinal freckling, multiple neurofibromas, and Lisch nodules. The disorder is caused by defects in the tumor-suppressor gene NF1. Mutation detection is complex and expensive due to the large size of the NF1 gene, the presence of pseudogenes, the lack of mutation hotspots as well as a large variety of minor and major deletions.

We have established a Next-Generation Sequencing (NGS)-based mutation detection method as a tool for routine analysis of the entire NF1 gene in patients with excluded deletion. So far, we have tested >45 patients with suspected NF1. 7% of the patients harbored a NF1 gene deletion, the remaining patients were subsequently examined using NGS: all protein-coding exons including the flanking splice consensus sites were amplified by PCR and afterwards sequenced using the Roche 454J platform. In >70% of the patients we have detected exonic and splice site mutations. All mutations identified by NGS were successfully validated by Sanger sequencing.

No causative mutation was found in over 20% of the patients, which might be explained either by the presence of deep intronic mutations or the fact that not all patients in our cohort met diagnostic criteria for NF1. To further increase the mutation detection rate we have recently included NGS-based testing of the SPRED1 gene, mutated in the clinically similar Legius syndrome.

We conclude that the use of NGS-based diagnostic procedures offers an affordable and highly sensitive alternative for NF1 diagnostic.

P12.161

Mutation analysis of NF1 and SPRED1 genes in Slovak patients

M. Nemethova[1], *A. Rybarova*[2], *D. Ilencikova*[2], *L. Kadasi*[3,1], *A. Zatkova*[1,3];
[1]*Laboratory of Genetics, Institute of Molecular Physiology and Genetics, Bratislava, Slovakia,* [2]*2nd Department of Pediatrics, Comenius University Medical School University and Children´s Hospital, Bratislava, Slovakia,* [3]*Department of Molecular Biology, Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia.*

Neurofibromatosis type 1 (NF1) is one of the most common autosomal dominant disorders with incidence of 1:3500. The main clinical features are “café au lait” macules, freckling, optical glioma, Lisch noduls, any types of neurofibromas, and dysplasia of bones. The disease is caused by inactivating mutations within the NF1 gene that maps to 17q11.2 and consists of 60 exons. Protein product of NF1 is a tumor suppressor neurofibromin that functions as a negative regulator of Ras proto onkogen.

Legius syndrome called NF1- like syndrome is disorder with similar clinical features like NF1. It is caused by mutation in the next negative regulator of MAPK signal pathway - SPRED1 (Sprouty-related EVH1 domain - containing protein 1). SPRED1 gene is localized on 15q13.2 chromosome and consist of 8 exons.

We identified 55 mutations in NF1 gene. 31 of them are new and 24 are recurrent. Using protocol base on sequencing of entire NF1 coding region developed by Messiaen and Wimmer (2008), we identified 25/55 (45%) frameshift, 8/55 (15%) splicing, 7/55 (13%) missense, 5/55 (9%) nonsence mutations and 1/55 (2%) small frame deletion. In all cases where no mutation was identified by sequencing we performed MLPA analysis we identified 5/55 (9%) deletions of entire gene type 1, 4/55 (7%) larger intragenic deletions of one or more exons.

If patients fulfil the main diagnostic criteria but they have no germinal mutation in NF1 gene we analysed SPRED1 gene. Analysis of SPRED1 gene was finished in 18 patients. No pathogenic mutation was found.

P12.162

Loss of neurofibromin increases micro- and macroporosity in cortical bone resulting in diminished mechanical resistance

J. Kühnisch[1], *C. Lange*[2], *J. Seto*[2], *J. Grohmann*[3], *S. Tinschert*[4], *K. Raum*[5], *T. el Khassawna*[5], *F. Elefteriou*[6], *U. Kornak*[1], *P. Fratzl*[2], *M. Kolanczyk*[1], *S. Mundlos*[1];

Skeletal manifestations such as osteoporosis, dystrophic scoliosis or tibial dysplasia are commonly in patients with neurofibromatosis type 1 (NF1). To further explore the origin of NF1 bone dysplasia we now performed detailed analysis of the cortical bone porosities in Nf1Prx1 mice and in NF1 patients employing high-resolution imaging techniques. One of our aims was to explore how NF1 loss of function affects osteocytes, the mechanosensory cells of the bone. The overall morphology of the humerus from Nf1Prx1 mice appeared severely disordered. Especially at the muscle to bone insertion sites we observed large amounts of fibrocartilaginous tissue. Within the diaphysis we detected large non-mineralized regions of bone tissue that are associated with blood vessels. Thus, the macroporosity was 5-fold increased in Nf1Prx1 mice as compared to controls. Microporosity, which is mainly determined by the size of osteocyte lacunae, was increased. While Nf1Prx1 cortical bone contained a normal number of osteocyte lacunae, the average lacuna volume was increased, yielding higher relative osteocyte volume per bone volume (3.4 % in the mutants vs. 2.0 % in controls). The osteocyte phenotype is likely cell autonomous as increased osteocyte lacuna volume was also detected in the Nf1Col1 mice. Similarly, a quantitative volumetric analysis of cortical bone samples from NF1 patients demonstrated increased osteocyte lacuna size. These findings suggest that neurofibromin is required for normal osteocyte function, and facilitates bone homeostasis. Thus, our collective data reveal a significant impact of neurofibromin on cortical porosity establishing a further aspect of NF1 bone dysplasia.

P12.163

In search of genetic defects in unrelated frontotemporal lobar degeneration patients using whole genome sequencing

S. Philtjens[1,2], *I. Gijselinck*[1,2], *T. Van Langenhove*[1,2], *J. van der Zee*[1,2], *S. Engelborghs*[2,3], *R. Vandenberghe*[4], *P. Santens*[5], *P. De Deyn*[2,3], *C. Van Broeckhoven*[1,2], *M. Cruts*[1,2];
[1]VIB Department Molecular Genetics, Antwerp, Belgium, [2]Institute Born-Bunge, University of Antwerp, Antwerp, Belgium, [3]Department of Neurology and Memory Clinic, Hospital Network Antwerp Middelheim and Hoge Beuken, Antwerp, Belgium, [4]Department of Neurology, University Hospitals Leuven and University of Leuven, Leuven, Belgium, [5]Department of Neurology, University Hospital Ghent and University of Ghent, Ghent, Belgium.

Frontotemporal lobar degeneration (FTLD) has a positive family history in up to 50% of patients and approximately 40% can be explained by causal mutations in one of the known genes. In spite of this, identifying and sampling informative families for genetic linkage studies becomes increasingly difficult due to a variable disease onset and penetrance, amongst other reasons. We use whole genome sequencing (WGS) as an alternative to identify Mendelian FTLD genes. We obtained the whole genome sequences of three affected sib pairs and ten unrelated at an average coverage of 70-fold capturing both alleles of 96.5% of the genome. Analysis of the genome sequences resulted in about four million variants per genome. Subsequent variant filtering procedures were based on sequence quality, genomic location, allele frequency, zygosity, predicted functional consequences and occurrence in sequenced patients. The number of variants was reduced to a manageable number of candidate variants, with 380 missense or splice variants segregating in each sib pair and 350 shared by at least three unrelated patients. We are now validating the selected variants and determining their frequency in neurologically healthy control individuals and extended patients cohorts. The identification of novel FLTD genes will provide valuable insights into the pathogenesis of the disease and will eventually lead to the development of e.g. disease models.

P12.164

Characterization of the delC.2970-2972 AAT mutation in exon 17 of the NF1 gene in Mexican patients with neurofibromatosis type 1 with no cutaneous neurofibromas

P. Hernandez-Alcantara[1], *L. Plaza-Benhumea*[1], *J. Cazarin-Barrientos*[2], *M. R. Rivera-Vega*[1], *L. M. Gonzalez-Huerta*[1], *H. Urueta-Cuellar*[1], *S. Cuevas-Covarrubias*[1];
[1]Genetica, Hospital General de Mexico, Mexico, D.F., Mexico, [2]Dermatologia, Hospital General de Mexico, Mexico, D.F., Mexico.

Neurofibromatosis type 1 (NF1) is one of most common genodermatosis inherited as an autosomal dominant trait with complete penetrance and variable expressivity. With an incidence of 1:3000, it is caused by mutations in the NF1 gene, which encodes the protein neurofibromin. Recent reports identified a three nucleotide deletion in exon 17 of neurofibromin gene associated with absence of neurofibromas and benign course. The aim of the study is the molecular analysis of the gene NF1 in Mexican patients with NF1 and no neurofibroms. Methods: 10 patients were screened through PCR and DNA sequencing from genomic DNA. Results: 10 patients (all >20 years old) with a mild NF1 phenotype and no neurofibroms were screened for deletion in exon17 (c.2970-2972 AAT) of the NF1 gene. All patients included in the study were negative for the deletion reported in other populations. Conclusions: In this study we found no association between the absence of neurofibromas and delc.2970-2972 AAT in exon 17 in patients with NF1.. We consider that other genes or environment factors could be associated with the absence of neurofibromas in neurofibromatosis type 1.

P12.165

Identification and characterization of SMPD1 mutations causing Niemann-Pick types A and B in Turkish Patients

A. Aykut[1], *E. Karaca*[1], *H. Onay*[1], *S. Kalkan*[2], *M. Coker*[2], *O. Cogulu*[1], *F. Ozkinay*[1];
[1]Department of Medical Genetics, Izmir, Turkey, [2]Department of Pediatrics, Izmir, Turkey.

Niemann-Pick disease Types A and B (NPD) are autosomal recessive sphingolipidoses caused by mutations in the sphingomyelin phosphodiesterase 1 (SMPD1) gene. These two types of the disease were described as early onset Type A disease and the milder Type B according to the presence (type A) or absence (type B) of neurological symptoms.
The 5 kb gene encoding the human SMPD1 gene (MIM# 607608,GenBank# M81780.1) is composed of six exons and is located at chromosome 11p15.1-11p15.4. Several mutations causing NPD have been described. We present a molecular analysis of six unrelated Turkish NPD patients in which mutant SMPD1 alleles were identified. One of the patients had type A and 5 had type B NPD. These mutations included two missense mutations: c.409T>C (p.L137P) and c.1262 A>G (p.H421R); the common frameshift mutation at codon 189, identified in 2 patient is caused by the deletion of the 567T introducing a stop codon 65 aminoacids downstream (p.P189fsX65) and a novel frameshift mutation c. 1755delC (p.P585PfsX24) which was not previosly reported. The known c.409T>C (p.L137P) and c.567delT (p.P189fsX65) were the most frequent mutations accounting for 50% and 25% the alleles, respectively. In this study genotype-phenotype correlations were established for the mutations.

P12.166

Frequent CLCN1 gene mutations in patients from Russian Federation (RF) with non-distrophic Thomsen and Becker myotonias

E. Ivanova[1], *V. Fedotov*[2], *S. Kurbatov*[2], *E. Dadali*[1], *G. Rudenskaya*[1], *A. Polyakov*[1], *A. Polyakov*[1];
[1]Russian Research Center for Medical Genetics, Moscow, Russian Federation, [2]Center of Genetic Consultation, Russia, Voronez, Russian Federation.

Non-dystrophic Thomsen and Becker myotonias are muscle channelopathies caused by mutations in CLCN1 (7q35). The study group consisted of 79 unrelated patients with revealed myotonia by clinical examination. Patient's DNA samples were analyzed by direct sequensing of all 23 exons of the CLCN1 gene and 40 different mutations were detected in 118 chromosomes in 21 family cases (9-AD and 12-AR) and 45 sporadic cases (84% altogether). Eighteen mutations haven't been described earlier. There were detected several frequent mutations: p.Gly190Ser (5,9%), c.1437-1450del (9,3%), p.Ala493Glu (5,1%), p.Thr550Met (3,4%), p.Tyr686Stop (5,1%) and p.Arg894Stop (30,5%) composed 59,3% all mutant chromosomes. The most frequent p.Arg894Stop was revealed in homozygous and compound-heterozygous cases and allelic frequency of p.Arg894Stop among the control population is 1,2% (12/488). As the founder effect was expected to cause the high frequency of the p.Arg894Stop we analyze haplotypes of mutant chromosomes in 28 patients and 17 relatives using microsatellite markers D7S1824, D7S2513, D7S3068, D7S661 and D7S2511. Despite most linked markers flanking CLCN1 gene was in 1,7 Mb(D7S2513) and 0,6 Mb(D7S3068) away from the gene it wasn't any common haplotype in mutant chromosomes. Possibly the distance between markers and the mutation wasn't enough close. So we analyzed haplotype using introgenic SNP markers (rs940864, rs2272251 upstream and rs4489232, rs6464546 downstream the mutation Arg894Stop). Founder haplotype was detected in 13 out of 17 mutant chromosomes (rs940864-rs2272251-rs4489232-rs6464546: A-T-T-A) and it is statistically significant comparably with control group (p=0,05). Resume this data widespread occurrence of mutation p.Arg894Stop in Russia is result of founder effect.

Non-progressive congenital ataxias (NPCA) with or without intellectual disability (ID) are clinically and genetically heterogeneous conditions. As a consequence, the identification of the genes responsible for these phenotypes remained limited. Using high resolution microarrays, we identified intragenic copy number variations in the CG-1 domain of the Calmodulin-binding Transcription Activator 1 (CAMTA1) gene, segregating with autosomal dominant ID with NPCA in two unrelated families, and a de novo deletion located in the same domain in a child presenting with NPCA. In the ID patients, the deletion led to a frameshift, producing a truncated protein, while this was not the case for the patient with isolated childhood ataxia. Brain MRI of the patients revealed a pattern of progressive atrophy of cerebellum medium lobes and superior vermis, parietal lobes and hippocampi. Although DNA sequencing of the CG-1 domain in 197 patients with sporadic or familial non-syndromic intellectual deficiency, extended to full DNA sequencing in 50 patients with ID and 47 additional patients with childhood ataxia, identified no pathogenic mutation, there is considerable evidence that CAMTA1 rearrangements are being disease causing. Indeed, CAMTA1 is a brain specific calcium responsive transcription factor expressed in the brain and cerebellum during development and later implicated in memory processes; intragenic rearrangements are concentrated in a highly conserved functional domain with transcription regulation ability and nuclear trafficking functions; CAMTA1 transcriptional studies have shown upregulation of genes already implicated in intellectual disability and autism spectrum disorder. Altogether, we show that CAMTA1 loss-of-function is responsible for NPCA with or without ID.

P12.168

The prevalence of *OTOF* mutations in Iranian deaf population

N. Bazazzadegan[1]*, N. Meyer*[2]*, K. Kahrizi*[1]*, M. Babanejad*[1]*, K. Jalalvand*[1]*, N. Nikzat*[1]*, S. Arzhangi*[1]*, R. J. H. Smith*[2]*, H. Najmabadi*[1]*;*
[1]*Genetics Research Center, University of Social Welfare and Rehabilitation Sciences,, Tehran, Islamic Republic of Iran,* [2]*Molecular Otolaryngology Research Laboratories, Department of Otolaryngology Head and Neck Surgery, University of Iowa, IA, IA, United States.*

Hearing impairment is the most common genetic sensory defect in humans worldwide. One in every 1,000 neonates is born with profound congenital deafness. About 70% of hereditary sensoryneural hearing loss (SNHL) is non-syndromic (DFN) and at least 80% of these cases have autosomal recessive (DFNB) inheritance. To date, genetic studies have shown that mutations in more than 90 loci and 40 genes are associated with DFNB. Mutations in *OTOF* gene are cause of neurosensory non-syndromic recessive deafness, DFNB9. *OTOF* gene contains 48 exons which encode a transmembrane protein, otoferlin. Several mutations in this gene have been found in Lebanese, Pakistani, Turkish, Colombian and Spanish families.

Recently, we observed an Iranian family with autosomal recessive non-syndromic hearing loss(ARNSHL),which showed linkage to *OTOF* gene. Mutation detection of this gene revealed a missense mutation. So we decided to screen our population for this gene.

One hundred and forty four ARNSHL families with two or more affected individuals originated from different ethnic groups of Iran were selected for this study. All the families were subjected to homozygosity mapping using flanking STR markers of *OTOF* gene. After screening all the families, one family showed linkageto this gene. Further analysis using direct sequencing of this gene revealed a splice site mutation (IVS28+2 T>C). So, in comparison with other countries such as our neighboring country, Pakistan, *OTOF* mutations are very rare in Iran.

P12.169

Exome sequencing identifies *PRPS1* as a major *locus* for X-linked nonsyndromic hearing loss in the Italian population

M. Robusto[1]*, J. Zhang*[2]*, R. Asselta*[1]*, J. Liang*[2]*, X. Liu*[2]*, P. Primignani*[3]*, P. Castorina*[4]*, S. Caccia*[5]*, U. Ambrosetti*[4]*, Y. Yin*[2]*, J. Wang*[2]*, S. Duga*[1]*, G. Soldà*[1]*;*
[1]*Dipartimento di Biologia e Genetica per le Scienze Mediche, Università degli Studi di Milano, Milano, Italy,* [2]*BGI-Shenzhen, Shenzhen, China,* [3]*S.O. Genetica Medica, Ospedale Niguarda Ca' Granda, Milano, Italy,* [4]*UO Audiologia, Fondazione IRCCS, Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milano, Italy,* [5]*Dipartimento di Scienze e Tecnologie Biomediche, Università degli Studi di Milano, Milano, Italy.*

An Italian family with two siblings affected by nonsyndromic sensorineural hearing loss (NSHL) and showing a recessive pattern of transmission was selected for whole-exome next-generation sequencing (NGS). Genomic capture and NGS on a HiSeq 2000 sequencer (Illumina) of the proband lead to the identification of a novel missense mutation within *PRPS1*. Mutations in this gene, which codes for the phosphoribosylpyrophosphate synthetase 1 (PRS-I) enzyme, were previously demonstrated to cause X-linked syndromic conditions associated with hearing impairment (e.g. Arts syndrome and Charcot-Marie-Tooth disease-5), and, most recently, NSHL in 4 families (DFNX1 *locus*). The identified mutation segregates with prelingual, bilateral, profound NSHL in the proband's family. A subsequent screening of the entire *PRPS1* gene by Sanger sequencing in 13 additional unrelated probands from NSHL families showing a likely X-linked inheritance pattern led to the discovery of a second missense mutation segregating with pre-lingual hearing impairment. The two novel variants were absent in a cohort of 126 Italian audiologically-tested, normal-hearing controls. Both amino-acid substitutions are predicted to cause a destabilization of the enzyme structure. The impact of both *PRPS1* mutations on the function of PRS-I is currently under analysis by measuring the enzyme activity in the patients' emolysates compared to controls. In conclusion, we provide evidence of the usefulness of whole-exome NGS for the genetic diagnosis of NSHL and we highlight the recurrence of *PRPS1* mutations, suggesting that it may represent a major *locus* for X-linked NSHL to be prioritised in genetic screenings.

P12.170

A custom multiplexing mutation panel for Noonan, Costello, LEOPARD and Cardiofaciocutaneous Syndromes

P. Tavares*, A. Lopes, L. Lameiras, L. Dias, J. Sá, P. Rendeiro, A. Palmeiro;*
CGC Genetics (www.cgcgenetics.com), Porto, Portugal.

Introduction: Noonan syndrome is a congenital genetic disease that affects both males and females equally. Often this syndrome is not diagnosed, but it is related to many complex problems such as coagulation defects and lymphatic dysplasias. Differential diagnosis includes major diseases in the same metabolic pathway - Costello, Cardiofaciocutaneous and LEOPARD Syndrome. Noonan Syndrome is often present in prenatal cases with increased nuchal translucency and normal karyotype. **Method:** We developed a custom multiplex mutation panel (CGC Mutation Panel - Pat. Pending) that contains a total of 81 point mutations on genes PTPN11, RAF1, SOS1 and KRAS, HRAS, BRAF, MAP2K1 and MAP2K2 involved in Noonan, LEOPARD, Costello and Cardiofaciocutaneous syndromes. With this panel we analysed 85 samples (35 prenatal and 50 postnatal). **Results**: From the 85 samples tested (35 prenatal and 50 postnatal), in 2 prenatal sample we detected mutations on PTPN11 gene allowing the diagnosis of Noonan and in 3 of the postnatal samples we found mutations on SOS1, BRAF and PTPN11 gene allowing the diagnosis of Noonan and Cardiofaciocutaneous syndromes. **Conclusion:** This approach is a valuable prenatal and postnatal diagnostics tool, since it detects the most common mutations associated with Noonan Syndrome and syndromes of the same metabolic pathway in a single test. This panel reduces time and costs to achieve a diagnosis improves its capability, independently of the sample type, allowing an earlier decision-making process in patient management, and is useful especially in prenatal diagnosis situations with increased nuchal translucency and normal karyotype.

P12.171

Novel mutations in PTPN11 gene in two girls with Noonan syndrome phenotype

E. Yilmaz Gulec[1]*, S. Candan*[1]*, E. Ataman*[1]*, C. Yarar*[2]*;*
[1]*Istanbul Kanuni Sultan Suleyman Training and Research Hospital, Medical Genetics Department, Istanbul, Turkey,* [2]*Istanbul Kanuni Sultan Suleyman Training and Research Hospital, Pediatric Neurology Department, Istanbul, Turkey.*

Noonan syndrome is an autosomal dominant disorder characterized by postnatally reduced growth, distinctive facial dysmorphic features, hypertrophic cardiomyopathy and/ or pulmonary valve stenosis , skeletal and hematological anomalies, and webbing of the neck. To date, mutations of nine different genes were identified as the molecular cause of this disorder. While mutations of these genes are responsible for the 75% of all the cases, mutations in PTPN11 is responsible for approximately 50% alone.

Here, we report two novel mutations c.A1690G and c.C155T in two girls with Noonan Syndrome phenotype, both with short stature, one with mild neuromotor developmental delay and the other with dysplastic pulmonary valve and pulmonary valve stenosis. We try to correlate genotype-phenotype relation.

P12.172

A spectrum of mutations in *PTPN11*, *SOS1* and *RAF1* genes in patients with Noonan syndrome clinical suspicion.

A. Abramowicz[1], *M. Gos*[1], *J. Klapecki*[1], *R. Frazao*[2], *J. Majewski*[2], *A. Szpecht-Potocka*[1], *A. Kutkowska-Kazmierczak*[1], *K. Szczałuba*[1], *P. Lepage*[2], *E. Obersztyn*[1], *J. Bal*[1], *E. Bocian*[1];
[1]Institute of Mother and Child, Warsaw, Poland, [2]McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada.

Noonan syndrome (NS) is a relatively common developmental syndrome belonging to the group of RASopathies, that are characterized by increased activity of the Ras/mitogen activated protein kinase (RAS/MAPK) signaling pathway. NS is known to be a disorder with variable phenotypic expression including symptoms like short stature, dysmorphic features, congenital heart defects and many other.

Noonan syndrome is caused by a germline mutation in one of the genes that encode proteins involved in RAS/MAPK signaling pathway. In NS patients, heterozygous mutations have been identified in *PTPN11, SOS1, RAF1, BRAF, KRAS, NRAS, SHOC2, MEK1* and *CBL* genes.

Three hundred eleven individuals (237 patients with clinical suspicion of NS and 74 relatives) were referred to our laboratory for molecular examination. The *PTPN11, SOS1* and *RAF1* genes were examined in 237, 70 and 28 patients, respectively. The analysis of coding sequence was performed using direct sequencing method.

The known NS causing missense mutations were found in 89 (37.5%) cases: 67 had mutation in *PTPN11*, 10 in *SOS1* and 12 in *RAF1*. All the identified mutations, according to the literature, were gain-of-function type. Although most of the probands with NS have a *de novo* mutation, we have identified 17 (50%) familial cases (14 - *PTPN11*, 2 - *SOS1*, 1-*RAF1*). The low frequency of identified mutations among patients included in the study might suggest that more stringent criteria should be used for patients' qualification for molecular testing.

Supported from NCN research project no. DEC-2011/01/D/NZ5/01347.

P12.173

Interpretation of atypical *NOTCH3* mutations: lessons from patients with novel large NOTCH3 alterations but no CADASIL

J. W. Rutten[1], *E. M. Boon*[1], *H. G. Dauwerse*[1], *P. Lakeman*[2], *M. K. Liem*[1], *E. J. Vollebregt*[1], *A. de Kort*[3], *M. H. Breuning*[1], *S. G. van Duinen*[1], *G. M. Terwindt*[1], *S. A. J. Lesnik Oberstein*[1];
[1]Leiden University Medical Center, Leiden, Netherlands, [2]VU medical center, Amsterdam, Netherlands, [3]St. Elisabeth Hospital, Tilburg, Netherlands.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is characterized by early onset stroke and vascular dementia. It is caused by stereotyped missense mutations in *NOTCH3*, which invariably lead to an uneven number of cysteines in one of the 34 EGFL domains that constitute the NOTCH3 ectodomain. In addition to missense mutations, a few small pathogenic *NOTCH3* deletions and insertions have been described. All changed the number, or the spacing, of cysteine residues. A frame shift mutation leading to a stop was reported as pathogenic, but molecular and clinical testing was incomplete.

We describe three patients with large *NOTCH3* alterations, of which the pathogenicity was initially unclear. We combined extensive laboratory analysis (MLPA, DNA and RNA analysis, Western Blotting) with thorough clinical evaluation. The first patient has a deletion of exon 3-16, leading to a premature stop, the second patient has an exon 3 stop mutation. Clinically, they did not have a CADASIL phenotype. Molecularly, the mutations are predicted to result in small NOTCH3 fragments that lack transmembrane and intracellular domains and are highly unlikely to be expressed at the cell surface. The pathogenicity of the mutation in the third patient, a splice site mutation causing exon 7 skipping, remains uncertain but does not give classical CADASIL

We conclude that *i)* clinical and molecular investigation by an experienced team is indispensable for the correct interpretation of atypical *NOTCH3* mutations *ii) NOTCH3* stop mutations do not cause CADASIL, arguing against the theory that hypomorphic *NOTCH3* alleles also cause CADASIL.

P12.174

Recessive mutations in MCM4/PRKDC cause a novel syndrome characterised by a primary immunodeficiency and impairments in DNA repair

J. P. Casey[1,2], *M. Nobbs*[3], *P. McGettigan*[4], *S. Lynch*[5], *S. Ennis*[2,5];
[1]National Children's Research Centre, Our Lady's Children's Hospital, Crumlin, Dublin, Ireland, [2]Health Sciences Centre, University College Dublin, Dublin, Ireland, [3]Bristol Genetics Laboratory, Bristol, United Kingdom, [4]College of Life Sciences, University College Dublin, Dublin, Ireland, [5]National Centre for Medical Genetics, Our Lady's Children's Hospital, Crumlin, Dublin, Ireland.

We present a study on ten children from three families with a novel syndrome born to consanguineous parents from the Irish Traveller population. The syndrome consists of failure to thrive, a natural killer cell deficiency, an atypical Fanconi's type DNA breakage disorder and features of familial glucocorticoid deficiency. In addition the children had delayed bone age, clinodactyly and some presented with hypoglycaemia. Using SNP homozygosity mapping, we identified a locus for this syndrome on 8p11.21-q11.22. Targeted resequencing of the candidate region revealed a homozygous mutation in *MCM4/PRKDC* in all ten patients that segregated with the phenotype. Consistent with the observed DNA breakage disorder, *MCM4* and *PRKDC* are both involved in the ATM/ATR DNA repair pathway which is defective in patients with Fanconi's anaemia. Deficiency of *PRKDC* in mice has been shown to result in an abnormal NK cell physiology similar to that observed in the patients. Mutations in *MCM4/PRKDC* represent a novel cause of DNA breakage and NK cell deficiency. Our findings suggest that clinicians should consider this disorder in patients with failure to thrive who develop pigmentation or who have recurrent infections.

P12.175

Oncogenic NRAS G12S discovered as a germline mutation in a patient with Noonan/CFC syndrome

S. Jakubiczka[1], *S. Spranger*[2], *A. Pekrun*[3], *C. Titgemeyer*[3], *C. Lißewski*[1], *M. Zenker*[1];
[1]Institute of Human Genetics, Magdeburg, Germany, [2]Praxis for Human Genetics, Bremen, Germany, [3]Hospital Bremen-Mitte, Bremen, Germany.

Noonan syndrome (MIM 163950) and cardiofaciocutaneous syndrome (CFC syndrome; MIM 115150) are clinically overlapping syndromes caused by mutations in various genes encoding components of the RAS/MAPK signalling pathway. Here, we report on a 1-year-old girl with facial anomalies, heart defect, and developmental delay leading to the differential diagnosis of Noonan or CFC syndrome. She has not had any signs of a myeloproliferative disease or other malignancy, so far. Mutation analysis revealed the heterozygous *NRAS* mutation c.34G>A (p.G12S) in leukocyte DNA. The presence of the mutation was also confirmed in the patient's buccal cells and could be ruled out in the parents, thus indicating a *de novo* mutational event in the germline. G12S is one of the most frequent somatic *NRAS* mutations and predominantly observed in cancers of haematopoietic and lymphoid tissues, thyroid, and skin. Only very few germline *NRAS* mutations sparing the classical oncogenic mutation hotspots have been identified to date in patients with Noonan syndrome. It has been hypothesized that oncogenic mutations when occurring in the germline might lead to embryonic lethality. Two anectdotal reports, however, described the known oncogenic *NRAS* mutation G13D being apparently present in the germline of patients with a hematologic phenotype but no obvious signs of Noonan syndrome. Our observation documents a clear RASopathy phenotype and absence of myeloproliferative disorder in a patient with oncogenic *NRAS* G12S as a constitutional mutation.

P12.176

Cornelia de Lange Syndrome diagnostics in times of NGS

P. Stöbe, *T. Schopen, H. Gabriel, M. Gencik, A. Gencik;*
diagenos, Osnabrück, Germany.

Cornelia de Lange Syndrome (CDLS) is a rare autosomal dominant disease with an incidence of 1 in 10.000 to 60.000 newborns. It leads to severe developmental anomalies. This disorder is characterized by skeletal, craniofacial deformities, gastrointestinal and cardiac malformations. The physical as well as intellectual development of a child is affected. Clinical diagnosis is based on the phenotype.

This disorder is mainly caused by mutations in the Cohesin complex genes NIPBL, SMC1A, and SMC3. Mutations in the NIBL gene are responsible for about 50% of the cases. The two latter genes cause a slightly milder form of CDLS. In addition, patients with mutations in the UBE2A gene show a CDLS like phenotype. So far, molecular validation of CDLS has been done by Sanger sequencing or MLPA with focus on NIPBL gene analysis. All coding exons and their corresponding splice sites were analyzed.

Recently, the high throughput pyrosequencing technique using the Roche 454J platform was implemented in our laboratory and an open and flexibly upgradeable diagnostic panel for CDLS including the genes NIPBL, SMC1A, SMC3 and UBE2A was established.

Here, we report on our analyses of CDLS patients applying NGS technology into routine diagnostics and compare its performance with standard mutation detection. The preliminary data show that our diagnostic panel is a real alternative to classical sequencing in respect to sensitivity, TAT and cost. In addition, our approach is optimal for molecular analysis of genetically heterogeneous diseases with distinct clinical manifestation and caused by mutations in a limited number of genes.

P12.177
New insights in non-syndromic albinism

M. Martínez-García[1,2], R. Riveiro-Álvarez[1,2], F. Blanco-Kelly[1,2], M. Á. Lopez-Martínez[1,2], A. Giménez[1,2], C. Vélez[1,2], L. Montoliu[2,3], C. Ayuso[1,2], M. J. Trujillo-Tiebas[1,2];
[1]Fundación Jiménez Díaz, Madrid, Spain, [2]Centro de Investigación Biomédica en Red de Enfermedades Raras, Madrid, Spain, [3]Centro Nacional de Biotecnología (CNB-CSIC), Madrid, Spain.

Background: Albinism is a complex group of genetic disorders characterized by reduced or complete absence of melanin pigment in the skin, hair, and eyes associated with decreased visual acuity, nystagmus, and photophobia. Oculocutaneous albinism (OCA) is classified into several types based on clinical and molecular categories. The prevalence of all forms of albinism varies considerably worldwide and has been estimated at approximately 1/17,000.

Patients and Methods: After informed consent was obtained, blood samples were collected from patients with clinical signs of OCA. We screened 13 families (7/13 Spanish, 1/13 Rusian and the 2/13 Africans) for sequence variations in the coding region of the *TYR* gene avoiding the *TYRL* pseudogene and the 6, 7 and 13 exons of the *OCA2* gene. Also MLPAp325 was performed in order to detect deletions or duplicacions in the *TYR* and *OCA2* genes.

Results: At least one single mutation in either or both *TYR* and *OCA2* genes has been identified in 12 out of 13 families. Most of the identified mutations were detected in a heterozygous pattern, but with the exception of the mutation p.Pro81Leu and the 2,7kb including exon 7.

Discussion: The entire coding regions of 4 genes associated with non-syndromic OCA have been analysed in many cases, however one single mutation have been identified in many of the cases analysed what suggests that other genes yet unidentified probably exist. Epistasic phenomenon also has been described in mice assays. The new technologies such as Next Generation Sequencing would provide us new insights in this disease.

P12.178
Novel *OFD1* mutations in males extend the phenotypic spectrum to vermis hypoplasia, polydactyly, hypothalamic hamartoma and *situs inversus*, and basal bodies docking impairment

OFD1 is classically responsible for dominant X-linked OFD I syndrome with male lethality, but mutations were recently reported in males, one syndromic mental retardation (MR) families (SGBS2, MIM300209) and two Joubert syndrome (JBS10, MIM300804) . We therefore sequenced the *OFD1* gene in a cohort of 92 males, including 32 JBS patients, 20 fetuses with Joubert/Meckel syndrome or ciliopathy spectrum, as well as 40 additional males with syndromic MR based on the association of at least 2/5 of the following criteriae: macrocephaly, obesity, polydactyly, recurrent respiratory infections, and retinopathy.

We identified 2 novel truncating *OFD1* mutations, both located in exon 21. The first *de novo* mutation was found in a fetus with polydactyly, vermis hypoplasia, but also hypothalamic hamartoma and *situs inversus* extending the phenotypic spectrum of *OFD1* mutations. The second maternally inherited mutation was found in a 10 year-old JBS male with polydactyly, obesity, recurrent bronchitis and abnormal nasal NO measurement. Electronic microscopy of airways epithelia in both cases showed cilia abnormalities and an abnormal centrosomal docking at the cell surface. *OFD1* expression analysis during early human development correlates with its phenotypic spectrum.

Our study further confirms that *OFD1* mutations in the C-terminal domain lead to syndromic recessive X-linked JBS in males. The *OFD1* gene should therefore be sequenced in JSRD males with molar tooth sign, in association with other suggestive features such as retinopathy, polydactyly, macrocephaly but also hypothalamic hamartoma and *situs inversus,* and recurrent bronchitis. Abnormal NO measurement might help orienting the molecular analysis towards *OFD1*.

P12.179
A compound heterozygous missense mutation and a large deletion in the *KCTD7* gene presenting as an opsoclonus-myoclonus ataxia-like syndrome

D. Lev[1,2], L. Blumkin[1], S. Kivity[1], R. Shomrat[3], T. Lerman-Sagie[1,2], E. Leshinsky-Silver[1,2];
[1]Wolfson Medical Center, Holon, Israel, [2]Sackler school of Medicine, Tel Aviv, Israel, [3]Pronto diagnostics, Tel Aviv, Israel.

Purpose: To describe a new presentation of KCTD7 mutations: an opsoclonus-myoclonus ataxia like syndrome with subsequent development of generalized continuous epileptic activity.

Methods: We recorded the clinical course of the disease, the evaluation and the response to steroid therapy. After excluding possible genetic causes, whole genome exome sequencing was performed in order to identify the causative gene. Sequence variants were filtered according to the phenotype. Sanger sequencing was performed to confirm the point mutation and MLPA was used for screening for a possible deletion in the second allele.

Key finding: Two pathological variants were found in the KCTD7 gene: R84W and a large deletion of exons 3 and 4. The father is heterozygous for the R84W mutation and the mother is heterozygous for the exon 3+4 deletion.

Significance: KCTD7 mutations were described in a single family with progressive myoclonus epilepsy. Our patient presented with non epileptic myoclonus, ataxia and opsoclonus responsive to corticosteroid treatment and only two years later developed an epileptic EEG witout overt seizures. The different phenotype broadens the spectrum of KCTD7 related diseases.

P12.180
Lack of mutations in COL1A2 gene in osteogenesis imperfecta patients from Russia

D. Nadyrshina[1,2], R. Khusainova[1], E. Khusnutdinova[1,2];
[1]Institute of Biochemistry and Genetict RAS, Ufa, Russian Federation, [2]Bashkir State University, Ufa, Russian Federation.

Osteogenesis imperfecta (OI) is a heritable disorder of connective tissue mainly caused by dominant mutations in type I collagen genes COL1A1 and COL1A2.

The aim of our study was to identify mutations in COL1A1 and COL1A2 genes in Russian OI patients.

We examined 54 patients with OI from 43 families and 50 healthy controls corresponding by age, gender, ethnicity and place of residence. All 51 coding exons in COL1A1 gene and 52 exons and flanking intronic regions in COL1A2 gene were analyzed by SSCP-analysis and direct sequencing.

One frameshift mutation (c.579delT (p.Gly194ValfsX71), three nonsense mutations (c.967G>T (p.Gly323X), c.1081C>T (p.Arg361X), c.2869C>T (p.Gln957X)) and one splice mutation (c.4005+1G>T) were identified in patients with autosomal dominant inheritance of OI type I. Two mutations (c.2444delG (p.Gly815AlafsX293) and c.3540_3541insC (p.Gly1181AlafsX38)) occurred in sporadic cases of OI type I, whereas c.1243C>T (p.Arg415X) mutation - of OI type 3.

In conclusion, the present study revealed eight mutations in COL1A1 gene (two of them observed de novo: c.967G>T (p.Gly323X) and c.3540_3541insC (p.Gly1181AlafsX38)) and no mutations in COL1A2 gene in Russian patients with OI. However, no predominant mutations were detected. Despite the previous studies indicating the vast majority (70%) of COL1A1/COL1A2 mutations causing OI being glycine substitutions to amino acid with a bulky side chain, we detected no missense ones. Interestingly, all detected mutations were unique for each family except for the frameshift mutation c.579delT (p.Gly194ValfsX71) observed in two unrelated families. Future research should focus on other genes responsible for OI development in Russian patients.

P12.181
LEPRE-1 gene in Osteogenesis Impefecta: study of mutations in Brazilian patients

F. Paula[1], C. Barbirato[1], M. G. Almeida[1], V. Sipolatti[2], M. R. G. O. Rebouças[2], V. Nunes[2], A. N. Akel Junior[2], I. D. Louro[1];
[1]Department of Biology, Federal University of Espírito Santo, Vitória, Brazil, [2]Hospital Infantil Nossa Senhora da Glória, Vitória, Brazil.

Osteogenesis Imperfecta (OI) is a heterogeneous genetic disease characterized by bone fragility, recurrent fractures and clinical variability. The majority of OI cases has autosomal dominant inheritance and is caused by mutations in genes that codify type I collagen protein. The *LEPRE1* gene is one of the most frequent mutated gene described in OI patients with recessive pattern. In order to characterize mutations in *LEPRE1* gene a total of 33 unrelated Brazilian OI patients were studied using SSCP screening and sequencing analyses. This study was approved by the Research Ethics Committee and all patients agree in participate of the work. The previously described African mutation (c.1080+1C>T) was found in homozygous state in one isolated case with severe OI. Two mutations were identified in heterozygosis: the c.1087A>G/p.Lys363Glu missense mutation detected in a sporadic case with severe form and the c.2024G>T/p.Trp675Leu change detected in a moderated case with recessive inheritance. In these patients the other changes were not found probably because of the technique limitations. The c.1720+52C>T mutation and c.1812C>T silence change were found in one patient with mild OI and dominant heritance, but absent in his affected mother, suggesting that these were no-pathogenic changes. Our results showed that almost 10% of Brazilian OI patients carry mutations in *LEPRE-1* gene. Moreover most of the carry patients have severe phenotype and are sporadic cases. These dates showed the importance of the study of *LEPRE-1* gene in OI and corroborate dates observed in other populations. Supported by Brazilian Institutions: CAPES, FAPES, FACITEC, CNPQ, Arcelor-Mittal, Brazil.

P12.183

An overview of clinical, biochemical and molecular findings in series of 36 COL1A1/COL1A2 mutation-negative osteogenesis imperfecta patients

F. Malfait, *S. Symoens, P. Coucke, A. De Paepe;*
Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Autosomal recessive osteogenesis imperfecta (OI) is associated with mutations in an expanding list of genes, encoding collagen-modifying enzymes and chaperones (CRTAP, LEPRE1, PPIB, FKBP10, SERPINH1 and PLOD2), and more recently SP7 and SERPINF1.

We studied the presence of mutations in these genes in a carefully selected cohort of 36 COL1A1 /COL1A2 mutation-negative patients with a clinical diagnosis of OI type II, III or IV, or with Bruck syndrome (BS), a related phenotype characterized by bone fragility and congenital contractures.

Homozygous/compound heterozygous mutations were found in 19/36 probands. The majority of mutations were present in LEPRE1 (n=6) and FKBP10 (n=5) and, to a lesser degree, in CRTAP (n=3), SERPINF1 (n=2), PPIB (n=1), SERPINH1(n=1) and PLOD2 (n=1). In agreement with previous reports, LEPRE1, CRTAP and PPIB defects cause a severe to lethal osteochondrodysplasia that overlaps with but is distinctive from OI type II/III, whereas FKBP10 and PLOD2 mutations are associated with Bruck syndrome. Two probands with progressive OI harboured homozygous SERPINF1 mutations, and a homozygous p.Arg222Ser was found in SERPINH1 in a patient with OI type III. Biochemical collagen studies provide a valuable contribution to the diagnostic work-up for recessive OI as important overmodification of the collagen type I α- chains is seen in the presence of CRTAP and LEPRE1 mutations. An abnormal electrophoretic pattern for type I collagen was also observed for the SERPINH1 mutation, but not for mutations in the other genes. Our findings also indicate that still other gene(s) are involved in the pathogenesis of OI.

P12.184

Identification of nucleotide substitutions and mutations in the *Otoferlin* (*OTOF*) gene in a cohort of patients with auditory neuropathy (AN)

A. Haenecour[1], *X. Pepermans*[1], *N. Deggouj*[2], *M. Vast*[1], *K. Dahan*[1], *K. Claes*[3], *E. De Leenheer*[4], *M. Vikkula*[1], *Y. Sznajer*[1]*;*
[1]*Center for Human Genetics, U.C.L, Brussels, Belgium,* [2]*Audiophonology Center, U.C.L, Brussels, Belgium,* [3]*Center for Human Genetics; U.Z Gent, Gent, Belgium,* [4]*ENT Dept, UZ Gent, Gent, Belgium.*

OTOF gene mutations were identified causative for an isolated autosomal recessive form of congenital auditory neuropathy, DFNB9. Since 1998, molecular investigation identified absence of hotspot mutations, numerous polymorphisms and variants of unknown significance. The first 10 local patients were reported at ESHG 2011 meeting. Additional patients were studied.

Material and methods: Patients were enrolled if they fulfill criteria for AN. Molecular investigation relied on complete ORF sequencing (NM_194248.2, long isoform, 1997aa). Our molecular lab is the only one in Belgium to sequence complete ORF of *OTOF* gene. Substitutions were noted as 'unclassified variants' when absent from Ensembl and Uniprot databases or from available publications. Family members were investigated when available.

Results: Among 32 patients referred for AN, 24 had isolated NA among whom 15 were congenital (prelingual).1/15 was identified with 1 homozygous mutation (c.3269C>A); 2/15 carried one mutation and a variant, probably pathogenic[1] (c.[2401G>T;2402A>T];[2464C>T] and c.[2401G>T ;2402A>T;c.4936C>T];[3608A>G]). These last two propositus originated from unrelated pedigrees from Congo and Burundi. 1 patient was carrier of 2 undetermined variants (c.[2123G>A];[206+9G>A]); 1 patient of 2 variants (c.[3751T>C(;)5063C>T]) and

6 patients had one variant only.

Conclusion: The present screening confirms substitutions considered as pathogenic reported once[1] and present in different genetic background population. Identified compound heterozygous (one mutation and one variant, this last reported so far as 'probably pathogenic') may account for a less severe phenotype. Precise genetic counseling remains delicate. Molecular strategy encompasses *GJB2* and *GJB6* genes before *OTOF* ORF sequence screening in AN.

P12.186

Novel mutation in Cathepsin C Gene (CTSC) and the Modeling of Mutated Protein in Three Iranian Families with Papillon Lefèvre Syndrome

E. Dadkhah[1], *M. Moghaddasian*[1], *H. Arab*[2], *H. Bustani Farkoush*[2], *M. Kazemi Noughabi*[1], *M. R. Abbaszadegan*[1]*;*
[1]*Human Genetics Division, Immunology Research Center, Avicenna Research Institute, Mashhad University of Medical Sciences (MUMS), Mashhad, Islamic Republic of Iran,* [2]*Department of Periodontology, School of Dentistry and Dental Research Center, Mashhad University of Medical Sciences (MUMS), Mashhad, Islamic Republic of Iran.*

Papillon-Lefèvre syndrome (PLS) is a rare autosomal recessive disorder characterized by hyperkeratosis followed later by periodontitis, destruction of alveolar bone and loss of primary and permanent teeth. Mutation of the lysosomal protease Cathepsin C (CTSC) gene is the genetic cause of PLS. The CTSC Gene was analyzed in three Iranian families with affected PLS showing premature tooth loss and palm plantar hyperkeratosis. Direct automated sequencing of genomic DNA was performed following amplification of exonic regions and associated splice intron site junctions of the CTSC gene. Mutation screening and sequence analysis of the CTSC gene revealed a novel mutation (P. 35delL) in exon 1 of one patient, and two previously reported mutations in other probands. The known mutations were a missense mutation in exon 4 which converts Arginine to Proline (CGT→ CCT, CM993131, codon 210) and a nonsense mutation in exon 6 that causes a stop codon (CGA→TGA, CM993134, codon 272) in the other two patients. RFLP for 100 normal alleles confirmed the new mutation. Protein modeling of the deduced novel mutation was performed by online server Swiss-Prot automated modeling and analyzed by special bioinformatic softwares including ZMM, ICM-browser and SPDB-viewer to better understand the structural defects. The structural defect caused by the mutation P. 35delL admits the polarity nature of the molecule. As this mutation occurred in the conserved domain of the CTSC, the structural analysis might reveal inconsistency of the special binding sites in the CTSC molecule which could be very important in the functionality of the protein.

P12.187

The guanine nucleotide exchange factor kalirin-7 is a novel synphilin-1 interacting protein and modifies synphilin-1 aggregate transport and formation

Y. Tsai, O. Riess, H. Nguyen, ***A. S. Soehn****;*
Department of Medical Genetics, University of Tuebingen, Tuebingen, Germany.

Synphilin-1 has been identified as an interaction partner of alpha-synuclein, a key protein in the pathogenesis of Parkinson disease (PD). To further explore novel binding partners of synphilin-1, a yeast two hybrid screening was performed and kalirin-7 was identified as a novel interactor. Kalirin-7 is a brain-specific guanine nucleotide exchange factor (GEF) enriched in the postsynaptic density (PSD) of excitatory synapses. It contains a SEC14 domain, a spectrin-like domain, a RhoGEF domain and a Pleckstrin homology domain (PH) which control multiple functions of the protein. Kalirin-7 activates Rac1 and regulates dendritic spine morphogenesis, plasticity and development. An interaction of kalirin-7 with huntingtin-associated protein 1 (HAP1), nitric oxide synthase (iNOS), and disrupted in schizophrenia 1 (DISC1) further links the protein to Huntington disease (HD), Alzheimer disease (AD), and schizophrenia.

In order to evaluate the functional relevance of this newly discovered interaction, we first focused on the ability of synphilin-1 to promote inclusion formation, as this feature provides a functional overlap of kalirin-7 and synphilin-1. By means of Co-immunoprecipitation, Fluorescent immunostaining, and Live cell imaging, a novel role for kalirin-7 in aggresome dynamics was identified.

P12.188

Parkinson disease: whole genome sequencing for the identification of novel genes

A. Verstraeten[1,2], D. Crosiers[1,2,3], P. Cras[2,3], C. Van Broeckhoven[1,2], J. Theuns[1,2];
[1]Neurodegenerative Brain diseases Group, Department of Molecular Genetics, VIB, Antwerp, Belgium, [2]Institute Born-Bunge, University of Antwerp, Antwerp, Belgium, [3]Department of Neurology, Antwerp University Hospital, Edegem, Belgium.

Gene identification studies can be instrumental in the elucidation of disease mechanisms underlying neurodegenerative brain diseases such as Parkinson disease (PD) and eventually support the development of earlier and more accurate diagnostic tools as well as formulation of preventive or curing therapies.

We therefore performed whole genome sequencing in a Flanders-Belgian PD patient with an onset age of 24 years and both unaffected parents. Successive filtering of the identified variations was based on sequence quality, genomic location and frequency in both the '1000 genomes project' and an extended collection of Flanders-Belgian individuals. Finally, variations were selected based on segregation in line with one of the four possible inheritance patterns. Focusing on high-confidence coding and splice site variations we identified 115 de novo, 40 homozygous recessive, 55 heterozygous compound recessive and 11 X-linked variations. Genetic validation in an extended cohort of geographically matched control individuals (N=1000), to exclude polymorphisms, resulted in 16 variations in 10 genes with a high potential to be linked to PD in this Flanders-Belgian nuclear family. We are currently estimating the contribution of these variations to PD pathogenesis in our cohort of Flanders-Belgian PD patients (N=600) using various genotyping platforms. Further we plan to sequence the selected candidate genes using a custom MASTR-NGS assay to identify other mutations in these genes to further support a role in PD pathogenesis. Eventually, functional characterization of the probable pathogenic variant(s) will be performed to gain insights into the mutation mechanism and disease processes.

P12.189

Caspase 8 and caspase 9 activation in peripheral blood lymphocytes of patients with LRRK2-associated Parkinson's disease

T. Usenko, A. Yakimovskii, A. Emelyanov, S. Pchelina;
Petersburg Nuclear Physics Institute, Saint-Petersburg, Russian Federation.

Mutations in the LRRK2 are the most frequent cause of familial Parkinson's disease (PD). Although the precise physiological and pathological role of LRRK2 is unclear, direct link between mutant LRRK2 and apoptosis has been suggested. There are two main caspase activation pathways of apoptosis, receptor-mediated sequential activation of caspase-8, and cytochrome c-dependent mediated caspase-9 activation. Earlier we showed higher level of spontaneous apoptosis in patients with LRRK2-associated PD compared to controls (persons without neurological disorders).

The aim of our present work was to examine the level of active caspase 8 and caspase 9 in peripheral blood lymphocytes (PBLs) after incubation (37°C, 5% CO2). PBLs of patients were isolated from venous blood. Cells were resuspended in RPMI1640 with Fetal Calf Serum and were incubated for 48 hours. We estimate the level of active caspase 8 of PBLs in two patients with LRRK2-associated PD (the G2019S mutation) compared controls (n=4) after 1h, 24h, 48h and caspase 9 after 24h of incubation by western blot analysis. β-actin was tested as an internal standard. The active enzyme subunits are 18kDa for caspase 8 and 10kDa for caspase 9. We found the activation of caspase 8 in both patients with the G2019S mutation and in all controls after 1h, 24h, 48h of incubation. The active caspase 9 was detected in both carriers of the G2019S mutation and in one from four controls after 24h of incubation. Thus, predominant activation caspase 9 in patients with LRRK2-associated PD could be suggested.

P12.190

Novel PCDH19 mutations in Bulgarian epilepsy cases

A. V. Kirov[1,2], P. Dimova[3], A. Todorova[1,2], T. Todorov[1,2], V. Bojinova[3], V. Mitev[1];
[1]Department of Medical Chemistry and Biochemistry, Medical University Sofia, Sofia, Bulgaria, [2]Genetic Medico-Diagnostic Laboratory Genica, Sofia, Bulgaria, [3]Clinic of Child Neurology, St. Naum University Hospital of Neurology and Psychiatry, Sofia, Bulgaria.

X-linked female-limited epilepsy is characterized by seizure onset in infancy or early childhood and cognitive impairment. The spectrum of phenotypes has been extended to include female patients with early infantile epileptic encephalopathy, type 9 (EIEE9). Heterozygous PCDH19 mutations were identified in EIEE9 patients. Interestingly, only heterozygous females are affected, while hemizygous males are devoid of seizures or cognitive impairment, although mosaic males can also be affected. This inheritance supposed cellular interference as possible pathogenic mechanism.

We report on two Bulgarian patients with typical clinical manifestation of EIEE9. Two novel mutations were detected in the PCDH19 gene: c.2705dupA; p(Asp902Lysfs*6) and c.1091delC; p.Pro364Argfs*4 (both in heterozygous state). Surprisingly, the mother of the first patient was heterozygous asymptomatic carrier of c.2705dupA. She has never suffered epileptic seizures and intellectual impairment. The second mutation c.1091delC was de novo.

To the best of our knowledge, this is the first case of a female heterozygous for a mutation in the PCDH19 gene who did not manifest any clinical features. Usually, the PCDH19 mutations arise de novo, are inherited by the unaffected carrier fathers or by affected mothers. The possibility for totally skewed X inactivation is very unlikely as it has never been detected in PCDH19 mutation-positive patients. Thus, one could speculate that, due to the complex interaction with other genetic, epigenetic factors, some PCDH19 mutation carriers could even fully "escape" any disease manifestation, and this could be the case in our patient's mother.

Identity-by-Descent Mapping Reveals a New Locus for Primary Congenital Glaucoma, GLC3E, on Chromosome 19p13.2

H. Verdin[1], B. Leroy[1,2], B. D'haene[1], F. Coppieters[1], S. Lefever[1], P. G. Kestelyn[2], E. De Baere[1];
[1]Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium, [2]Department of Ophthalmology, Ghent University Hospital, Ghent, Belgium.

Primary congenital glaucoma (PCG) is caused by developmental anomalies of the trabecular meshwork and the anterior chamber angle, resulting in an increased ocular pressure (IOP) and optic nerve damage from birth or early infancy. In general PCG displays an autosomal recessive inheritance and is genetically heterogeneous. To date, four PCG loci are known (GLC3A-D), in which two genes have been identified, *CYP1B1* and *LTBP2*. Here, we aimed to map the disease gene in a large, four-generation consanguineous family with PCG, originating from Jordan. Mutations in known PCG genes were excluded. Identity-by-descent (IBD) mapping was performed in six affected members using genome-wide SNP genotyping with 250K arrays. The common IBD regions did not overlap with any known PCG loci. Filtering on both size of the region and number of consecutive homozygous SNPs revealed a new candidate region on 19p13.2, named GLC3E. This region measures 2.67 Mb and contains 93 genes. Using prioritization tools, *BEST2* was selected as the best candidate gene. Indeed, Best2 is expressed in non-pigmented epithelial cells of ciliary body, which is responsible for formation of aqueous humour. Also, Best2-/- mice have significantly lower IOP than wild type littermates. Sanger sequencing of *BEST2* in affected individuals revealed no mutations however. To analyze the other genes in the IBD region, two affected individuals underwent exome sequencing for which data analysis is currently ongoing. We identified a potential new PCG locus, named GLC3E, confirming the genetic heterogeneity of PCG, and representing a unique opportunity to identify the third PCG gene.

Molecular genetic background of PEHO syndrome

A. Laari[1,2], A. K. Anttonen[1,3,4], O. Kopra[1,2], M. Somer[5,6], E. Jakkula[7], T. Joensuu[1,2], A. E. Lehesjoki[1,2];
[1]Folkhälsan Institute of Genetics, Helsinki, Finland, [2]Neuroscience center, University of Helsinki, Helsinki, Finland, [3]Molecular Medicine, University of Helsinki, Helsinki, Finland, [4]Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland, [5]Vaestoliitto, The Family Federation of Finland, Helsinki, Finland, [6]Department of Medical Genetics, University of Helsinki, Helsinki, Finland, [7]Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland.

The PEHO syndrome (Progressive encephalopathy with Edema, Hypsarrhytmia and Optic atrophy; MIM 260565) is a severe autosomal recessive inherited progressive infantile encephalopathy. The main features of PEHO syndrome are hypotonia, infantile spasms and/or hypsarrhytmia, psychomotor retardation, absence or early loss of visual fixation, edema of the face and limbs, and typical dysmorphic features. Brain atrophy is progressive and most prominent in the cerebellum, where the molecular layer is strongly reduced, Purkinje cells are abnormally small and misaligned, and the cells of the internal granular cell layer are almost absent. Based on imaging and neuropathological findings we have divided the PEHO syndrome into two types, the cortical atrophy and loss of myelin being pronounced in type 2.

Using a 318 k genome-wide SNP scan we identified a 435 kb region on chromosome 17 that was homozygous in Finnish type 1, but not type 2 patients. Sequencing of positional candidate genes revealed a missense mutation in a gene not previously associated with human disease in all but one patient with type 1 PEHO. Mutations were not present in type 2 patients. The

"PEHO1" gene encodes a protein possibly involved in transcriptional regulation. It is widely expressed in the brain, the expression pattern being compatible with the neuropathological findings. In developing mouse brain, the "PEHO1" protein expression is strong in neural progenitor and migrating premature granular cells. Transient overexpression studies revealed no difference in subcellular localization. This is the first step towards understanding the pathogenesis of PEHO, that is genetically heterogeneous.

P12.193
Perrault syndrome: Evidence for genetic heterogeneity and whole-exome sequencing to identify novel molecular mechanisms

F. E. Percin[1], *Y. Li*[2], *B. Cavdarli*[1], *B. Wollnik*[2];
[1]*Gazi University, Faculty of Medicine, Dept. of Medical Genetics, Ankara, Turkey,* [2]*Institute of Human Genetics, University of Cologne, Cologne, Germany.*

Autosomal recessively inherited Perrault syndrome (MIM233400) is a clinically and genetically heterogeneous disorder. It is typically characterized bilateral hearing loss, ovarian dysgenesis in female patients, and can be associated with neurological manifestations such as mental retardation and cerebellar ataxia. A proposed clinical classification suggests type I does not show neurological symptoms while type II patients do show variable affection of the nervous system. Recently, mutations in HSD17B4 and in HARS2 genes were described in some, but not all, patients with Perrault syndrome. Here we report a 16 years old girl with Perrault syndrome born to consanguineous parents, who presented with ovarian agenesis, microcephaly, mental retardation, neurologic abnormalities including ataxic gait, and no speech acquisition. Hearing impairment was not observed. Her karyotype was normal (46,XX). We excluded homozygosity of regions of described genes for Perrault syndrome by marker analysis. Subsequently, we performed whole-exome sequencing. Our strategy for the identification of the causative gene is based on an initial determination of homozygous stretches using all identified variants followed by a prioritization of likely damaging variants within these homozygous stretches. Using this innovative filter strategy we aim to identify a new gene underlying Perrault syndrome giving more insights into the pathogenic mechanism of the disease

P12.194
A novel splice site B3GALTL mutation confirms typical Peters plus syndrome in two Tunisian patients

O. Siala[1], *N. Belguith*[2], ***H. Kammoun***[3], *B. Kammoun*[4], *N. Hmida*[5], *I. Chabchoub*[6], *F. Fakhfakh*[1];
[1]*Laboratory of Human Molecular Genetics, SFAX, Tunisia,* [2]*Laboratory of medical genetic, SFAX, Tunisia,* [3]*Laboratory of Medical Genetic, SFAX, Tunisia,* [4]*Service d'ophtalmologie, SFAX, Tunisia,* [5]*Service de Néonatologie, SFAX, Tunisia,* [6]*Service de Pédiatrie., SFAX, Tunisia.*

Peters plus syndrome is an autosomal recessive rare disorder comprising ocular anterior segment dysgenesis, short stature, hand abnormalities, distinctive facial features, and often other major/minor additional defects. Only six mutations in the B3GALTL gene were recently reported in patients with Peters plus syndrome, leading to the inactivation of the B1, 3 -glucosyltransferase involving in the synthesis of a rare disaccharide that occurs on thrombospondin type 1 repeats of many biologically important proteins. In our study, we screened the B3GALTL gene in two unrelated Tunisian patients with typical Peters plus Syndrome. A novel homozygous c.597-2 A->G mutation was identified in both patients. Bioinformatic analyses using the MFOLD and the EMBOSS programs showed that this mutation modulates the pre mRNA secondary structure of the gene, and decreases the score value related to the formation of splicing loops. Moreover, the c.597-2 A->G mutation is located in a CpG island of the B3GALTL coding region, eliciting a potential epigenetic role of this position including gene's methylation and regulation. These data confirm an important role of the B3GALTL gene test that provides diagnosis confirmation and improves dramatically genetic counselling for the families.

P12.195
Molecular genetic analysis of PAH gene in Belarus: two novel mutations

J. V. Tsukerman, *K. A. Mosse*;
National Center of Applied and Research Medicine "Mother and child", Minsk, Belarus.

Phenylketonuria (PKU) is one of the most common inherited monogenic diseases in Belarus, its frequency is 1:6000 newborns. Classical PKU (OMIM#261600) is caused by mutations in PAH gene.

We completed the molecular-genetic analysis of R158Q, R261Q, Y414C, IVS10-11G> A and IVS12+1G>A mutations and sequencing of six exons of PAH gene in patients with PKU in Belarus. Identified mutations are shown in table 1.

Table 1. Mutations of PAH gene in patients with PKU in Belarus.

* identified by RFLP-analysis
** novel mutation

We identified two novel mutations, each on single chromosome: duplication c.1127_c.1132 in exon 11 and deletion 427C in exon 12. Both mutations were found in compound heterozygosity with R408W. In addition to mutation R408W, significant frequency in the Belarus population also have mutations R158Q (6,4%), E280K (2,4%), R261Q (1,4%), R252W (1,3%) and IVS12+1G>A (1,3%).

P12.196
Improvement of the PKHD1 mutation database for autosomal recessive polycystic kidney disease (ARPKD)

A. Venghaus, *I. Rieck, J. von Bothmer, K. Zerres, N. Ortiz Brüchle;*
Institute of Human Genetics, RWTH University Hospital, Aachen, Germany.

Mutations in the PKHD1 gene on 6p12 are associated with autosomal recessive polycystic kidney disease (ARPKD). This primary ciliopathy is characterized by enlarged bilateral polycystic kidneys and congenital hepatic fibrosis. The PKHD1 gene (longest ORF 66 exons) is highly complex due to its genomic size (470 kb). Its gene product polyductin/fibrocystin contains 4074 aa. Mutation detection rate is up to 90% with at least one detected mutation. The mutations are scattered throughout the whole gene. The vast majority of PKHD1-mutations are "private" mutations. Pathogenic mutations divide into about 60% missense and 40% truncating/splice mutations. Our PKHD1 mutation database (http://www.humgen.rwth-aachen.de) has been established to catalogue all changes detected in the PKHD1 gene in a disease specific database e. g. for use in clinical practice. Here we report about the revision and extension of the database with the aim to alleviate the evaluation of PKHD1 variants regarding their possible clinical significance. For this purpose evolutionary conservation and a more detailed bioinformatic validation of the 329 included missense changes (PolyPhen2) and segregation analyses data were re-evaluated and included. Additionally all changes were synchronized to dbSNP (version 135) entries, the allele frequencies and rs-numbers of 116 changes were added. Furthermore about 50 new variants have been added. In total the database now includes 752 entries dividing into 396 clearly pathogenic changes, 202 likely neutral and 154 changes of unknown significance. Evaluation of these changes will be the topic of further studies.

P12.197
AMH gene mutations in two Egyptian families with persistent mullerian duct syndrome

I. Mazen[1], *M. El Gammal*[1], *K. Amr*[1], *M. Abdel Hamid*[1], *A. Aref*[2];
[1]*National research Center, Cairo, Egypt,* [2]*Faculty of Medecine, Cairo, Egypt.*

Introduction: The anti-mullerian hormone (AMH) is responsible for regression of müllerian ducts during male sexual differentiation. Mutations in AMH or its type II receptor lead to persistence of the uterus and fallopian tubes in male children i.e. persistent müllerian duct syndrome (PMDS). Both conditions are transmitted according to a recessive autosomal pattern and are symptomatic only in males.

Patients and Methods: We report two unrelated Egyptian consanguineous families with PMDS. The first family comprised 3 affected prepubertal sibs complaining of undescended testis, pelvic exploration and laparotomy revealed mullerian derivatives. The other family was presenting with an adolescent male with impalpable left testis and pelvic exploration showed remnant of fallopian tubes and rudimentary uterus. AMH levels were very low and almost undetectable in all affected patients in both families. Direct sequencing of the coding region of the AMH gene identified two homozygous mutations in exon 1, R95X in the first family and V12G in the second family.

Conclusion: These data confirmed the autosomal recessive type of the PMDS, which needs molecular investigations of this rare disorder on large number of cases with undescended testis in Egypt will be of great value for proper diagnosis and genetic counseling.

P12.198

Phenotype and genotype variability of the PMM2 gene mutation among the same Egyptian family

S. Türkmen[1], *H. Afifi*[2], *M. Zaki*[2];
[1]Charité Virchow-Klinikum Institut für Medizinische Genetik und Humangenetik, Labor Berlin Charité Vivantes, Berlin, Germany, [2]National Research Centre Clinical Genetics Department, Cairo, Egypt.

Deficiency of phosphomannomutase (PMM2) is considered the most common congenital disorder of glycosylation (CDG) and designated as CDG1a. Phenotypic presentation is variable from severe disorder to milder phenotype. Here we describe an Egyptian family with 4 affecteds from 2 generations with mutation in PMM2 gene with different genotype and phenotype presentation in each generation. The older generation with 3 affected who was the paternal side sibship for our proband and were derived from first cousin parents. All of them had moderate to severe psychomotor retardation, the male patient never experienced walking and was non educable The older female affected was able to walk at the age of 6 year, and the younger female was able to walk with support and had a mild intellectual impairment. Interestingly, the female patients had no menstrual cycle. The hormonal and abdominopelvic sonar investigations revealed a premature ovarian failure in the affected females. Our proband was a six years old male patient from far relative parents with a normal cognitive function He had hypotonia, mild intesion tremors and ataxic gait although his MRI scans showed severe cerebellar atrophy. Strabismus was note in the second year of life and corrected by surgical intervention. The sequence analysis of the PMM2 gene revealed a compound heterozygous mutation in Exon 5 and in exon 8 in the proband and a homozygous mutation in Exon 8 in the other affected family members. This consanguine family demonstrated a phenotype and genotype variability of the PMM2 gene.

P12.199

Mutations in Rotatin link primary cilia function to organization of the human cerebral cortex

G. M. Mancini[1], *S. Kheradmand Kia*[1], *E. Verbeek*[1], *E. Engelen*[1], *R. Schot*[1], *R. Poot*[1], *I. de Coo*[1], *M. Lequin*[1], *C. Poulton*[1], *F. Pourfarzad*[1], *F. Grosveld*[1], *A. Brehm*[2], *M. de Wit*[1], *R. Oegema*[1], *W. Dobyns*[3], *F. Verheijen*[1];
[1]ErasmusMC, Rotterdam, Netherlands, [2]University of Madeira, Funchal, Portugal, [3]Center for intergative brain research, Seattle, WA, United States.

Polymicrogyria is a post-migratory organization defect of the cerebral cortex characterized by many small gyri with abnormal cortical lamination. Here, we identified autosomal recessive mutations in the Rotatin gene, *RTTN*, in patients with polymicrogyria from separate families. Rotatin determines early embryonic axial rotation as well as anteroposterior and dorsoventral patterning in mouse. We show that Rotatin colocalizes with the basal bodies at the primary cilium. Cultured fibroblasts from patients have structural abnormalities of the cilia and show down-regulation of *BMP4*, *WNT5A* and *WNT2B*, key regulators of planar cell polarity, expressed at the cortical hem, the cortex organizing center giving birth to Cajal-Retzius (CR) neurons. Indeed, in mouse embryos Rotatin expression co-localizes with CR neurons. Knockdown experiments in human fibroblasts and neural stem cells confirm a role for Rotatin in cilia structure and function. Rotatin mutations thereby link aberrant ciliary function to abnormal development and organization of the cortex in human patients.

P12.200

Mutations in a novel dynein assembly factor PF22 (DNAAF3) cause cilia dysmotility and left-right-axis defects

M. Schmidts[1], *J. Freshour*[2], *N. T. Loges*[3,4], *A. Dritsoula*[1], *D. Anthony*[1], *R. A. Hirst*[5], *C. O'Callaghan*[5], *H. Blau*[6], *T. Yagi*[7], *H. Mussaffi*[6], *E. Chung*[8], *H. Omran*[3,4], *D. Mitchell*[2], *H. M. Mitchison*[1];
[1]Molecular Medicine Unit, Institute of Child Health, University College London (UCL), London, United Kingdom, [2]Cell & Developmental Biology, SUNY Upstate Medical University, Syracuse, NY, United States, [3]Department of Pediatrics and Adolescent Medicine, University Hospital Freiburg, Freiburg, Germany, [4]Department of Pediatrics and Adolescent Medicine, University Hospital Münster, Münster, Germany, [5]Department of Infection Immunity and Inflammation, University of Leicester, Leicester Royal Infirmary, Leicester, United Kingdom, [6]Pulmonary Unit, Schneider Children's Medical Center of Israel, Petah-Tikva, Sackler School of Medicine, Tel-Aviv University, Tel-Aviv, Israel, [7]Department of Cell Biology and Anatomy, Graduate School of Medicine, University of Tokyo, Tokyo, Japan, [8]General and Adolescent Paediatric Unit, University College London (UCL), London, United Kingdom.

Primary ciliary dyskinesia (PCD) is an autosomal recessive disorder arising from dysmotility of cilia in the respiratory tract, brain ventricles, oviduct and the embryonic node leading to chronic obstructive pulmonary disease, reduced fertility and situs abnormalities. With a frequency of up to 1 in 10,000 PCD is a rather common "rare disease". To date, 12 genes causing approximately 40% of all cases have been identified, two encoding proteins (KTU, LRRC50) involved in cytosolic axonemal dynein co-assembly. Using homozygosity mapping and subsequent Sanger sequencing we have identified mutations in a new gene, C19ORF51 in PCD patients with absent dynein arms. We find that the Chlamydomonas ortholog of C19ORF51, PF22, is involved in the cytoplasmic assembly of the outer dynein arms preceeding their import into the axoneme. In PF22 mutants, axonemal dynein heavy chain stability as well as co-assembly of heavy with intermediate chains is significantly disturbed and PF22 appears to act downstream of KTU and LRRC50 in the dynein preassembly pathway. In zebrafish, PF22 knockdown results in a typical ciliopathy phenotype (axis curvature, pronephric cysts, hydrocephalus and situs inversus) due to loss of the axonemal dynein arms resulting in cilia dysmotility. We therefore propose a conserved multi-step pathway for formation of assembly-competent dynein complexes, and that PF22 (renamed DNAAF3, "dynein axonemal assembly factor 3") mutations causes PCD with situs inversus due deficient cytoplasmic dynein assembly resulting in absent dynein arms.

P12.201

Novel molecular findings in patients with primary hyperoxaluria and implications for advanced molecular testing strategies

Primary hyperoxaluria (PH) constitutes a group of autosomal recessive disorders characterized by excessive endogenous oxalate synthesis resulting in nephrocalcinosis and/or urolithiasis. Currently three types of PH (PHI-III) can be accurately defined. In contrast to the well-characterized entities of PHI and PHII, the pathophysiology and prevalence of recently described PHIII, caused by *HOGA1* mutations, is largely unknown.

In this study, we analyzed a large patient cohort previously tested negative for PHI/II by complete *HOGA1* sequencing. Seven distinct mutations, among them four novel, were identified in 15 patients. In patients of non-consanguineous European descent the previously reported c.700+5G>T splice-site mutation was predominant and represents a potential founder mutation. *In vitro* analysis of the c.700+5G>T mutation using a minigene assay showed activation of a new splice site 52 bases downstream from the wild-type donor splice site leading to an in-frame insertion of 17 amino acids to the native protein. Interestingly, we furthermore identified a family where a homozygous mutation in *HOGA1* (p.P190L) segregated in two siblings with an additional *AGXT* mutation (p.D201E).

First functional analysis revealed that HOGA1 deficiency is causing PHIII, yet reduced HOGA1 expression or aberrant subcellular protein targeting are unlikely the responsible pathomechanisms.

Our results strongly suggest *HOGA1* as a major cause of PH, indicate a greater genetic heterogeneity of hyperoxaluria spectrum, and point to an exceptionally favourable outcome of PHIII despite incomplete or absent biochemical remission. Potential multiallelic inheritance in PH has implications for genetic testing strategies and might represent an unrecognized mechanism for phenotype variability.

P12.202

Etiopathogenesis of primary lymphedema

M. Amyere[1]*, S. Greenberger*[2]*, D. Chitayat*[3]*, E. Pras*[4]*, K. Chong*[3]*, T. Uster*[3]*, H. Reznik-Wolf*[4]*, D. Marek-Yagel*[4]*, A. Mendola*[1]*, M. Schlögel*[1]*, L. Boon*[5]*, P. Brouillard*[1]*, M. Vikkula*[1,5,6]*;*
[1]*Laboratory of Human Molecular Genetics, de Duve Institute, Université catholique de Louvain,, Brussels, Belgium,* [2]*Vascular Biology Program and Department of Surgery, Children's Hospital Boston and Harvard Medical School,, Boston, MA, United States,* [3]*The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital; University of Toronto, Toronto, ON, Canada,* [4]*Danek Gartner Institute of Human Genetics, Sheba Medical Center, Ramat-Gan, Israel,* [5]*Centre for Vascular Anomalies, Cliniques Universitaires Saint-Luc, Université catholique de Louvain, Brussels, Belgium,* [6]*Walloon Excellence in Lifesciences and Biotechnology (WELBIO), Université catholique de Louvain, B-1200, Brussels, Belgium.*

Lymphedema is a soft tissue swelling resulting from abnormal accumulation of interstitial fluid containing high molecular weight proteins due to abnormal drainage of lymph by the lymphatic vasculature. Primary lymphedema is due to an abnormal development and/or function of the lymphatic system. Some of the cases are inherited with autosomal dominant or recessive mode of inheritance with incomplete penetrance and variable expression. Mutation screening of a large series (n=400) of sporadic and familial index patients led us to discover several mutations in syndromic and non-syndromic patients in the known lymphangiogenic, including FOXC2, VEGFR3, SOX18, CCBE1, PTPN14, GCJ2, GATA2 and KIF11. Yet, only 10% of the patients are explained by (an) identified inherited dominant or recessive mutation, or a de novo change. Samples without a mutation are extremely valuable for our ongoing genome-wide strategies to identify additional genes mutated in primary lymphedema. Among them, we have two consanguineous families with recurrence of a congenital lymphedema without a mutation in the known genes. Whole genome scan using Affymetrix SNP-Chip 250K was thus performed and no copy number change was identified in the affected members. Autozygosity mapping and parametric linkage analysis confirmed the exclusion of the 8 candidate lymphedema-genes. Interestingly, three overlapping autozygous regions were identified in the two families. These three identified loci are analyzed using massive parallel sequencing to identify novel lymphedema-causing mutations and genes. Our findings provide clear evidence for the existence of (a) new causative gene / genes associated with the autosomal recessive form of the disease. (miikka.vikkula@uclouvain.be).

P12.203

Clinical and genetic study of 46 Italian patients with primary lymphedema

D. Degiorgio[1]*, S. Michelini*[2]*, M. Cestari*[3]*, D. Corda*[4]*, M. Ricci*[5]*, M. Cardone*[2]*, A. Mander*[6]*, L. Famoso*[3]*, E. Contini*[4]*, R. Serrani*[5]*, L. Pinelli*[1]*, S. Cecchin*[1]*,* ***M. Bertelli***[1]*;*
[1]*Laboratory of Molecular Genetics, International Association of Medical Genetics (MAGI-onlus), Rovereto (TN), Italy,* [2]*Department of Vascular Rehabilitation, San Giovanni Battista Hospital, Roma, Italy,* [3]*Pianeta Linfedema Study Center, Terni, Italy,* [4]*Centro Medico e Riabilitativo per la Ricerca la Diagnosi e la Cura del Linfedema, Polimedica San Lanfranco, Pavia, Italy,* [5]*Medicina Riabilitativa, Azienda Ospedaliero-Universitaria Ospedali Riuniti di Ancona, Ancona, Italy,* [6]*Rehabilitative Centre Vaclav Vojta, Roma, Italy.*

Primary lymphedema is characterised by altered morphological development of lymphatic vessels causing fluid accumulation in interstitial spaces. In familial forms, it is transmitted as a dominant Mendelian trait with heterozygous mutations in genes involved in lymphangiogenesis. We used PCR and direct sequencing to analyse only the region of the FLT4 gene encoding the „tyrosine-kinase domain" and the single exon of the FOXC2 gene, in 46 Italian probands with primary lymphedema, 43 of whom had familial forms. We identified 12 mutations in 12 patients (12/46, 26%), six in the FLT4 gene and six in the FOXC2 gene; most of the mutations (9/12, 75%) were new and none were identified in 100 healthy subjects or listed in the NCBI dbSNP. Two of the new mutations determine the synthesis of a prematurely truncated protein, while the other seven cause amino-acid changes that we classified in three distinct categories according to their degree of conservation in the course of evolution, and chemico-physical parameters of wild-type and mutant amino acids. A clear relation emerged between genotype and phenotype because 4 (80%) of the 5 probands with onset at birth showed FLT4 mutations and 4 (80%) of the 5 probands without distichiasis and with FOXC2 mutations had an amino-acid substitution outside the forkhead domain, in line with data recently reported by van Steensel MAM et al. (2009). Besides allelic heterogeneity shown by „private" mutations in each proband, the absence of mutations in almost 75% of familial cases of primary lymphedema also suggests genetic heterogeneity.

Restrictive dermopathy-like phenotype caused by the homozygous mutation *LMNA* p.R435C due to partial uniparental disomy of chromosome 1

M. Wehnert[1]*, P. Meinke*[1]*, S. Starke*[2]*, W. Schröder*[1]*, W. Kiess*[2]*, U. Felbor*[1]*;*
[1]*Institute for Human Genetics Greifswald, University Medicine Greifswald, Greifswald, Germany,* [2]*Universitätsklinik und Poliklinik für Kinder und Jugendliche Department für Frauen- und Kindermedizin Leipzig, Leipzig, Germany.*

Restrictive Dermopathy (RD) is a rare autosomal recessive disorder characterized by intrauterine growth retardation, tight and rigid skin with prominent superficial vessels, bone mineralization defects, dysplastic clavicles, arthrogryposis and early death soon after birth. RD can be caused by mutations in *LMNA* or *FACE1*. *FACE1* codes for the ZMPSTE24 protein, which is necessary for the processing of prelamin A. *LMNA* mutations may affect the cleavage site for ZMPSTE24 resulting in progeroid syndromes. We report a patient affected by a progeroid syndrome with RD-like features. Besides missing hairiness, stagnating weight and growth, RD-like features including skin swelling and solidification, acrocontractures, osteolysis and muscular hypotension were continuously progressive until the patient died at the age of 11 month. For mutational analysis, the complete coding region including intron/exon boundaries of the *LMNA* and *FACE1* genes was amplified and used for direct Sanger sequencing. As a result, the homozygous mutation *LMNA* p.R435C was found. Interestingly, this mutation is not located at the cleavage site necessary for processing of prelamin A by ZMPSTE24. This might explain the atypical phenotype compared to other published cases of RD. Sequencing of the not consanguineous parents showed that the mutation was present only in the mother in heterozygous state, but not in the father who was wild type. MLPA analysis confirmed that the patient had two copies of the gene. Direct Sanger sequencing of highly polymorphic markers on chromosome 1 showed a partial uniparental disomy of chromosome 1 (1q21.3 to 1q23.1) including the *LMNA* gene.

Homozygosity mapping of two Omani Arab families with progressive myoclonic epilepsy

A. H. Alkhayat AlShehi[1]*, H. Alshukaili*[1]*, A. Alasmi*[2]*, M. M. Alhabsi*[1]*, R. Nandhagopal*[3]*, S. Alrasbi*[2]*, A. H. Crosby*[4]*;*
[1]*Sultan Qaboos University, Muscat, Oman,* [2]*Sultan Qaboos University Hospital, Muscat, Oman,* [3]*Sultan Qaboos University Hospital, london, United Kingdom,* [4]*St Georges University of London, London, United Kingdom.*

Progressive myoclonic epilepsy (PME) refers to a group of neurodegenerative diseases which are clinically and genetically heterogeneous. Five specific disorders have identified as the most frequent causes of PME including: Unverricht-Lundborg disease (Baltic myclonus); myoclonus epilepsy and ragged red fibres (MERRF syndrome); Lafora body disease (LBD); neuronal ceroid lipofuscinoses (NCL); and type I sialidosis. The main clinical feature shared by this group of disorders is progressive neurodegeneration accompanied by myoclonias and epilepsy. As a part of a larger research project on the genetics of inherited neurological disorders in Oman, this study was carried out to investigate genetic abnormalities in two Omani families with PME. The study comprised of two families with total of five affected individuals initially diagnosed with PME . Age of onset ranged from 7-17 years. Symptoms included progressively increasing myoclonic jerks with action and stimulus sensitive myoclonus, generalized tonic-clonic seizures, and ataxia**.** Some patients suffered also from memory and mental impairment and visual deterioration. Genome-wide homozygosity mapping was performed using Illumina 33K SNP arrays. SNP microarray analysis identified a shared 1.7 Mb autozygosity region between the affected sibs on chromosome 12q22.3, flanked by the two markers; rs13048089 and rs3788151. This region encompasses 54 genes, among which is *CSTB* which known to cause myoclonic epilepsy of Unverricht and Lundborg (ULD, or EPM1). Other candidate genes associated with epilepsy in this region include *PDXK* and *TRAPPC10*. Sequencing of candidate genes is in progress.

P12.206

Mutation in CUL3 is the cause for Pseudohypoaldosteronism type II in a Turkish family.

E. C. Friesema, *A. J. Verkerk, R. H. Koole, J. van Rooij, R. Kraaij, A. G. Uitterlinden, E. J. Sijbrands, A. H. van den Meiracker;*
Erasmus University Medical Center, Rotterdam, Netherlands.

A rare Mendelian form of hypertension is Pseudohypoaldosteronism type II (PHAII), also known as Gordon hyperkalemia-hypertension syndrome (OMIM 145260). Mutations in *WNK1* and *WNK4*, and two recently identified genes (*KLHL3* and *CUL3*) have been reported as causes of monogenic hypertension. In a Turkish family (parents and 5 children) one daughter was suspected of PHAII. This daughter has been diagnosed at age 24 years with severe hypertension (200/130 mm Hg), hyperkalemia (6.5 mmol/l; normal range 3.5-5.1), and normal renal function. All other family members are healthy.

We hypothesized that a *de novo* mutation in the daughter is the most likely cause of her disease. Sanger sequencing of *WNK1* and *WNK4* and SNP array analysis (OmniExpress, Illumina) did not reveal any mutation or large chromosomal abnormality. Full exome sequencing (Nimblegen SeqCapEZV2, Illumina HiSeq2000) of all seven family members identified 34,733 unique variants in our patient. Filtering against dbSNP, 1000Genome project, variants found in unaffected family members, and selecting loss or gain of function mutations resulted in 481 possible disease-causing variants. By comparing the recent mutations reported by Boyden et al (Nature, Febr 2012), we found an identical *de novo* mutation in *CUL3*, a splice acceptor site mutation in intron 8 resulting in the skipping of exon 9. This results in an in-frame 57 amino acid deletion abrogating the function of CUL3.

This *de novo* splice acceptor site mutation found in a second patient with PHAII confirmed *CUL3* as a cause of PHAII in line with Boyden et al.

P12.207

RUNX2 overexpression provides evidence for the involvement of a pro-osteogenic signaling pathway in pseudoxanthoma elasticum

M. J. Hosen[1], *O. M. Vanakker*[1], *P. J. Coucke*[1], *O. Le Saux*[2], *A. De Paepe*[1];
[1]*Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium,* [2]*Dpt. of Cell and Molecular Biology, John A. Burns School of Medecine, University of Hawaii, Honolulu, HI, United States.*

Aim. Pseudoxanthoma elasticum (PXE) is characterized by oculocutaneous and cardiovascular manifestations, due to mineralization and fragmentation of elastic fibers. The pathophysiology of ectopic calcification is unclear and hypotheses include oxidative stress and an unidentified serum factor. PXE patients also have diminished vitamin K (VK) serum concentrations, leading to inefficient activation of the VK-dependent mineralization inhibitor matrix gla protein (MGP). MGP acts as inhibitor of the pro-calcifying Bone Morphogenetic Protein 2 (BMP2). One of several BMP2-associated pathways is the "BMP2-Smad-RUNX2" pathway, where RUNX2 acts as transcriptional regulator of proteins involved in mineralization, osteogenesis and apoptosis. We studied the role of this signaling pathway in PXE.

Methods & Results. Immunohistochemistry for BMP2, Smad 1-4-5-8 and RUNX2 in whiskers of Abcc6 knock-out mice and human PXE dermis showed positive labeling, co-localizing with mineralization compared to controls, which was confirmed via qPCR on human PXE fibroblasts. TUNEL assays revealed significant increase in apoptosis in PXE fibroblasts. Caspase 3 stains demonstrated co-localization of apoptosis with mineralization foci in all tissues. Comparable qPCR results and apoptosis rates were obtained on PXE serum inoculated control fibroblasts.

Discussion & Conclusion. Our results indicate the involvement of the pro-osteogenic BMP2-Smad-RUNX2 pathway in PXE. RUNX2 upregulation can explain the expression profile of proteins previously implicated in PXE, leading to ectopic mineralization or neovascularisation. By also demonstrating an effect of oxidative stress and PXE serum, three principal pathophysiological observations in PXE can be merged in this pathway, which may provide therapeutic options through small-molecule inhibitors of BMP receptors.

Rhizomelic Chondrodysplasia Punctata (RCDP) is a peroxiomal biogenesis disorder which is categorized into three types. The genetic abnormality that causes RCDP type1 is *PEX7,* which is responsible for peroxisomal sorting of peroxisomal targeting signal type 2 containing proteins. Peroxisomal targeting signal type 2 consists of a nonapeptide that is located at the N-terminus of several peroxisomal matrix proteins.

In the present study, mutational analysis performed on an Iranian patient's fibroblast cells with RCDP distinct clinical phonotype. At the first step, total RNA extraction and cDNA synthesis carried out. RT-PCR product consisting whole length of *PEX7* cDNA was inserted into T/A cloning vector and sequenced. To evaluate functionality of detected mutation, mutant and normal CDS of *PEX7* was cloned into an expression vector PDB2 and co-transfected into fibroblast cells.

Sequence data revealed a missense homozygous mutation of G to A at nucleotide 257 in exon3 of *PEX7* coding sequence. Moreover, genomic analysis of *PEX7* gene confirmed the mutation in the mentioned location. This mutation caused one amino acid residue substitution of Cys to Tyr at codon 86 located on WD1 repeat domain region severely affected the functionality of *PEX7* protein. Back-transfection of vector containing mutant CDS of *PEX7* did not restore the normal peroxiome function in RCDP patient's fibroblasts unlike the native type of *PEX7*.

Renal tubular dysgenesis (RTD) is an autosomal recessive disease, which was described in stillborn siblings in 1983 by Allanson. In 2005 Gribouval et al. first reported that mutations in the genes coding renin-angiotensin system (RAS) are associated with RTD. The disease is characterised by an early onset and persistent fetal anuria that results to oligohydroamnion, Potter ,s syndrome, lung hypoplasia and calval hypoplasia. Inherited RTD represents a disease with a very severe course, which is lethal in most of the cases.

Specific pathomorphological change found in kidney with RTD are represented by either absence or poorly developed renal proximal tubules. Here we report a casuistic of a newborn with RTD - this is the first reported case of inherited RTD in Slovakia with evidence of a novel mutation in RAS. A male infant died eleven hours after birth because of a respiratory failure. Renal histology and following genetic analysis confirmed diagnosis of renal tubular dysgenesis. A novel homozygous R259C mutation in the gene coding angiotensin-converting enzyme (ACE) was found. This mutation was evaluated with the prediction tool PolyPhen-2. R259C mutation is predicted to be probably damaging with a score of 1.000. Consequent mutation analysis found the same heterozygous mutations in both parents, who are asymptomatic. Identification of this mutation now allows genetic counseling and prenatal diagnosis.

This work was supported by Center of Excellence for II (co-financed from ES ITMS code 26220120036), by MBRKM (ES IMTS code 26220220113), and by education grant from Pfizer code 26220220113.

Purpose: Mutations in the CRB1 gene have been associated with severe con-

genital and early-onset forms of retinal dystrophies including Leber congenital amaurosis (LCA), retinitis pigmentosa (RP) and cone-rod dystrophies. The aim of this study was to determine the incidence of CRB1 mutations in Spanish patients with congenital and/or early-onset retinal dystrophies.
Methods: 91 LCA and 255 Early-Onset RP unrelated Spanish patients were first analyzed with an APEX based microarray (LCA or ARRP chip, Asper Ophthalmics). All mutations were confirmed by direct sequencing and familial segregation was also verified. In patients without any mutation or with only one mutation, high-resolution melting (HRM) and multiplex ligation-dependent probe amplification (MLPA) analysis were further performed to complete the mutational screening of the CRB1 gene. Haplotype analysis and whole genome homozygosity mapping were also performed in 143 families.
Results: Known variants in CRB1 were identified in 42 of 346 (12%) patients by genotyping microarray, of them 31 patients (10%) carried two pathogenic disease alleles.
Conclusions: This study proved that 10% of Spanish patients with early onset Retinal dystrophies carried mutations in CRB1, ranging from 7% of early-onset RP cases to 15% of LCA families. The most frequent mutation in our cohort was p.Cys948Tyr, which was present in 22% of the alleles (15/68) in 13 families.

P12.211

Next-generation sequencing of 53 known genes for retinitis pigmentosa and allied diseases identifies the causative mutations in the majority of 40 patients

T. Eisenberger[1], B. Lorenz[2], A. Gal[3], S. Ghaffari[4], C. Decker[1], M. Schürmann[5], S. Baig[6], M. Preising[2], C. Schell-Apacik[7], C. Friedburg[2], C. Neuhaus[1], C. Bergmann[1,8], ***H. J. Bolz**[1,9];*
[1]Center for Human Genetics, Bioscientia, Ingelheim, Germany, [2]Department of Ophthalmology, Justus-Liebig University Giessen, Giessen, Germany, [3]Institute of Human Genetics, University Medical Center Hamburg-Eppendorf, Hamburg, Germany, [4]Comprehensive Genetic Center, Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran, [5]Institute of Human Genetics, University of Lübeck, Lübeck, Germany, [6]Human Molecular Genetics Laboratory, Health Biotechnology Division, National Institute for Biotechnology and Genetic Engineering, Faisalabad, Pakistan, [7]Praxis für Humangenetik am DRK-Klinikum Westend, Berlin, Germany, [8]Department of Human Genetics, RWTH Aachen University, Aachen, Germany, [9]Institute of Human Genetics, University Hospital of Cologne, Cologne, Germany.

Retinitis pigmentosa (RP), Leber congenital amaurosis (LCA) and Stargardt disease (STGD) are genetically extremely heterogeneous conditions, making mutation analysis difficult. We developed a diagnostic next-generation sequencing (NGS) approach targeting all coding exons of 53 genes: 31 for autosomal recessive RP (arRP; 413 exons), 23 for autosomal dominant RP (adRP; 248 exons) and 15 LCA genes (196 exons). We investigated 40 patients (33 with arRP, sporadic RP or STGD; 1 with adRP; 6 with LCA/early-onset severe retinal dystrophy). Sequence variants were identified using an in-house bioinformatic pipeline and JSI SeqNext-Software, and verified by Sanger sequencing. Biallelic mutations in *ABCA4*, *RP1*, *CRB1*, *TULP1*, *EYS* and *PDE6B* were found in 2 - 5 patients each and accounted for 50% of cases. Biallelic mutations in *C2ORF71*, *MERTK*, *RPGRIP1*, *CEP290* and *RDH5* were identified in single individuals. In one patient, a heterozygous truncating mutation was identified in the autosomal recessive disease gene *SAG*. Two patients turned out to be affected by adRP that appeared sporadic due to incomplete penetrance of *PRPF31* mutations in first-degree relatives, and the only patient with a family history indicating adRP carried a novel heterozygous *RHO* mutation. In summary, we identified the genetic basis of disease in 29/40 patients (72.5%). The identification of dominant mutations in apparently recessive cases and the involvement of 14 genes (although mutations in 6 genes account for two thirds of cases) illustrate the benefit of massively parallel sequencing of all RP genes regardless of the assumed mode of inheritance.

P12.212

Clinical and molecular analysis of Rett syndrome patients from the University Hospital of Medical School from Ribeirao Preto - Brazil

***G. A. Molfetta**[1,2], T. M. Assis[1,2], C. A. Ferreira[1,2], W. A. Silva Jr[1,2];*
[1]University of Sao Paulo, Ribeirao Preto, Brazil, [2]National Institute of Science and Technology in Stem Cell and Cell Therapy, Regional Blood Center of Ribeirão Preto, Ribeirão Preto, Brazil.

Rett Syndrome is a developmental disorder caused by mutations in the MECP2 gene located on X chromosome. Generally affects feminine individuals with an incidence of 1 in each 10.000-15.000 newborn girls. The syndrome leads to total or partial loss of cognitive, sensorial, emotional, motor and autonomic functions of the brain. Patients generally present deficits in the areas of learning, speaking, sensorial perception, mood management, movements, breathing, heart function, severe scoliosis, and even on the chewing, swallowing and digesting areas. These symptoms arise in 6 to 18 months old girls, after an apparently normal development, when the deficit of the psychomotor abilities becomes more evident. Laboratorial diagnosis can be done by screening for mutations along the coding region of the MECP2 gene and its adjacencies. This work focus on identifying and characterizing mutations on the MECP2 gene in patients clinically diagnosed as Rett syndrome, and to study the relationship between their genotype and phenotype. DNA was extracted from blood samples after parents signing the informed consent form, and High Resolution Melting technique and DNA sequencing were employed to screen for mutations. While searching for mutations in MECP2 exons, we have found a missence mutation (T158M) (GenBank X99686). All the four exons and the promoter region will be screened and genetic counseling will be offered to the families carrying mutations. This methodology is efficient for confirming the diagnosis of patients under suspect of Rett syndrome, a subdiagnosed pathology due to its complex clinical suspicion.
Financial Support: FAPESP, INCTC.

P12.213

Comparison of MLPA, microarray and qPCR data in patients with Rubinstein-Taybi syndrome and CREBBP deletions

***D. Galetzka**, M. Linke, J. Schröder, S. Lechno, U. Zechner, O. Bartsch;*
Institute of Human Genetics, University Medical Center of the Johannes Gutenberg University Mainz, Mainz, Germany.

There are mainly three techniques for DNA copy number analysis in the genome: (i) multiplex ligation-dependent probe amplification (MLPA), (ii) genome-wide microarray analysis, and (iii) quantitative PCR (qPCR). We aimed to compare the precision of MLPA and microarray results in breakpoint determination using a cohort of patients with RTS.
Using MLPA (Kit P313, MRC Holland), we identified 16 patients with Rubinstein-Taybi syndrome (RTS) and CREBBP deletions. Eleven patients (73%) had deletions extending beyond CREBBP: 7 patients (47%) showed (only) distally flanking deletions, 3 patients (20%) showed (only) proximally flanking deletions, and one patient (7%) demonstrated a large deletion flanking CREBBP on both sides, encompassing 860 kb and ~20 genes (from pter to qter: ZNF597-NAA60-CLUAP1- NLRC3-SLX4-TRAP1-DNASE1-TRAP1-CREBBP-ADCY9-SRL-TFAP4-GLIS2-PAM16-CORO7-VASN-DNAJA3-HMOX2-NMRAL1-C16orf5). Four patients (27%) showed both breakpoints within the CREBBP gene. Excluding one case due to insufficient DNA, data on 17 breakpoints within CREBBP could be precisely compared using MLPA, microarray analysis (Affymetrix 6.0), and qPCR. Comparison of MLPA and microarray data yielded consistent results for 9 breakpoints, differences of only 1 exon for five further cases, and for 2 and more exons in 3 cases with qPCR in most cases confirming the MLPA data. Taken together, genome-wide microarray analysis may at least in some cases give less precise data than other methods like MLPA or qPCR and may, in particular, overlook small deletions. The combination of the three techniques may improve the diagnosis and avoid later alternative and expensive diagnostics and/or management strategies.

P12.214

Twelve new mutations in the EP300 gene in patients with Rubinstein-Taybi syndrome.

***M. J. van Belzen**, C. A. C. van der Lans, D. J. M. Peters;*
Leiden University Medical Center, Leiden, Netherlands.

Rubinstein-Taybi syndrome (RSTS) is a rare disorder affecting approximately 1/100,000 newborns. The syndrome is characterized by mental and growth retardation and a particular dysmorphology mainly concerning the face, hands and feet. The most frequent cause of RSTS are mutations in the CREBBP gene, which are found in 30-50% of patients. Furthermore, microdeletions involving the CREBBP gene have been found in ~10% of patients. Mutations in EP300 have been published, but seem to be rare with a frequency of 1-3%.
In a cohort of 119 patients suspected of having RSTS, in 12 patients (6%) a pathogenic mutation in the EP300 gene was found. Eleven EP300 mutations were small sequence variants: three frameshift mutations, five nonsense mutations, one splice site mutation, one insertion/deletion mutation and one (de novo) missense mutation in the functional HAT domain. In addition, a deletion of exons 24 to 29 was detected. About one third of patients in this cohort (32%) could be explained by a mutation in the CREBBP gene, so in the majority of patients no mutation could be identified. In conclusion, these results show that mutations in the EP300 gene are a rare cause of Rubinstein-Taybi syndrome, but perhaps not as rare as previously thought.

SCA 36 was recently shown to be caused by a GGCCTG repeat expansion in intron 1 of NOP56 in Japanese families. NOP56 encodes a component of the ribonucleoprotein complex and plays a role in transcription and splicing processes. We found the same mutation in ten families, including two very large kindreds from the coastal region in Northwestern Spain (Costa da Morte, Galicia). The screening of the NOP56 expansion, carried out with Southern Blot analysis and repeat-primed PCR, revealed expanded alleles ranging from 650-2500 repeats, within a unique haplotype. The most recent common founder chromosome was dated over 600 years ago. We have studied 66 mutation carriers and observed both further expansions and contractions of the repeat upon transmission. The main clinical characteristics of the disease are a late-onset cerebellar syndrome with upper and lower motor neuron signs, oculomotor abnormalities and sensorineural hearing loss. SCA36 represents the most frequent SCA type so far in our region, with epidemiological implication for South American countries, the main destiny of traditional Galician emigration, where thus additional SCA36 cases might be identified. Together with the recent description of the intronic C9ORF72 hexanucleotide expansion in amyotrophic lateral sclerosis, our findings further highlight the increasing recognition of a major role of abnormal RNA processing in neurodegeneration.Acknowledgements: Xunta de Galicia-Consellería de Sanidade (PGIDT05SAN26PR), Consellería de Economía e Industria (10PXIB9101280PR) and Consellería de Innovación (Lucas Labrada contract to MG-M). Genotype-phenotype correlations in epilepsy patients with the SCN1A point mutations

***D. Hoffman-Zacharska**[1], E. Szczepanik[2], I. Terczynska[2], R. Tataj[1], J. Bal[1];*
[1]Department of Medical Genetics; Institute of Mother and Child, Warsaw, Poland, [2]Clinic of Neurology of Child and Adolescents; Institute of Mother and Child, Warsaw, Poland.

SCN1A, the gene encoding the sodium channel alpha 1 subunit, is now one of the most important epilepsy genes. SCN1A-related seizure disorders encompass a spectrum ranging from simple febrile seizures (FS), generalized epilepsy with febrile seizures plus (GEFS+) to Dravet syndrome (DS) and intractable childhood epilepsy with generalized tonic-clonic seizures (ICEGTC). Mutations of this gene were also detected in less common phenotypes. More than 700 mutations in SCN1A gene have already been associated with DS/GEFS+, mainly sequence alterations (80%). All mutations' are dominant and most of them occur de novo, however familial cases also been described (5-10%). In such cases proband, usually shows the most severe form, while the remaining family members milder phenotypes.

We present analysis of the distribution and type of SCN1A point mutations, we have identified in 50 patients clinically diagnosed as DS/GEFS+ and referred for molecular testing. Most of them showed sporadic form of disease (each with different mutation), but we also identified familial forms (3 families). Because all identified familial cases have mutation at this same protein residue p.Arg1596 (p.Arg1596His and p.Arg1596Cys) we show not only phenotypic heterogeneity between family members
but also interfamilial disease course and clinical picture differences.

P12.218

Delineation of a novel syndrome caused by biallelic SEMA3A mutations

***K. Hofmann**[1], M. Zweier[1], C. Zweier[1], W. Wittmann[2], H. Sticht[3], J. Hoyer[1], S. Uebe[1], C. Thiel[1], A. B. Ekici[1], A. Reis[1], A. Rauch[4];*
[1]Institute of Human Genetics, Friedrich-Alexander University Erlangen- Nuremberg, Erlangen, Germany, [2]Kinderzentrum St.Martin, Regensburg, Germany, [3]Institute of Biochemistry, Friedrich-Alexander University Erlangen- Nuremberg, Erlangen, Germany, [4]Institute of Medical Genetics, University of Zurich, Schwerzenbach-Zurich, Germany.

Molecular karyotyping is commonly used to identify disease causing de novo copy number variants in patients with developmental delay and multiple congenital anomalies. In such a patient with multiple congenital anomalies we now observed an 150 kb deletion on chromosome 7q21.11 affecting the first exon of the axon guidance molecule gene SEMA3A. This deletion was inherited from the healthy father, but considering the function of SEMA3A and phenotypic similarity to the knock-out mice, we assumed a recessive defect. Sequencing of the SEMA3A gene in the patient revealed the de novo in-frame mutation p.Phe316_Lys317delinsThrSerSerAsnGlu. Cloning of the mutated allele in combination with two informative SNPs confirmed compound heterozygosity in the patient. While the altered protein structure was predicted to be benign, aberrant splicing resulting in a premature stop codon was proven by RT-PCR to occur in about half of the transcripts from this allele. Expression profiling in human fetal and adult cDNA panels, confirmed a high expression of SEMA3A in all brain regions as well as in adult and fetal heart and fetal skeletal muscle. We therefore report the first bona fide human mutations in the SEMA3A gene delineating a novel autosomal recessive disorder characterized by postnatal short stature with relative macrocephaly, camptodactyly, septal heart defect and several minor anomalies. Normal intellectual development in the patient was surprising but may be explained by the remaining 20% of SEMA3A expression level demonstrated by quantitative RT-PCR.

P12.219

Clinical, in-silico and experimental evidence for pathogenicity of two novel splice site mutations in the *SH3TC2* gene

***P. Lassuthova**[1], M. Gregor[2], L. Sarnová[2], E. Machalová[1,2], R. Sedláček[2], P. Seeman[1];*
[1]DNA lab, Department of Paediatric Neurology, 2nd Faculty of Medicine, Charles University in Prague a, Prague, Czech Republic, [2]Institute of Molecular Genetics, Czech Academy of Sciences, Prague, Czech rep., Prague, Czech Republic.

Introduction: Charcot-Marie-Tooth (CMT) neuropathy is the most common inherited neuromuscular disorder. CMT is genetically very heterogeneous. Mutations in the *SH3TC2* gene cause Charcot-Marie-Tooth neuropathy type 4C (CMT4C), a demyelinating form with autosomal recessive inheritance. Two novel splice site mutations in the *SH3TC2* gene have been studied (c.279G>A, c.3676-8G>A).

Patients and Methods: Mutation c.279G>A was detected on one allele in two unrelated families with CMT4C in combination with a known pathogenic mutation (c.2860 C>T in one family, c.505T>C in the other) on the second allele of *SH3TC*2. Variant c.3676-8G>A was detected in one patient on one allele of the *SH3TC*2 in combination with c.2860 C>T on the other allele.

In-silico tests were performed and Exon Trap experiments were undertaken to prove the effect of both mutations on proper splicing of SH3TC2. Fragments of *SH3TC2* were subcloned into pET01 Exon Trap vector (Mobitec) and transfected into COS-7 cells.

Results: Aberrant splicing was predicted by computer tests for both mutations, which was confirmed by Exon Trap analysis. For c.279G>A it was shown that 19 bases from intron 3 are retained in cDNA. For c.3676-8G>A it was shown that the mutation produces a novel splice acceptor site for exon 17 and complex changes in splicing were observed.

Conclusions: We present evidence that mutations c.279G>A and c.3676-8-G>A in the *SH3TC2* gene cause aberrant splicing and are therefore pathogenic and causal for CMT4C. This report broadens the spectrum of causal mutations in the *SH3TC2* gene.

Ciliogenesis associated signal transduction is altered by NEK1 mutations in short rib-polydactyly syndrome type Majewski

***K. Kessler**[1], A. Giessl[2], J. H. Brandstätter[2], A. Rauch[3], C. T. Thiel[1];*
[1]Institute of Human Genetics, Friedrich-Alexander University Erlangen-Nuremberg, Erlangen, Germany, [2]Animal Physiology, Friedrich-Alexander University Erlangen-Nuremberg, Erlangen, Germany, [3]Institute of Medical Genetics, University of Zurich, Schwerzenbach-Zurich, Switzerland.

Defects of ciliogenesis have been implicated in a wide range of human phenotypes and play a crucial role in different signal transduction pathways and cell cycle coordination. We recently identified nonsense and splice site mutations in *NEK1* as the underlying cause of short rib-polydactyly syndrome type Majewski (SRPS II) (Thiel et al. 2011). According to their phenotype the short rib-polydactyly syndromes (SRPS) are classified into four distinct types: Saldino-Noonan (I), Majewski (II), Verma-Naumhoff (III) and Beemer (IV) and include the phenotypically related asphyxiating thoracic dystrophy (ATD) and Ellis-van Crefeld syndromes (EVC). Here, mutations in *EVC1/2*, *IFT80*, and *DYNC2H1* have been observed.

Absence of full-length NEK1 leads to a severely reduction of primary cilia length and a significant decrease of ciliated fibroblasts. The primary cilium acts as a chemosensor for important developmental pathways like hedgehog, wnt and the platelet-derived growth factor (PDGF) pathways. Thus we performed quantitative real-time PCR experiments to elucidate expression level changes of the crucial genes of these pathways and the other known SRPS genes. The overall difference of expression levels was increased up to 3.8 fold in our patient fibroblasts in comparison with controls. We further evaluated the changes of expression levels under starvation conditions to initiate ciliogenesis. These results confirm that disturbed cilia formation by the loss of *NEK1* affect signal transduction in these pathways explaining the clinical variability.

Shox2 and Tbx4 operate in a feedback loop during murine limb development

A. Glaser[1], *R. Arora*[2], *S. Puskaric*[1], *L. Li*[3], *N. Gretz*[3], *K. U. Schneider*[1], *V. E. Papaioannou*[2], *G. Rappold*[1];

[1]Department of Human Molecular Genetics, University Heidelberg, Heidelberg, Germany, [2]Department of Genetics and Development, Columbia University, New York, NY, United States, [3]Medical Research Centre, University Heidelberg, Mannheim, Germany.

The paralogous genes *SHOX* and *SHOX2* encode for homeodomain transcription factors with important functions during embryonal development. *SHOX* was identified as a human growth control gene as mutations in this gene lead to the skeletal deformities seen in Leri-Weill and Langer syndrome as well as idiopathic short stature. Although its closely related counterpart *SHOX2* could not be linked to any human phenotype so far, analysis of *Shox2* deficient mouse models revealed that *Shox2* also plays a crucial role in limb development where it controls neural, muscular and skeletal processes. To gain more insight into Shox2 dependent signalling pathways, we searched for target genes using microarray expression profiling and identified several interesting candidates such as different members of the T-Box transcription factor family as well as extracellular matrix protein encoding genes. For further analysis we focussed on the T-Box transcription factor *Tbx4* as a putative *Shox2* target gene which has essential functions in skeletal and muscular development of the limbs, similar to *Shox2*. We could demonstrate a dynamic regulatory effect of *Shox2* on *Tbx4* specifically in forelimbs. In turn, we uncovered *Tbx4* as a novel transcriptional activator of *Shox2* and therefore postulate *Shox2* as a feedback modulator of *Tbx4* during murine limb development.

Activating mutations in *PTPN11* cause Noonan syndrome (NS), the most common non-chromosomal disorder affecting development and growth. *PTPN11* encodes SHP2, an SH2 domain-containing protein tyrosine phosphatase that positively modulates RAS function. Here, we characterized functionally all possible amino acid substitutions arising from single-base changes affecting codons 62 and 63 to explore the molecular mechanisms lying behind the largely invariant occurrence of the Tyr62Asp and Tyr63Cys substitutions recurring in NS. We provide structural and biochemical data indicating that the autoinhibitory interaction between the N-SH2 and PTP domains is perturbed in both mutants as a result of an extensive structural rearrangement of the N-SH2 domain. Most mutations affecting Tyr^{63} exerted an unpredicted disrupting effect on the structure of the N-SH2 phosphopeptide-binding cleft mediating SHP2's interaction with signaling partners. Among all the amino acid changes affecting that codon, the disease-causing mutation was the only substitution that perturbed the stability of SHP2's inactive conformation without severely impairing proper N-SH2's phosphopeptide binding. On the other hand, the disruptive effect of the Tyr62Asp change on the autoinhibited conformation of the protein was balanced, in part, by less efficient binding properties of the mutant. Overall, our data demonstrate that the selection-by-function mechanism acting as driving force for *PTPN11* mutations affecting codons 62 and 63 implies balancing of counteracting effects operating on the allosteric control of SHP2's function.

P12.223

Novel mutations in a family with Maroteaux type of acromesomelic dysplasia and Sjögren's syndrome associated with neuropathy

C. Yang[1], *J. Wu*[1], *F. Tsai*[2], *Y. Chen*[1];

[1]Academia Sinica, Taipei, Taiwan, [2]China Medical University Hospital, Taichung, Taiwan.

Sjogren's syndrome is a chronic autoimmune disorder and displays a strong female predominance. We identified a consanguineous family with one affected female with Maroteaux type of acromesomelic dysplasia (AMDM) and Sjögren's syndrome associated with neuropathy. These symptoms are inherited as autosomal recessive traits. Exome sequencing of one affected and one normal individual in the family using Illumina Hiseq2000 was subjected and identified a homozygous nonsense mutation on a known AMDM gene, NPR2 gene, for the AMDM syndrome. For Sjögren's syndrome associated with neuropathy, we identified a novel homozygous variant on a gene that is highly expressed in immune cells and is a neurogenesis inhibitor. This variant is not present in 376 Taiwanese controls and we are now screening for its allele frequency in other patients with Sjögren's syndrome associated with neuropathy.

P12.224

Spectrums and frequencies of SLC26A4 and SLC26A5 genes mutation among patients with non-syndromic hearing loss from different regions of Russia

S. Lobov, *L. Dzhemileva, E. Khusnutdinova*;

Institute of Biochemistry and Genetics of Ufa Science Center RAS, Ufa, Russian Federation.

Background: The molecular etiology of hearing impairment in Russia has not been fully investigated. Study of GJB2, GJB6, GJB3, 12SrRNA, tRNASer(UCN) and MYO7A genes revealed that 55% of the patients with hearing loss carried GJB2 mutations in different regions of Russia. The SLC26A4 and SLC26A5 genes mutations are analyzed in this study.

Methods: Two hundred and fifty unrelated deaf patients were included. The all coding exons of SLC26A4 and first ten exons of SLC26A5 genes were sequenced in all 250 patients, including 130 patients carrying bi- and monoallelic recessive GJB2 mutations, two patients carrying a known GJB2 dominant mutation c.224G>A (p.Arg75Gln), as well as six patients with mtDNA (m.1555A>G, m.961insC(n), m.961delTinsC(n) and m.7444G>A) mutations.

Results: Eight patients (3,2%, 8/250) with non-syndromic hearing loss were found carrying SLC26A4 and SLC26A5 mutation and polymorphic variants. Among them, one patient with bi-allelic SLC26A4 mutations (c.85G>C (p.Glu29Gln) and c.149T>G (p.Leu50Arg)) had EVA by CT scan. One patient with non-syndromic hearing loss was heterozygous for mutations c.919-2-A>G in SLC26A4 gene. The most common SLC26A5 gene mutation, g.-53-2A>G, accounted for 0,4% (1/250) of all SLC26A4 mutant alleles. Two patients with non-syndromic hearing loss were heterozygous for polymorphic variant c.49548A>G (p.Gly740Ser) in SLC26A4, and one was heterozygous for polymorphic variant g.38190T>C in SLC26A5. The novel SLC26A4 gene mutation g.29607delA was identified in one patient with EVA.

Conclusion: Our results suggest that GJB2, SLC26A4 and SLC26A5 mutations together make up a major cause of congenital hearing loss in the different populations from Russia.

P12.225

FL-SMN and *PL3* expression in discordant spinal muscular atrophy (SMA) siblings and asymptomatic *SMN1* deletans

G. Dubsky de Wittenau[1], *S. Radovic*[2], *N. Passon*[3], *F. Curcio*[3,4], *C. Pucillo*[3], *M. Morgante*[2,5], *R. Lonigro*[3,6];

Danieli, via J. Linussio 51, Udine, Italy, [6]Dipartimento di Medicina di Laboratorio, SOC Istituto di Patologia Clinica, A.O.U., Udine, Italy.

Survival motor neuron1 gene (*SMN1*) is the main determinant for SMA disease while plastin3 (*PLS3*) is referred as a neuroprotective gene allowing genotype/phenotype discrepancy for healthy *SMN1* deletans. We compared the transcript levels of *FL-SMN* and *PLS3* in peripheral blood mononuclear cells (PBMCs) and EBV-immortalized cells from three individuals harbouring a homozygous deletion of *SMN1*. Two subjects are male and female discordant siblings haploidentical for the SMA locus (0 *SMN1*/4 *SMN2*), one subject is a asymptomatic unrelated female (0*SMN1*/5 *SMN2*). We analyzed the expression of *FL-SMN* and *PLS3* in those individuals by qRT-PCR in PBMC and EBV-immortalized cells. All three individuals similarly express both genes in PBMC suggesting that none of the two is responsible for neuroprotection of the asymptomatic females. In EBV-immortalized cells instead, we measured comparable expression levels only for *FL-SMN* transcripts across the subjects tested, while a dramatic reduction for PLS3 transcripts, ranging from 25 to 100-fold less, was observed in two out of three SMN1 deletans. A strong reduction of PLS3 expression could reflect an EBV-dependent event or particular feature of B lymphocytes. To address this question we compared transcript levels of PLS3 in B and NON-B cells from the two unrelated, phenotypically discordant subjects and observed a decrease in B cells only, ranging between 1,6 and 5-fold less than those in PBMC. We conclude that PLS3 transcript levels, at least in pheripheral blood is unrelated to health/disease condition of SMA deletans and that an EBV-dependent immortalization could alter gene expression.

P12.226

A novel SMAD3 variation in a family variably affected by symptoms of aneurysms-osteoarthritis syndrome

B. Keyser[1], *M. Mair*[2], *J. Schmidtke*[1], *E. Weis*[3], *O. Bartsch*[3], *M. Stuhrmann-Spangenberg*[1];
[1]*Institute of Human Genetics, Hannover Medical School, Hannover, Germany,* [2]*Institute of Human Genetics, Saarland University, Homburg/Saar, Germany,* [3]*Institute of Human Genetics, University Medical Center of the Johannes Gutenberg-University, Mainz, Germany.*

Thoracic aortic aneurysm and dissection (TAAD) is a condition which can occur isolated or in combination with other syndromes, such as Marfan syndrome or Loeys-Dietz syndrome. Recently a new syndrome, termed aneurysms-osteoarthritis syndrome (AOS), has been described (van de Laar et al. 2011). AOS is an autosomal dominant disorder. The main features of AOS are aortic aneurysms and dissection, osteoarthritis and aneurysms of other vessels, such as the cerebral arteries. Mutations responsible for this disease were found in the SMAD3 gene. The SMAD3 protein is activated by TGF-ß via the TGF-ß receptors 1 and 2 and functions as a transcriptional modulator.
We report on a family in which the affected members present with diverse symptoms, including aortic aneurysms, skeletal and ophthalmological manifestations, and with variable expressivity. We identified a novel sequence variation, c.934G>A (p.Ala312Thr), in the SMAD3 gene. The variation is located in exon 7 in the MH2 domain of SMAD3, which is responsible for oligomerization of SMAD3 with SMAD4. The mutated alanine residue is highly conserved among other species and biometric analysis predicted this variation to be pathogenic. In one family member with skeletal manifestations we could not detect the SMAD3 variation. This could indicate that the SMAD3 variant acts as one of several genetic and non-genetic factors predisposing for the disease in this family.

P12.227

A restricted spectrum of mutations in the *SMAD4* tumor-suppressor gene underlies Myhre syndrome

V. Caputo[1], *L. Cianetti*[1], *M. Niceta*[1], *C. Carta*[1], *A. Ciolfi*[1], *G. Bocchinfuso*[2], *E. Carrani*[1], *M. L. Dentici*[3], *E. Biamino*[4], *E. Belligni*[4], *L. Garavelli*[5], *L. Boccone*[6], *D. Melis*[7], *A. Generoso*[7], *B. D. Gelb*[8], *L. Stella*[2,9], *M. Silengo*[4], *B. Dallapiccola*[3], *M. Tartaglia*[1];
[1]*Istituto Superiore di Sanita', Rome, Italy,* [2]*Università di Roma „Tor Vergata", Rome, Italy,* [3]*Ospedale Bambino Gesù, Rome, Italy,* [4]*Università di Torino, Turin, Italy,* [5]*IRCCS Arcispedale Santa Maria Nuova, Reggio Emilia, Italy,* [6]*Ospedale Microcitemico, Cagliari, Italy,* [7]*Università "Federico II", Naples, Italy,* [8]*Mount Sinai School of Medicine, New York, NY, United States,* [9]*Neuromed, IRCCS, Pozzilli (IS), Italy.*

Myhre syndrome is a developmental disorder characterized by reduced growth, generalized muscular hypertrophy, facial dysmorphism, deafness, cognitive deficits, joint stiffness and skeletal anomalies. Here, by performing exome sequencing of a single affected individual coupled to a hypothesis-driven filtering strategy, we establish that heterozygous mutations in *SMAD4*, which encodes for a transducer mediating TGFβ and BMP signaling branches, underlie this rare Mendelian trait. Two recurrent *de novo SMAD4* mutations were identified in eight unrelated subjects. Both mutations were missense changes altering Ile^{500} within the evolutionary conserved MAD homology 2 domain, a well known mutational hot spot in malignancies. Structural analyses suggest that the substituted residues are likely to perturb the binding properties of the mutant protein to signaling partners. While *SMAD4* has been established as a tumor suppressor gene somatically mutated in pancreatic, gastrointestinal and skin cancers, and germline loss-of-function lesions and deletions of this gene have been documented to cause disorders predisposing to gastrointestinal cancer and vascular dysplasias, the present report identifies a previously unrecognized class of mutations in the gene with profound impact on development and growth.

P12.228

The mutation status of BMPR1A, SMAD4, PTEN and STK11 genes in Polish patients with hamartomatous polyposis syndromes

M. Podralska[1], *W. Cichy*[2], *A. Pławski*[1], *R. Słomski*[1];
[1]*Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland,* [2]*Karol Marcinkowski University of Medical Sciences, Poznan, Poland.*

The hamartomatous polyposis syndromes are a heterogeneous group of disorders that share an autosomal-dominant pattern of inheritance and are characterized by hamartomatous polyps of the gastrointestinal tract. These syndromes not only carry the risk of developing colorectal cancer, but also increase the risk of malignant transformation in other organs. In this study four hamartomatous polyposis syndromes (juvenile polyposis syndrome, Peutz-Jeghers syndrome, Cowden syndrome and mixed polyposis syndrome) were investigated. Mutations in SMAD4, BMPR1A, STK11 and PTEN are responsible for developing hamartomatous polyps. The study group consisted of 62 Polish families. Mutation screening methods and MLPA technique were used. The sequence analysis was performed for fragments with difference SSCP/duplex patterns and for verification of MLPA method. As a result of molecular analysis 32 pathogenic mutations in 34 patients were identified. Three mutations were detected in BMPR1A gene. In four families with juvenile polyposis syndrome has been identified pathogenic mutations in SMAD4. In STK11 gene was detected 12 types of mutations in 13 families with Peutz-Jeghers syndrome. Two substitutions were detected in families with Cowden syndrome. Moreover, numerous of polymorphic changes in both the coding and intronic sequences were observed. The majority of mutations are large changes and they represent 40% of all detected mutations. Mutations established in Polish population have heterogeneous nature. Only three mutations were recurrent. In addition, there was no strong genotype-phenotype correlation in all studied hamartomatous polyposis. In all cases, MLPA analysis should be performed as a first step to improve efficiency of molecular diagnostics.Supported by grant NN401014435

P12.229

Modifiers of Smith-Lemli-Opitz Syndrome and implication for mutation databases

B. Lanthaler, *J. Zschocke*, ***M. Witsch-Baumgartner***;
Medical University Innsbruck, Innsbruck, Austria.

Background The Smith-Lemli-Opitz Syndrome (SLOS [MIM 270400]) is an autosomal recessive malformation syndrome that shows a great variability regarding severity. SLOS is caused by mutations in the Δ7sterol-reductase gene (DHCR7; E.C. 1.3.1.21) which disrupt cholesterol biosynthesis. Phenotypic variability of the disease is already known to be associated with maternal *ApoE* genotype. Recently a second modifier of this monogenic disease has been demonstrated which is ABCA1. The existing LOVD based mutation databases includes the *DHCR7* genotype for each phenotypical described patient. It includes the so-called severity score, *DHCR7* haplotypes, geographic origin, and cholesterol data if present.
Findings on modifier Regarding ApoE there are the known allelic variants ApoE2, E3, E4 determined in the mothers who play a role in phenotypic variability and cholesterol concentrations of the patient. Regarding ABCA1 it is the maternal genotype of the SNP p.Arg1587Lys that is associated with severity of the disease and in an already unknown manner with the viability of SLOS foetus.
Implication for mutation databases The aim of patient based mutation database is to interpret molecular findings concerning the accurate diagnosis, getting information about prognosis and possible useful therapies. Hence the existing database is complemented now by additional data about maternal ApoE genotype. Adding all known sequencing results (SNPs) of the concerned genes, and additionally molecular data of modifier genes makes particularly sense in atypical patients.

P12.230

Study of positive modifiers of spinal muscular atrophy severity in Russian patients.

M. Maretina[1], ***A. Kiselev***[2], *G. Zheleznyakova*[1], *A. Egorova*[2], *V. Baranov*[2,1];
[1]*Saint-Petersburg State University, Saint-Petersburg, Russian Federation,* [2]*Ott's Institute of Obstetrics and Gynecology RAMS, Saint-Petersburg, Russian Federation.*

Spinal muscular atrophy (SMA) is autosomal recessive neuromuscular disorder caused by homozygous mutation within the *SMN1* gene. The ability of *SMN2* gene, a nearly identical copy gene of *SMN1,* to produce 10% of full-length transcript makes it principal positive disease modifier. The *SMN2* copy number correlates with patients' phenotypes and is used as reliable biomarker for SMA diagnostics. The second positive disease modifier is c.859G>C substitution in *SMN2* gene. The aim is to evaluate role of positive disease modifiers in Russian patients. We have developed fast and reliable test based on RFLP and sequence-specific primers to perform screening of c.859G>C mutation. Totally 145 individuals with mild phenotypes were tested. No patients with mutation were found which could be explained by population differences. *SMN2* gene dosage analysis was performed for 117 patients with I (39), II (50) and III (28) SMA types by means of real-time PCR. Most of type I patients had 2 *SMN2* copies (76,92%), 20,51% of patients had 3 copies and one person (2,56%) had 1 copy. Most of type II patients showed 3 copies (78%), 12% and 10% of patients had 4 and 2 copies accordingly. 50% of type III patients had 4 copies, 46,43% - 3 copies and only one person (3,57%) possess 2 copies. We observed marked differences in frequency of *SMN2* gene copies between patients with different SMA types. Our results confirm genotype-phenotype correlation between *SMN2* copy number and SMA severity and allow to use it as important biomarker for determination of disease phenotype.

P12.231

Investigating autosomal recessive cerebellar ataxias: clinical, biochemical and neuroimaging studies of 262 Brazilian patients

***C. M. Lourenco**, C. Sobreira, C. Funayama, W. Marques Jr;*
University of Sao Paulo, Ribeirao Preto, Brazil.

Autosomal recessive cerebellar ataxias (ARCAs) comprise a heterogeneous group of inherited neurodegenerative disorders that affect the cerebellum, the spinocerebellar tract and/or the sensory tracts of the spinal cord. They lead to progressive cerebellar ataxia in association with other neurological or extra-neurological signs. The epidemiological features and the relative frequency of such disorders are quite unknown yet. We prospectively studied 262 suspected ARCA patients from Brazil between 2005 and 2011. All patients were evaluated in the neurogenetics clinics with a standard evaluation, neuroimaging studies (CT scan, brain MRI with spectroscopy), ophtalmological and auditory evaluations, neurophysiological studies (EEG, ERG, and EMG/NCV), hormone and biochemical tests, muscle biopsy with respiratory chain mitochondrial analysis, screening for inborn errors of metabolism (enzyme studies, peroxisomal and sterol panels, cholestanol dosage, organic acids, aminoacids chromatography), molecular studies for the FRDA expansion , mitochondrial point mutations and SCAs 1, 2,3, 6,7,10,12,17 - when indicated, nerve/skin biopsy for EM studies and karyotype were also performed. A conclusive diagnosis was established for 196 patients. The most frequent causes seen in our cohort were Friedreich ataxia, leukodystrophies, Joubert syndrome, ataxia with oculomotor apraxia types I and II, mitochondrial disorders and neurolipidoses. ARCAs are rare disorders with a wide differential diagnosis. Recognition of the most frequent genetic causes of ARCA can lead to a sequential evaluation capable of establishing a definitive diagnosis in the majority of patients; new techniques as SNP arrays and exome sequencing can be extreme useful in identification of new ARCAs, although they were not available for our study.

P12.232

Search for a novel gene locus for spinocerebellar ataxia in combination with leukodystrophy: Genome wide linkage, fine mapping and exclusion of candidate genes in a German family

*I. Duske[1], K. Hinderhofer[2], S. Heinrich[1], A. Köhler[1], J. Zschocke[3], U. Müller[1], **D. Nolte**[1];*
[1]Justus-Liebig-Universität, Giessen, Germany, [2]Universitätsklinikum Heidelberg, Heidelberg, Germany, [3]Universität Innsbruck, Innsbruck, Austria.

We investigated three brothers affected by severe, progressive gait and limb ataxia in combination with dysarthria and nystagmus starting early in childhood. MRI revealed white matter loss. Since the mother is also affected, but signs and symptoms started in her late twenties, we postulate autosomal dominant or X-chromosomal recessive inheritance.

After exclusion of all known genes mutated in spinocerebellar ataxia (SCA), we additionally excluded diseases such as Pelizaeus-Merzbacher Disease/ Paraplegia, Typ 2 (PLP) and Alexander Disease (GFAP).

Since we were not able to detect a disease-causing mutation in any of the analyzed genes, we performed genome wide linkage analysis. Ten genomic regions linked to the disease were identified. Among those, regions on 1q, 3p, 7q, 7q, 21q and Xq. We subsequently further delineated the critical regions and searched for copy number variations. Linked regions and candidate genes based on expression data and function will be presented.

P12.233

Influence of mutations in first nucleotides of exons on splicing of the btk gene

***L. Grodecká**, B. Ravčuková, T. Freiberger;*
Molecular Genetics Laboratory, CKTCH, Brno, Czech Republic.

Splicing is a crucial step of eukaryotic gene expression which takes place at loosely defined splice sites. Apart from alterations in conserved dinucleotides, it is difficult to predict effect of mutations located in splice sites just from sequence change itself. Mutations in the first nucleotide of exons affect splicing when found in AG-dependent 3‘ splice sites typically possessing weak and/or short polypyrimidine tracts while exons with AG-independent splice sites are resistant to this type of mutations. Recent study showed that mutations in the +1 G impaired splicing in exons with preceeding polypyrimidine stretches (PPS) from 4 nt do 10 nt long whereas those with PPS from 9 to 16 nt long were normally spliced.

We identfied three changes of first nucleotides of exons in our patients with *btk* mutations. Two of them were point mutations of +1 G located in 3‘ splice site with borderline PPS length (8 nt), though just one of them affected the process of splicing. The third mutation was a deletion of four nucleotides in a splice site with 10 nt long PPS (but the affected exon started with A nucleotide). This mutation did not influence splicing of the gene. We sought to examine how the most commonly used *in silico* splicing prediction tools would cope with the effect of these mutations on splicing. We found that all herein described mutations decreased predicted scores in NNSPLICE, MaxEnt and PSSM. However, with an exception of MaxEnt program, the score change was rather mild.

P12.234

Novel mutations in a family with spondylocostal dysostosis

***J. Wu**[1], F. Tsai[2], C. Yang[1], Y. Chen[1];*
[1]Inst. of Biomedical Sciences, Taipei, Taiwan, [2]China MedicalUniversityHospital, Taichung, Taiwan.

Spondylocostal dysostosis (SCDO) is a heterogeneous group of disorders with multiple vertebral segmentation defects that results in hemivertebrae, rib fusions and deletions. We characterized a SCDO family with two affected children inherited as an autosomal recessive mode in Taiwan. Four known genes causing autosomal recessive forms of SCDO were excluded to be disease-causing gene for this family by direct Sanger sequencing. Exome sequencing of this family using Illumina Hiseq2000 was subjected to identify novel homozygous variants and compound heterozygous variants. A novel homozygous insertion variant that results in a frameshift in amino acid sequence was identified in a gene that has caused other disorders with vertebral malsegmentation and much severe clinical manifestations. This variant is not present in 376 Taiwanese controls. This finding expends the phenotypic spectrum resulting from novel mutation of the gene.

P12.235

Genetic testing of Stargardt disease as a model for high-throughput analysis of heterogenous diseases

H. L. Schulz[1]*, L. G. Fritsche*[1], F. Bambl[2], B. H. Weber[2];*
[1] Authors contributed equally / Institute of Human Genetics, Regensburg, Germany, [2]Institute of Human Genetics, Regensburg, Germany.*

Stargardt disease (STGD), a frequent maculopathy with juvenile onset, is caused by mutations in ABCA4, CNGB3, and ELOVL4. To date, more than 550 distinct ABCA4 mutations have been reported to cause disease. Nevertheless, the genetic heterogeneity of STGD and the complexity of the ABCA4 gene, which has 50 coding exons, often hinder routine application in genetic testing. We therefore developed an Affymetrix-based resequencing array that allows analysis of STGD-related genes in a cost- and time-saving procedure.

A challenging task is the interpretation of sequence data and the identification of disease-relevant variants. Consequently, we have generated an automated variant interpretation pipeline which is linked to ongoing international DNA variant project efforts such as the 1,000 Genomes Project or the NHLBI Exome Sequencing Project which currently has data from 3,510 individuals of European descent. In addition, the pipeline automatically queries in-silico prediction tools such as MutationTaster and PolyPhen-2. Neutral and intronic sequence changes not affecting the canonical splice-acceptor or splice-donor sites are analyzed with the Alamut decision-support software. So far, we have included a total of 158 STGD patients in our analysis. This identified 1,027 distinct variants, of which 20% (n=199) were defined as pathogenic or likely pathogenic and 91 as variants of uncertain significance (UVs). From the 120 unique possibly pathogenic variants, 35 (29%) are novel. These data provide an excellent starting point for functional assessment of the defined variants. Overall, our approach provides the basis for further tackling the demanding task of introducing multi-gene analysis in routine diagnostics.

P12.236

Alu elements cause most common mutation of STK11 gene in Peutz Jeghers patients

P. Borun[1], D. Lipiński[1], T. Banasiewicz[2], W. Cichy[2], **A. Plawski**[1];
[1]Institute of Human Genetics, Poznan, Poland, [2]University of Medical Sciences, Poznan, Poland.

The STK11 gene mutations cause the occurrence of the Peutz-Jeghers syndrome. These mutations are heterogeneous, but a significant proportion of them are large rearrangements. The occurrence of large mutations may be associated with the presence of interspersed repeats or microhomologies. In the STK11 gene, only one type of interspersed repeats is observed -Alu elements. Alu sequences represent 19% of the entire gene sequence. Among large mutations of STK11 gene the deletion of exons 2 and 3 has been described four times so far in different European populations. In two cases the deleted sequence was described in detail and in another two, deletions were identified only on the basis of the MLPA results. The deletion of exons 2 nad 3 was also observed by us in one of the cases of Polish families. The deleted sequence endpoints are localized in Alu elements. We can assume that Alu elements localized in regions including nucleotides c.280+5594 and c.464+384 are responsible for causing one of the most common recurrent mutation of STK11 gene in Peutz-Jeghers patients.

Sudden death and next generation sequencing: characterization of heart disease using a 72-gene NGS panel

D. Garcia-Alfonso[1], D. Cantalapiedra[1], C. Collado[1], V. Fernández-Pedrosa[1], A. Romera[1], V. Felipe[1], J. Triviño[1], S. Zúñiga-Trejos[1], A. Forteza[2], L. Moreno[3], B. Pérez-Ortega[4], P. Chevalier[5], B. Gerull[6], M. Martínez-Atienza[7], A. Pereira[8], G. Millat[9], A. Jamsheer[10], M. Gil[1], R. Sáez-Villaverde[11], A. Repáraz[12], S. Santillán[1];
[1]Sistemas Genómicos, Paterna, Spain, [2]Marfan Unit, Hospital 12 de Octubre, Madrid, Spain, [3]Servicio de Pediatría, Hospital Virgen del Camino, Pamplona, Spain, [4]Laboratorio Médico Echavarria, Bogotá, Colombia, [5]Service de Rythmologie, Hôpital cardiologique Louis Pradel, Hospices Civils de Lyon, Lyon, France, [6]Departments of Medical Genetics and Cardiac Sciences, University of Calgary, Calgary, AB, Canada, [7]Hospital Virgen de la Nieves, Granada, Spain, [8]Genia Genética Molecular, Montevideo, Uruguay, [9]Laboratoire de Cardiogénétique Moléculaire - Centre de Biologie et Pathologie Est, Lyon, France, [10]University of Medical Sciences, Poznan, Poland, [11]Hospital Donostia, San Sebastián, Spain, [12]Complexo Hospitalario de Vigo Hospital Xeral, Vigo, Spain.

Purpose - Genetic characterization of heart disease patients in a fast, comprehensive, and cost-effective manner using a 72 gene NGS approach, coupled with a bioinformatics pipeline.

Methods - A methodology was developed for resequencing 72 genes (44 genes associated with cardiomyopathies, arrhythmogenic right ventricular dysplasia, Marfan syndrome, aortic aneurysm, and 28 genes associated with Brugada syndrome, long QT and short QT syndromes, familial atrial fibrillation and catecholaminergic polymorphic ventricular tachycardia). The design included 750 Kb of exons, splicing regions, 5' UTR and 3' UTR. Targets were captured (SureSelect, Agilent), and then sequenced in a SOLiD v4 platform. The bioinformatics pipeline consisted of mapping and aligning reads against the GRCh37/hg19 sequence, classification and identification of point variations, structural variations, and small indels, as well as their involvement at the transcriptional level. Results were confirmed by Sanger sequencing. A set of 12 cases with a known mutation was used for validation studies.

47 patients were studied (20 cases with aortic aneurysm/Marfan syndrome, 2 cases with ARVC/D, 7 cases with hypertrophic cardiomyopathy, 1 case with dilated cardiomyopathy, 2 cases with familial cardiomyopathy, 6 cases with long QT syndrome, 1 case with Brugada syndrome, 3 cases with familial arrhythmia, and 5 cases with family history of sudden death).

Results - 91 relevant nucleotide changes were found: 14 pathogenic mutations; 77 unclassified variations, of which, using in silico predictions, 9 are likely pathogenic and 7 are unlikely pathogenic.

Conclusions - Targeted resequencing enables the efficient analysis of genes associated with heterogeneous heart diseases.

P12.238

Defects in the Ski complex, a multi protein complex involved in aberrant mRNAs decay, cause Syndromic Diarrhea

A. Fabre[1], C. Martinez-Vinson[2], V. Colomb[2], O. Egritas[3], E. Sayar[4], B. Roquelaure[5], J. Sarles[5], N. Levy[1], **C. Badens**[1];
[1]UMR 910- AP HM, Marseille, France, [2]AP HP, Paris, France, [3]School of medicine, Ankara, Turkey, [4]School of medicine, Antalya, Turkey, [5]AP HM, Marseille, France.

Syndromic Diarrhea (SD) is a rare and severe disorder characterized by intractable diarrhea, dysmorphism, immunodeficiency and hair abnormalities. This syndrome has been recently associated with mutations in *TTC37* in 21 patients but several other individuals with typical SD present no variation in this gene. The function of TTC37 in humans is not known but it is reported in databases as being the human ortholog of Ski3p, one of the yeast Ski complex cofactors. The Ski complex is required for the exosome-mediated RNA surveillance including normal mRNAs regulation and non-functional mRNAs decay such as non-sense mediated mRNA decay, no-go decay or non-stop decay. Considering TTC37 homology with Ski3p, we assumed that other genes encoding Ski complex proteins might be responsible for SD in patients without variation in *TTC37* and confronted this hypothesis with the results of a linkage analysis performed in a consanguineous family with such a patient. We noticed, in a region of homozygosity, a gene encoding another cofactor of the Ski complex, SKIV2L. Direct sequencing of *SKIV2L* in seven patients presenting typical SD without variation in *TTC37* identified stop or frameshift mutations in all seven.

Although genetically heterogeneous, SD is extremely homogenous clinically suggesting that a defect in the Ski complex function is a key mechanism responsible for the clinical features.

Our results show that mutations in genes encoding cofactors of the human Ski complex cause SD, establishing for the first time, a link between defects of the exosome complex and a Mendelian disease.

P12.239

Mutational analysis for thoracic aortic aneurysm and dissection (TAAD) using a custom resequencing array

U. Kathiravel[1], B. Keyser[1], S. Hoffjan[2], J. Kötting[2], M. Müller[3], S. Sivalingam[3], M. Bonin[4], M. Arslan-Kirchner[1], Y. von Kodolitsch[5], P. Binner[3], T. Scheffold[6], S. Manfred[1], S. Waldmüller[3,6];
[1]Institute for Human Genetics, Hannover, Germany, [2]Department of Human Genetics, Bochum, Germany, [3]CorTAG, Dortmund, Germany, [4]Institute for Human Genetics, Tübingen, Germany, [5]Department of Diagnostics and Interventional Radiology, Hamburg, Germany, [6]Institute for Heart and Circulation Research, Witten, Germany.

TAAD is a severe cardiovascular complication that may occur in isolation (FTAAD) or as part of syndromic conditions such as Marfan Syndrome. To date, more than eight genes are known to harbour mutations causing TAAD. Subsequent analysis of these genes with standard methods is costly and parallel sequencing on a single platform has not yet been established.

We describe a 100-kb resequencing array, the MFSTAAD chip, which allows the simultaneous resequencing of the genes *ACTA2*, *COL3A1*, *FBN1*, *MYH11*, *NOTCH1*, *SLC2A10*, *TGFBR1* and *TGFBR2*. A total of 181 positive controls with known mutations such as point mutations, deletions and insertions were used to determine the analytical sensitivity of the assay and the mutation yield was evaluated in a cohort of 28 TAAD patients, 18 of these subjects were previously been tested negative for mutations in the genes *FBN1* and *TGFBR2*. An average call-rate of 99.9% was obtained using Sequence Pilot SeqC data analysis software. The assay showed a high analytical sensitivity for point mutations (100%) and an overall sensitivity of 85%. The largest deletion could be detected by a striking decline in the hybridization line. Upon analysis of the 28 TAAD patients, with this assay we could detect 4 known mutations and 6 possibly pathogenic point mutations (mutation yield: 32%).

In conclusion, the MFSTAAD chip is a feasible tool that can facilitate the genetic analysis of TAAD in routine genetic testing. Future modification for the detection of gross changes such as deletions and insertions will make this assay even more applicable.

P12.240

The first case of Tenascin-X deficient type Ehlers-Danlos syndrome in Japan

A. Watanabe[1], A. Fujita[1], M. Hatakeyama[1], H. Watanabe[1], T. SHIMADA[1], K. Matsumoto[2];
[1]Nippon Medical School, Tokyo, Japan, [2]Shimane University, Shmane, Japan.

Tenascin-X is a large extracellular matrix glycoprotein and is known to be associated with an autosomal recessive type of Ehlers-Danlos syndrome (EDS). Here we report the first case of Tenascin-X deficient type EDS in Japan. The patient of 39-year-old male was born in breech position, had cast immobilization for congenital hip dislocation until 9months of age, diagnosed as EDS for skin hyperextensibility, laxity in finger joints, softness of heels.

At the age of 18months he was treated for inguinal hernia and snaping finger of thumbs, left middle finger and right annular finger. Other skin manifestation is easy bruising, but the wound repair had been normal. Recurrent dislocations of the shoulders and sprains were seen from his childhood. His foot went flat when loaded. He had gone through keloid/ lump formation, hemorrhoid associated bleeding problems and diverticulitis several times into the adulthood. He was referred to our clinic after his fragile intestinal tract tissue ruptured during his operation of diverticulitis. A complete absence of tenascin-X was identified on triplicate testing of the proband's serum. *TNX-B* mutation analysis was performed and showed a homozygous 1-bp deletion in exon 25, encoding fibronectin type III repeat. The parental serum tenascin-X values were both on the lower side of the normal distribution and intermediate between the proband and the background population. Further analysis is currently underway.

P12.241

Leri's pleonosteosis results from a genetic defect causing dysregulated TGF-beta signalling

S. Banka, *S. Cain, S. Daly, J. Urquhart, G. Erdem, M. Bottomley, B. Kerr, H. Kingston, S. Carim, C. L. R. Merry, C. M. Kielty, W. G. Newman;*
University of Manchester, Manchester, United Kingdom.

The Transforming Growth Factor-beta (TGF-β) signalling pathway is key to many cellular processes and its dysregulation has been documented in a number of Mendelian phenotypes characterised by joint contractures and scleroderma, including stiff skin syndrome, Myhre syndrome, acromicric and geleophysic dysplasias.

Leri's pleonosteosis [MIM 151200] is a rare autosomal dominant condition characterized by flexion contractures of the interphalangeal joints, restricted motion of multiple joints, facial dysmorphism, bony overgrowths, short broad hands and feet and occasional sclerodermatous thickening of skin.

We genotyped the two most distantly related individuals in a large family with Leri's pleonosteosis by Affymetrix SNP6.0 array. Copy number analysis revealed a shared ~1Mb duplication of chromosome 8q22.1 that segregated with the phenotype and was confirmed by QPCR. The duplication was not present in polymorphism databases and over 500 controls. We identified an overlapping 8q22.1 duplication in an unrelated patient with Leri's pleonosteosis to confirm the causal relationship.

The minimum critical region consists of six genes, including *SDC2* encoding the transmembrane heparan sulphate proteoglycan, syndecan-2. We show that overexpression of *SDC2* causing altered TGF-β signaling in fibroblasts is the major molecular contributor to the clinical phenotype. We therefore add Leri's pleonosteosis as a further disorder to a spectrum of conditions characterized by dysregulation of TGF-β signaling and importantly, provide an insight into role of altered proteoglycan homeostasis in this pathway.

P12.242

Multiplex assay for the detection of common Mediterranean beta-thalassemia mutations

B. L. Atanasovska, *G. L. Bozhinovski, D. Plaseska-Karanfilska, L. Chakalova;*
Research Centre for Genetic Engineering and Biotechnology, Skopje, The Former Yugoslav Republic of Macedonia.

Hemoglobinopathies are the most abundant group of genetic abnormalities in humans, caused by genetic defects affecting the globin genes encoding for the hemoglobin alpha and beta chains. In particular, a great variety of mutations present in heterozygous, homozygous and compound heterozygous states disturb the function of the HBB gene. Molecular characterisation of the causative genetic variants is an essential part of the diagnostic process. The unusually large number of individual mutations presents technical challenges. However, in any particular population, a limited number of genetic variants are responsible for the vast majority of hemoglobinopathy cases. Developing reliable, rapid and cost-effective molecular diagnostic assays targeting particular populations greatly facilitates routine hemoglobinopathy investigations. We developed a one-tube single-nucleotide primer extension assay for the detection of eight common Mediterranean beta-thalassaemia mutations: IVS-I-110 (G->A), IVS-I-1 (G->A), IVS-I-6 (T->C), Codon 39 (C->T), IVS-II-745 (C->G), Codon 5 (-CT); CCT(Pro)->C--, Codon 6 (-A); GAG(Glu)->G-G, and Codon 8 (-AA); AAG(Lys)->--G. According to available mutation frequency data, these eight sequence variations together account for a large proportion of the hemoglobinopathy cases in Macedonia (89%). The novel assay offers superior accuracy achieved through double mutation interrogation on both genomic strands. We validated the new assays using previously genotyped samples obtaining 100% agreement between independent genotyping methods. Our protocol, applicable in a range of Mediterranean countries, provides a cost-effective diagnostic tool of unmatched precision. It can be further adapted to particular populations by including/excluding assayed mutations. We facilitate future modifications by providing detailed information on assay design.

P12.243

The modifying effect of Xmn1-HBG2 on thalassemia phenotype is associated with its linked elements in beta globin LCR

M. Neishabury[1], *S. Zamani[1], A. Azarkeivan[2], F. Zamani[1], S. Abedini[1], H. Darvish[1], H. Najmabadi[1,3];*
[1]Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran, [2]Thalassemia Clinic, Research Center, Iranian blood transfusion Organization(IBTO), Tehran, Islamic Republic of Iran, [3]Kariminejad and Najmabadi Pathology and Genetics Center, Tehran, Islamic Republic of Iran.

The core sequence of 5′HS4-beta globin locus control region and Xmn1-HBG2 site were analyzed and compared among 86 thalassemia patients with homozygous or compound heterozygous beta globin gene mutations and 101 normal individuals. Frequency of the G allele in the polymorphic palindromic sequence of 5′HS4 (TGGGGA/G CCCCA) and positive Xmn1-HBG2 profile was significantly higher in thalassemia patients compared to the normal population. Linkage disequilibrium was observed between the G allele and positive Xmn1-HBG2 profile in patient population. Furthermore, dominance of IVSII-1 in the mutation spectrum of the patients enabled us to identify linkage disequilibrium relationships between IVSII-1, positiveXmn1-HBG2 and the G allele at 5′HS4. The frequency of milder clinical phenotype was significantly higher in patients with GG/++than cases with AA/--genotypic pattern in 5′HS4/Xmn1-HBG2 loci. These data together with biochemical evidence suggesting a role for the A/G polymorphism at 5′HS4 palindromic site on modifying chromatin structure and in the absence of any evidence from functional studies relating the Xmn1-HBG2 site to the increased gamma chain expression, suggest that the phenotype modifying role long time assigned to Xmn1-HBG2 is possibly played by more functionally potent elements linked to it in LCR.

P12.244

A new TP63 mutation in a patient with cleft lip, split hand, and tibial agenesis

M. Simioni, *R. G. Faria, T. K. Araujo, J. R. Prota, C. V. Maurer-Morelli, D. P. Cavalcanti, V. L. Gil-da-Silva-Lopes;*
Faculdade de Ciências Médicas, Campinas, Brazil.

TP63 gene, located at 3q27 chromosome region, encodes a transcription factor that plays an essential role in the development of epidermis, upper lip and limbs. Homozygous tp63 null mice exhibit craniofacial abnormalities, limb truncations, and absence of epidermal appendages. In humans, mutations in TP63 can give rise to a series of syndromes characterized by various combinations of ectodermal dysplasia, limb malformations and orofacial clefting. The propositus here reported is the first child of a non-consanguineous couple. Some individuals of the maternal family were referred, but not examined, to be affected by some of the malformations found in the propositus, suggesting an autosomal dominant inheritance. The main clinical features included left cleft lip, bilateral split hand, bilateral tibial agenesis, club feet and absence of the right hallux. No ectodermal abnormalities were observed. Despite of mild hypotonia in the first months, neuropsychomotor development was apparently normal. The analysis of copy number variations (CNVs) was performed using the Genome-Wide Human SNP Array 6.0 (Affymetrix). None potential pathogenic CNVs were found. Subsequently, TP63 gene was sequenced. A four-nucleotide insertion (AGAG) was detected at 5'UTR region of this gene resulting in a frameshift mutation. Considering the site of this mutation, it might have caused an alteration in the pattern of expression of TP63 gene. To our knowledge this is the first time that a mutation in the TP63 has been associated with this pattern of malformation - cleft lip, split hand and preaxial limb reduction defect in lower limbs.

Auto-regulation of the *THAP1* (DYT6) gene and THAP1-mediated activation of *SGCE* (DYT11) gene expression.

F. J. Kaiser[1], *A. Erogullari[1], P. Seibler[2], D. Braunholz[1], A. Grünewald[2], R. Depping[3], J. Eckhold[1], A. Rakovic[2], G. Gillessen-Kaesbach[1], C. Klein[2], K. Lohmann[2];*
[1]Institut für Humangenetik, Lübeck, Germany, [2]Section of Clinical and Molecular Neurogenetics at the Department of Neurology, Lübeck, Germany, [3]Institute of Physiology, Center for structural and cell biology in Medicine, Lübeck, Germany.

Mutations in Thanatos-associated [THAP] domain-containing apoptosis-associated protein 1 (THAP1) cause a form of pure dystonia (DYT6). THAP1 encodes a transcription factor that regulates the expression of the DYT1 dystonia gene *TOR1A*. Here, we investigated whether THAP1 also influences the expression of the myoclonus-dystonia (DYT11) associated gene *SGCE* and its own expression. Using in-silico prediction and luciferase reporter gene assays, we characterized the *SGCE* and *THAP1* promoters. Interestingly, these two core promoters contained one or five THAP binding sequences (THABS). Luciferase reporter gene assays revealed that THAP1 activates the expression of *SGCE* and that this activation is disturbed by different THAP1 mutations. In addition, THAP1 represses its own expression. Binding of THAP1 to the core promoters was demonstrated using chromatin immunoprecipitation (ChIP). Further, THAP1 binding to the THABS within the *SGCE* promoter was confirmed by electromobility shift assay (EMSA). To test for *in-vivo* changes of expression levels, we re-programmed fibroblast cells from a *THAP1* mutation carrier (Leu159fs180X) and controls to pluripotent induced stem (iPS) cells that were differentiated into neurons. Quantitative PCR in these cells did not reveal a significant difference of *SGCE* expression in a THAP1 mutation carrier compared to wildtype samples. However, *THAP1* expression was increased in mutant THAP1 cells suggesting an autoregulation of THAP1. In conclusion, we identified two additional targets for *THAP1, SGCE* and *THAP1* itself, *in vitro* and confirmed *THAP1* in vivo. It is conceivable that the autoregulation compensates for alterations in the expression of other target genes to a certain degree.

P12.246

Transcriptome profiling during early neuronal differentiation in Lissencephaly associated with DCX mutations

J. Schuster[1], *M. Sobol*[1], *T. Bergström*[1], *D. Raykova*[1], *S. Kundu*[1], *M. Bartish*[1], *B. Anderlid*[2], *G. Annerén*[1], *K. Forsberg Nilsson*[1], *N. Dahl*[1];
[1]Uppsala University, Uppsala, Sweden, [2]Karolinska Institute, Stockholm, Sweden.

Genetic factors play a major role in a large proportion of patients with congenital neurological and neurodevelopmental disorders. Despite the progress related to genotype-phenotype associations, little is known about how specific gene mutations mediate abnormal cellular and molecular processes during early neuronal differentiation. Induced pluripotent stem cell (iPSC) technology has emerged as an indispensable tool to model genetically determined phenotypes at the cellular and molecular levels in non-accessible tissues. We have initiated an iPSC based effort to model different monogenic phenotypes derived from neuronal or neural crest cells, e.g. Lissencephaly. Lissencephaly is a neurodevelopmental disorder characterized by abnormal cerebral surface, mental retardation and seizures. The disease is caused by insufficient migration of maturing neurons, although disease mechanisms are not fully understood. We have generated iPSC from skin fibroblasts of two Lissencephaly patients with different doublecortin (*DCX*) mutations.
To study perturbations of neuronal differentiation and function in more detail we established iPSC lines from the Lissencephaly patients and healthy controls. All lines were characterized and showed the capacity to form all three germ layers in embryoid body differentiation assays. IPSC lines were differentiated into neuronal precursor cells (NPC) and further into neuronal cells. Total RNA samples are obtained from the iPSC and NPCs and sequenced using the SOLiD platform. The aim is to identify and compare transcriptome signatures during early neuronal differentiation.
We present how this "pipe-line" may be used as a sensitive method to characterize and mirror molecular abnormalities associated with *DCX* mutations at early stages of neuronal differentiation.

P12.247

A novel exon 2-skipped TNFR1 transcript: regulation by *TNFRSF1A* rs1800692 and possible role on TNFR-associated Periodic Syndrome (TRAPS) phenotype

C. Rittore[1], *E. Sanchez*[1], *S. Soler*[1], *M. Barat-Houari*[2], *M. Albers*[3], *L. Obici*[4], *M. F. McDermott*[5], *I. Touitou*[1,2,6], ***S. Grandemange***[1];
[1]INSERM U844, Montpellier, France, [2]CHRU Montpellier, Montpellier, France, [3]University Medish Centrum, Utrecht, Netherlands, [4]Biotechnology Research Laboratories, Pavia, Italy, [5]6. NIHR-Leeds Musculoskeletal Biomedical Research Unit, Leeds, United Kingdom, [6]Université Montpellier 1, Montpellier, France.

Binding of TNFα to one of its cell surface receptors, TNFR1 induces various cellular responses including cell death, differentiation or inflammation. Several polymorphisms in the *TNFRSF1A* gene, encoding TNFR1, have been repeatedly associated with diseases of the immune system, and heterozygous mutations are responsible for the dominant autoinflammatory disease, TNFR-associated periodic syndrome (TRAPS).
We identified the first spliced transcript named TNFR1-d2. This novel transcript, lacking exon 2, is expressed in a tissue-specific manner. To search for a possible regulatory element of *TNFRSF1A* expression, we checked for a possible effect of polymorphisms present along the *TNFRSF1A* sequence. We found the rs1800692 polymorphism (c.473-33C>T) in intron 4 of particular interest because we observed that the T/T genotype was absent in our TRAPS group. Splicing alternative assays showed that this polymorphism can modulate exon 2 skipping and luciferase assays revealed that intron 4 contains transcriptional regulatory element. Thus the exon 2 skipping in TNFR1-d2 may be controlled via transcriptional regulation in a cell-specific manner. Moreover, by *in vitro* studies, we showed that one particular mutation, identified among TRAPS patients involves a translation defect of TNFR1-d2 suggesting that its altered function may account for some of the inflammatory processes occurring in TRAPS.
We suggested that the transcript ratio, depending on the *TNFRSF1A* alleles, may partly account for the inter-individual variations observed in patients with a TRAPS phenotype and possibly in patients suffering from other inflammatory conditions and that, this new protein could have a role on the physiopathology of TRAPS.

P12.248

Frequency of *POLR1D*, *POLR1C* and *TCOF1* Mutations in a Large Cohort of Patients with Treacher Collins Syndrome

A. W. O'Rourke, *M. Bowman, C. Archer, M. Oldridge, A. Seller, T. Lester;*
Regional Molecular Genetics Laboratory, Oxford, United Kingdom.

Treacher Collins syndrome (TCS) is a disorder of craniofacial development characterised by a combination of bilateral downward slanting palpebral fissures, coloboma of the lower eyelid, micrognathia, malformation of the external ear and bilateral conductive hearing loss.
TCS type 1 is caused by dominant loss-of function mutations in the *TCOF1* gene. The Oxford Molecular Genetics Laboratory, UK, has provided a molecular diagnostic service for this gene since 2005. To date 119 referrals with a good clinical diagnosis of TCS have been analysed and pathogenic variants have been detected in approximately 70% of patients (of which around 4% were large deletions) [1]. In approximately 30% of referrals, no pathogenic variant was detected.
Mutations in the *POLR1D* and *POLR1C*, components of RNA polymerases I and III, have recently been reported in individuals with TCS [2]. Sequencing analysis of these genes was undertaken in a cohort of 26 patients strongly suspected of having TCS, in whom a pathogenic *TCOF1* variant was not detected. Probable pathogenic variants in the *POLR1D* gene were detected in 6 out of the 26 patients (23%) tested to date. The mutation spectrum includes novel frameshift, missense and nonsense variants, all predicted to result in loss of protein function. No pathogenic variants were detected in the *POLR1C* gene.
Data from our cohort suggests that approximately 7% of individuals with a strong clinical diagnosis of TCS may have a pathogenic mutation in the *POLR1D* gene.

P12.249

A novel TRPS1 gene mutation in the family with Trichorhinophalangeal syndrome from Russia

T. V. Fedotova[1], *T. A. Adyan*[2], *V. P. Fedotov*[1], *A. V. Polyakov*[2];
[1]1 Regional Clinical Hospital, Voronezh, Russian Federation, [2]Research Center for Medical Genetics, Moscow, Russian Federation.

Trichorhinophalangeal syndrome I (MIM 190350) is a malformation syndrome characterized by the distinctive craniofacial and skeletal abnormalities and is inherited as an autosomal dominant. Patients have sparse scalp hair, bulbous tip of the nose, long flat philtrum, thin upper vermilion border, and protruding ears. Skeletal abnormalities include cone-shaped epiphyses at the phalanges, hip malformations, and short stature. We presented five patients from four generation family with TRPS I type transmitted as an autosomal-dominant trait from Russia. All patients had uniform symptoms. Proband 18-old man had the height 174 cm, typical symptoms: facial features included low-set, posteriorly rotated ears, prominent malar eminence and orbital ridge, bulbous nose, hypoplastic nasi alae nasi, hypotrichosis, and long philtrum. He also had brachymesophalangy, wide halluces, and flat arches. Radiographs showed short metacarpals, cone-shaped epiphyses of middle and proximal phalanges (2nd, 3rd, 4th fingers). This leads to varying degrees of brachydactyly without short stature. For this proband we conducted direct automated sequencing of zinc finger transcription factor gene TRPS1, encodes the 1281 amino acids protein TRPS1, participating in the regulation of chondrocytes and the perichondrium, as result the novel mutation c.2800G>A (Gly934Ser) in exon 6 had been found in the heterozygous state. By the additional research, this mutation was not detected among the 60 population samples (120 chromosomes). The same mutation was also detected in the DNA sample of proband's mother suffering TRPS I type.
Thus, these data support the fact that the detected change is a pathological mutation.

P12.250

Fragile X mental retardation 1 (FMR1) premutations: instability and associated phenotypes

J. Loureiro[1], *P. Jorge*[2], *I. Marques*[2], *R. Santos*[2], *A. I. Seixas*[1], *M. Martins*[3], *J. Vale*[4], *J. Sequeiros*[1,5], *I. Silveira*[1];
[1]UnIGENe and CGPP, IBMC- Instituto de Biologia Molecular e Celular, Universidade do Porto, Porto, Portugal, Porto, Portugal, [2]U&D Centro de Genética Médica Dr Jacinto Magalhães, INSA, Porto, Porto, Portugal, [3]Maternidade Júlio Dinis, CHP, Porto, Portugal, Porto, Portugal, [4]Serviço de Neurologia, Hospital de Egas Moniz, Lisboa, Portugal, Lisboa, Portugal, [5]ICBAS, Universidade do Porto, Portugal, Porto, Portugal.

Fragile X syndrome (FXS) is the most common hereditary form of intellectual disability with an estimated frequency of 1/4000 males and 1/8000 females. FXS is caused by a $(CGG)_n$ expansion of over 200 repeats, in the 5'UTR of the *FMR1* gene, which as a result is methylated and gene silenced. Based on $(CGG)_n$ length, four classes of alleles can be distinguished: normal (5-44), intermediate (45-54), premutated (55-200) and fully mutated (>200; FM) alleles. Both *FMR1*-related primary ovarian insufficiency (FXPOI) and fragile X-associated tremor/ataxia syndrome (FXTAS) have been described in premutation carriers. To gain insights into instability of *FMR1* $(CGG)_n$ and associated phenotypes, we assessed repeat-length in 541 individuals from 128 Portuguese FXS families. We found 5.3% of intermediate, 29.9% of premutated and 26.6% of FM alleles. For a total of 115 transmissions of the maternal premutation, 26 (23%) with alleles ranging 60-98, the average expansion was 17 repeat units, whereas 89 (77%) with alleles 66-199, expanded to FM. In 44 transmissions of maternal FM, the offspring inherited the FM. For 10 paternal transmissions of premutations, ranging 56-120, all the daughters inherited a premutation, with an average expansion of 7 repeat units. We identified one male with FXTAS and two females with FXPOI among seven investigated premutation carriers; the remaining premutation individuals were not yet examined. In conclusion, in Portuguese FXS families, allele instability upon transmission is in agreement with previous reports, where the risk of premutation to FM expansion is linked to the premutation size of the transmitting mother.

Tuberous sclerosis complex (TSC) is a rare genetic disorder, that belongs to neurocutaneous syndromes where both the skin and central nervous system are involved. It is characterized by an autosomal dominant pattern of inheritance and a variable penetrance. The symptoms of tuberous sclerosis vary from person to person and may include seizures, developmental delay, skin abnormalities, lung and kidney disease.

TSC is caused by a mutations in the genes *TSC1* or *TSC2*, which encode the protein hamartin and tuberin respectively. These proteins act as tumor growth suppressors, agents that regulate cell proliferation and differentiation.

Molecular analysis can detect mutations in about 85% of cases and is complicated by the size of both genes, absence of mutations hotspots and a high rate of *de novo* mutations. Untill now DGGE mutations scanning, direct sequence analysis in combination with deletions/duplications analysis of in *TSC1* or *TSC2* was performed in patients with suspected TSC.

In respect to the progress of new molecular genetic technologies we have adapted next-generation sequencing (NGS, Roche GSJ) into routine testing of TSC patients. All relevant areas of genes *TSC1* and *TSC2* were amplified by gene-specific primers with universal tail and marked by MID adaptors (Multiplex Identifier Adaptors), to differentiate between patients. We used Geneious software with ADINIS-MultipluginG to handle NGS data. Here we report on our experience of routine diagnostics for TSC profiting from the power of NGS.

P12.252

Targeted next-generation sequencing identifies a homozygous ABHD12 nonsense mutation in a family clinically diagnosed with Usher syndrome type 3

R. Slim[1], ***T. Eisenberger***[2], *A. Mansour*[3], *C. Decker*[2], *C. Dafinger*[4], *I. Ebermann*[4], *C. Bergmann*[2,5], *H. J. Bolz*[2,4];
[1]Department of Human Genetics, McGill University Health Center, Montreal, QC, Canada, [2]Center for Human Genetics, Bioscientia, Ingelheim, Germany, [3]Department of Ophthalmology, American University of Beirut, Beirut, Lebanon, [4]Institute of Human Genetics, University Hospital of Cologne, Cologne, Germany, [5]Department of Human Genetics, RWTH Aachen University, Aachen, Germany.

Usher syndrome (USH) is an autosomal recessive disorder with congenital sensorineural hearing impairment (HI) and retinitis pigmentosa (RP). There are three clinical subtypes: USH1 presents with severe to profound HI, facultative vestibular impairment and early RP, whereas USH2 is characterized by moderate to severe HI and RP in adolescence. USH3 is rare and variable; it may resemble USH1 or USH2, and vestibular dysfunction may occur. Clarin-1 (*CLRN1*) is the only known USH3 gene (locus: *USH3A*). We have previously identified a consanguineous Lebanese family with an USH3 phenotype. Microarray SNP analysis identified three homozygosity-by-descent regions: 1q43-q44 (8.54 Mb), 20p13-p12.2 (10.48 Mb), and 20p11.23-q12 (19.35 Mb). We excluded mutations in ninein-like protein (*NINL*) on chromosome 20p11.21, an interactor of the USH protein complex. Using a capture array targeting all three candidate regions and next-generation sequencing, we subsequently identified a homozygous nonsense mutation, c.193C>T (p.Arg65X), in a neighboring gene, *ABHD12*. Of note, truncating *ABHD12* mutations have recently been shown to cause PHARC, a neurodegenerative disease with polyneuropathy, hearing loss, ataxia, retinitis pigmentosa, and early-onset cataract. Both patients from our family display HI, ataxia, RP, and cataracts, but no polyneuropathy. ABHD12 hydrolyzes 2-arachidonoyl glycerol, an endocannabinoid lipid transmitter that acts on cannabinoid receptors CB1 and CB2. This pathway is probably unrelated to the USH interactome. Consequently, the phenotype in our family rather represents a variant of PHARC, an entity that should be taken into account as differential diagnosis for Usher syndrome.

Comprehensive molecular genetic analysis for Usher syndrome including conventional and next-generation sequencing and MLPA: Proposal of a diagnostic strategy

C. Neuhaus[1], *T. Eisenberger*[1], *K. Busch*[1], *C. Decker*[1], *B. Lorenz*[2], *M. Preising*[2], *I. Kennerknecht*[3], *M. Pfister*[4], *B. Schulze*[5], *D. Mitter*[6], *M. Kautza*[7], *C. Bergmann*[1,8], *H. J. Bolz*[1,9];
[1]Center for Human Genetics, Bioscientia, Ingelheim, Germany, [2]Department of Ophthalmology, Justus-Liebig University Giessen, Giessen, Germany, [3]Institute of Human Genetics, University of Münster, Münster, Germany, [4]Department of Otorhinolaryngology, University of Tübingen, Tübingen, Germany, [5]Praxis für Humangenetik Dr. B. Schulze, Hannover, Germany, [6]Institute of Human Genetics, University Hospital of Leipzig, Leipzig, Germany, [7]Institute of Human Genetics, University Hospital Schleswig-Holstein, Campus Kiel, Christian-Albrechts University Kiel, Kiel, Germany, [8]Department of Human Genetics, RWTH Aachen University, Aachen, Germany, [9]Institute of Human Genetics, University Hospital of Cologne, Cologne, Germany.

Usher syndrome (USH) is an autosomal recessive disorder with congenital sensorineural hearing impairment (HI) and retinitis pigmentosa (RP). USH1 presents with severe to profound HI, facultative vestibular impairment and early RP, USH2 with moderate to severe HI and RP in adolescence. USH3 is rare and variable. Because of the mostly large size of the 10 USH genes, genetic confirmation of the diagnosis is the exception. We have applied a novel and efficient diagnostic strategy to 32 patients. For USH2, we sequenced *USH2A*, followed by *USH2A*-MLPA and next-generation sequencing (NGS) of all USH genes. For USH1 or atypical USH samples, we sequenced *MYO7A* (USH1B) before NGS was available to us; now, they directly undergo NGS. We found *USH2A* mutations in 18 out of 19 USH2 patients, including large intragenic deletions and duplications. NGS revealed *GPR98* (USH2C) mutations in one USH2 patient, but no USH gene mutations in the only patient with a monoallelic *USH2A* mutation. All three atypical USH patients and 4 of the 10 USH1 cases carried *MYO7A* mutations. *CDH23* mutations were found in one USH1 patient, and linkage analysis with subsequent sequencing and MLPA identified *PCDH15* mutations in two USH1 families from Syria. NGS for three *MYO7A*-negative USH1 patients is ongoing. In conclusion, our results with *USH2A* as the major USH2 gene and mutations more evenly distributed in USH1 support the following diagnostic procedure (in the order of listing): USH2: *USH2A* sequencing, *USH2A*-MLPA, NGS. USH1 and atypical USH: NGS, MLPA or linkage-based approaches where applicable.

P12.254

Mutations in KIAA1632 cause Vici syndrome, a multisystem disorder with defective autophagy

T. P. Cullup[1], *F. Smith*[1], *B. Brandmeier*[2], *M. Simpson*[3], *C. Dionisi-Vici*[4], *S. Abbs*[1], *M. Gautel*[2], *H. Jungbluth*[5];
[1]GSTS Pathology, London, United Kingdom, [2]Randall Division of Cell & Molecular Biophysics, King's College, London, United Kingdom, [3]Genetics and Molecular Medicine, King's College, London, United Kingdom, [4]Bambini Gesu Children's Hospital, Rome, Italy, [5]Paediatric Neurology, Evelina Children's Hospital, London, United Kingdom.

Vici syndrome is a rare, recessively inherited multisystem disorder with markedly reduced life expectancy, characterised by callosal agenesis, cataracts, cardiomyopathy, combined immunodeficiency, hypopigmentation and an associated myopathy.

We sequenced the exomes of four affected individuals from three families and found homozygous and compound heterozygous mutations in *KIAA1632* in all four patients. Affected individuals from eleven additional Vici syndrome families were analysed by Sanger sequencing of *KIAA1632*. Mutations were detected in ten families. No *KIAA1632* mutations were identified in the remaining family nor in two further families with similar features, suggesting locus heterogeneity.

KIAA1632 was recently identified as the human homologue of the metazoan-specific autophagy gene *epg-5 (ectopic pgl granules family member 5)* (Tian et al) encoding a key protein of the autophagy pathway implicated in the formation of degradative autolysosomes. Immunohistochemical, histological and functional studies were consistent with homozygous or compound heterozygous null mutations in *KIAA1632* causing autophagy defects.

The remaining human homologues of the metazoan-specific autophagy genes identified in Tian et al, *VMP1* and *EI24*, were screened in the three Vici syndrome / Vici-like families without *KIAA1632* mutations. No mutations were identified.

Tian, Y., Z. Li, et al. (2010). „C. elegans screen identifies autophagy genes specific to multicellular organisms." Cell 141(6): 1042-1055.

P12.256

A novel mutation in the distant sonic hedgehog (SHH) cis-regulator ZRS in family with Werner mesomelic syndrome from Russia

V. Fedotov[1], *N. Galeeva*[2], *A. Polyakov*[2];
[1]Regional Clinical Hospital, Genetic counseling, Voronezh, Russian Federation, [2]Research Center for Medical Genetics, Moscow, Russian Federation.

Werner mesomelic syndrome (WMS)-autosomal dominant tibial hemimelia-polysyndactyly-triphalangeal thumbs syndrome (MIM 188770). We present a family with 2 affected members in 2 generations from Russia. Propositus, 17-old age boy and his mother, have bilateral hypoplasia of the tibia with preaxial polydactyly in the feet and hands. The height of the boy is 128 cm and his mother is 135 cm. The right hand of the boy is characterized by 6 and the left hand by 7 isodactylous digits (on the left hand I and II digits are triphalangeal), the thumbs is nonopposable. Also boy has short legs due to tibial hypoplasia (length of tibias is 152 and 54 mm) and bilateral preaxial polydactyly of the feet with 7 triphalangeal digits. Radiologically and MRI legs showed thicken of fibula and dysplasia of hip. His mother on the hands has 5 digits, I digits is triphalangeal on both hands, the thumbs is nonopposable. On the feet she has 6 triphalangeal digits and tibial hypoplasia which lead to shortening of legs. The molecular-genetic study of boy and his mother identified heterozygosity for a 403G>C transversion in the zone of polarizing activity (ZPA) regulatory sequence (ZRS) in intron 5 of the LMBR1 gene in both patients. Population analysis of 150 unaffected people did not detect this mutation.

P12.258

Novel mutations in the POU3F4 gene in patients with X-linked hearing loss

A. Schoener[1], *A. Giesemann*[2], *H. Hartmann*[3], *J. Schmidtke*[1], *M. Stuhrmann*[1];
[1]Institute of Human Genetics, Hannover Medical School, Hannover, Germany, [2]Institute of Diagnostic and Interventional Neuroradiology, Hannover Medical School, Hannover, Germany, [3]Clinic for Paediatric Nephrology, Hepatology and Metabolic Disorders, Hannover Medical School, Hannover, Germany.

Up to half of the X-linked hearing loss cases are caused by mutations in the single exon gene POU3F4 which encodes a 361 aa POU domain transcription factor mainly expressed in the inner ear and central nervous system. Intragenic mutations as well as deletions of the coding region or the upstream region of POU3F4 have been reported. Most affected males show a profound sensorineural hearing loss with or without a conductive component (which can be masked by the sensorineural loss). Common features are stapedial fixation and temporal bone anomalies (including dilation of the internal auditory canal, visible in computed tomography (CT)) leading to a perilymphatic gusher following stapedectomy or during cochlear implantation.

We extracted DNA from blood samples of five patients with a characteristic temporal bone CT and sequenced the coding region of the POU3F4 gene and its flanking sequences. For the detection of larger deletions or duplications MLPA analysis was applied. In three patients we found intragenic mutations which have not been described so far: one missense mutation (c.844C>T, p.Arg282Trp), classified as probably pathogenic by biometric analysis, and two frame shift mutations (c.226delC, p.Leu76Trpfs*6; c.346dupG, p.Ala116Glyfs*77) leading to a truncated protein lacking both DNA-binding domains. The two other patients showed deletions of the POU3F4 coding exon.

Our study shows that POU3F4 mutations are frequently found in patients with X-linked hearing loss and that genetic testing may contribute to the confirmation of the clinical diagnosis.

P12.259

X-exome sequencing identifies the causal variant in a large pedigree with X-linked intellectual disability, truncal obesity, gynecomastia, hypogonadism and unusual face

M. Harakalova[1], *M. J. H. van den Boogaard*[1], *R. J. Sinke*[2], *S. van Lieshout*[1], *M. van Tuil*[1], *K. Duran*[1], *I. Renkens*[1], *P. A. Terhal*[1], *C. G. F. de Kovel*[1], *I. J. Nijman*[1], *M. M. van Haelst*[1], *N. V. A. M. Knoers*[1], *G. van Haaften*[1], *W. P. Kloosterman*[1], *R. C. M. Hennekam*[3], *E. Cuppen*[1], *H. K. Ploos van Amstel*[1];
[1]Department of Medical Genetics, UMCU, Utrecht, Netherlands, [2]Department of Genetics, University Medical Center Groningen (UMCG), University of Groningen, Groningen, Netherlands, [3]Pediatrics, Academic Medical Center (AMC), Amsterdam, Amsterdam, Netherlands.

We characterized a large Dutch family with 7 males affected by a rare syndrome of X-linked intellectual disability (XLID), hypogonadism, gynaecomastia, truncal obesity, short stature, small head, short ears and recognizable craniofacial deformities. Eight females in this pedigree showed a much milder expression of the phenotype, comprising learning disorder and recognizable facial features. We performed X chromosome exome (X-exome) sequencing in five individuals from this family and identified a novel intronic variant in a histone deacetylation family member. The gene is located in the region for which linkage was established in this family with a maximum LOD-score of 4.93. The variant was shown to affect normal splicing, resulting in exon skipping and introduction of a premature stop. The mutation completely co-segregates with the phenotype in this family and is absent in Dutch controls or available exome databases. Interestingly, affected female carriers show a markedly skewed X-inactivation pattern in blood where all cells show the mutated chromosome X completely inactive. The mutated gene is important for epigenetic control of developmental processes and a knock-out model supports the facial phenotype present in our patients. In summary, we provide genetic evidence for the involvement of the histone deacetylation pathway in a syndromic form of XLID.

P12.260

Sequencing X-chromosome exomes: A diagnostic approach in non-syndromic intellectual disability

P. Bauer, *C. Dufke, C. Bauer, M. Sturm, C. Schröder, A. Dufke, A. Riess, U. Grasshoff, M. Kehrer, O. Riess, A. Tzschach;*
Department of Medical Genetics, Tübingen, Germany.

Non-syndromic intellectual disability (ID) imposes a considerable diagnostic demand, as more than 100 genes have been associated with familial forms of ID. Since X-chromosomal genes greatly contribute at least in affected males, diagnostic tools for the detection of causal genetic changes are a prerequisite for molecular diagnoses.

In order to test, whether NGS provides us with a diagnostic platform in XLID, we have established a sequencing pipeline involving target enrichment for all coding sequences of the X chromosome. Sequencing of males patients with non-syndromic ID typically yielded in 60-100x coverage of X chromosomal genes and a robust base calling in these hemizygous individuals. Moreover, even drop-out of single exons could be monitored in our patients as measured as a significant reduction in read coverage per exon.

A first patient cohort of 12 XLID patients allowed us to work out the sensitivity of the system for the analysis of 88 XLID genes: More than 50 genes have been completely sequenced > 10x and only four genes had less than 90% of all coding bases covered less then 10x (ARX, IQSEC2, IKBKG, and NHS). Typically, less than 3-5 novel variants were found per patient, and further validation steps allowed us to reduce the list of potential disease-causing variants to 0-1 observations.

In summary, X-ome sequencing represents a robust tool for the detection of established XLID and thus closes a longstanding gap in the diagnostic repertoire for children with XLID.

P12.261

Two forms of rare short stature syndromes in Yakuts

N. R. Maksimova[1], *A. Nogovicina*[2];
[1]Yakutsk Science Center of Complex Medical Problems of Russian Academy of Medical Sciences, Yakutsk, Russian Federation, [2]Republican Hospital N1, Yakutsk, Russian Federation.

Hereditary short stature syndrome is one of the major concerns in Yakuts. We have identified 49 patients with short stature syndrome in 43 Yakut families with pre- and post-natal non-progressive growth failure, facial dysmorphism and normal intelligence. A genome-wide linkage analysis for these families revealed linkage to region 6p21.1 with the highest multipoint LOD score of 24.6 at D6S282. We applied a homozygosity mapping approach and narrowed the causative gene to the same locus of the 3-M syndrome (Huber et al, 2005). We found a novel homozygous 4582insT mutation in CUL7, which resulted in a frameshift and subsequent premature stop codon at 1553 (Q1553X). Second form of short stature is characterised by autosomal recessive inheritance, severe postnatal growth retardation, facial dysmorphism with senile face, small hands and feet, normal intelligence, Pelger-Hue¨t anomaly of leucocytes, and optic atrophy with loss of visual acuity and colour vision. This new syndrome is designated as short stature with optic atrophy and Pelger-Huet anomaly (SOPH) syndrome. Genomewide homozygosity mapping was conducted in 33 patients in 30 families. The disease locus was mapped to the 1.1 Mb region on chromosome 2p24.3, including the neuroblastoma amplified sequence (NBAS) gene. Subsequently, 33 of 34 patients were identified with SOPH syndrome and had a 5741G/A nucleotide substitution (R1914H) in the NBAS gene in the homozygous state. Immunohistochemical analysis revealed that the NBAS protein is well expressed in retinal ganglion cells, epidermal skin cells, and leucocyte cytoplasm in controls as well as a patient with SOPH syndrome.

P12.262

ZNF750 downregulation in keratinocytes promotes cell proliferation and decreases apoptosis

I. Cohen[1,2], *R. Y. Birnbaum*[1,2], *K. Leibson*[1,2], *R. Taube*[3], *S. Sivan*[1,2], *O. S. Birk*[1,2,4];
[1]The Morris Kahn Laboratory of Human Genetics, National Institute of Biotechnology in the Negev, Ben-Gurion University, Beer-Sheva, Israel, [2]Dept. of Molecular Genetics and Virology, Ben-Gurion University, Beer Sheva, Israel, [3]Dept. of Molecular Genetics and Virology, Ben-Gurion University, Beer-Sheva, Israel, [4]Genetics Institute, Soroka Medical Center, Beer Sheva, Israel.

Seborrheic dermatitis (SD) and Psoriasis are common dermatologic diseases with overlapping features. Each of the two dermatoses affects 2-3% of the population worldwide. The molecular mechanisms leading to excessive keratinocyte proliferation, the hallmark of both diseases, remain elusive. *ZNF750* mutations were previously reported to be associated with psoriasiform SD and with familial psoriasis. *ZNF750* encodes a putative transcription factor that is highlyexpressed in keratinocytes and represents a psoriasis candidate gene.

To understand ZNF750 function, we initially determined the sub-cellular localization of ZNF750 and assessed the effect of *ZNF750* silencing on cell proliferation and apoptosis in the human keratinocyte cell line, HaCaT. Immunofluorescence and subcellular fractionation followed by western blot analysis showed nuclear localization of ZNF750. In addition, using EGFP-tagged constructs, we identified which of the two ZNF750 nuclear localization signals is functional. As excessive proliferation of keratinocytes is a hallmark of both psoriasis and SD, we examined the effects of *ZNF750* silencing in HaCaT keratinocytes on cell proliferation (Ki67 assay) and apoptosis (annexin V assay). In comparison to controls, HaCaT cells in which *ZNF750* expression was down-regulated exhibited a 10-fold increase in cell proliferation and a 3-fold decrease in apoptosis.

We are currently performing genome wide expression microarray analyses of *ZNF750* silenced cells and ChIP-Seq analysis to identify downstream targets of ZNF750. Unraveling the role of ZNF750 in keratinocyte cell proliferation and determining its downstream pathways might open new insights to the events leading to excessive keratinocyte proliferation in psoriasiform SD and psoriasis.

P12.263

Distribution of the Q318X and R356W mutations of the CYP21A2 gene in Macedonian patients with classic 21-hydroxylase deficiency

V. Anastasovska[1], *M. Kocova*[2];
[1]Genetic Laboratory, Skopje, The Former Yugoslav Republic of Macedonia, [2]Genetic Laboratory, Department of Endocrinology and Genetics, Skopje, The Former Yugoslav Republic of Macedonia.

Background: Deficiency of 21-hydroxylase is present in 90-95% of all cases with congenital adrenal hyperplasia (CAH), an autosomal recessive disorder. Phenotype in all clinical forms of the disease: calssic salt wasting (SW) and simple virilizing (SV) and nonclassic late onset form (LO) corresponds to the genetic lesion in the CYP21A2 gene. The Q318X nonsense and R356W missense mutations at exon 8 that totally ablate 21-hydroxylase activity are most often associated with salt wasting disease.

Method: Using the PCR/ACRS method, we have performed direct molecular detection of the Q318X and R356W mutations in 35 Macedonian patients with classic clinical form of CAH (23 had SW and 12 had SV form), diagnosed according to standard clinical criteria at the Department of Endocrinology and Genetics, University Children's Clinic, Skopje, Republic of Macedonia.

Results: Mutations were detected in 20% (7/35) of all patients, Q318X in 5 (14.3%) and R356W in 2 (5.7%). In 17.4% (4/23) of the SW patients Q318X mutation was detected (three homozygotes and one heterozygote), and only one was heterozygote for R356W (4.3%). Among SV patients mutations Q318X and R356W were detected in one heterozygote (8.3%) each.

Conclusion: The R356W distribution in the Macedonian patients with classic CAH is comparable whereas the Q318X frequency was higher than reported in the most European populations. However, these findings further support a role of the severe mutations Q318X and R356W in the salt wasting form of the 21-hydroxylase deficiency.

Craniosynostosis, the premature fusion of one or more cranial sutures in the skull, is a common malformation, affecting 1 out of 2,500 live born babies. Sagittal craniosynostosis is the most common type, accounting for 40 to 58% of all cases. We conducted the first genome-wide association study (GWAS) for non-syndromic sagittal craniosynostosis using 130 European American case-parent trios. The strongest associations reached $p = 1.13 \times 10^{-14}$ (OR = 4.57) in the 3' UTR of BMP2 on chromosome 20 and $p = 1.61 \times 10^{-10}$ (OR=0.19) in an intron of BBS9 on chromosome 7. We replicated these associations ($p = 4.08 \times 10^{-32}$ and $p = 2.31 \times 10^{-15}$, respectively) in an independent European American population of 186 unrelated probands with non-syndromic sagittal craniosynostosis and 564 unaffected controls. We focused our studies on the locus on chromosome 20. We did not find coding region mutations of *BMP2* by direct sequencing; but by using quantitative real-time PCR, we found a significant increase in BMP2 expression in three of eight calvarial osteoblast cell lines derived from affected individuals as compared to control calvarial osteoblasts. ELISA assays and protein immunoblots showed that two of the same osteoblast lines have higher levels of BMP2 protein and increased phosphorylation of SMAD 1/5/8. In summary, we have identified two candidate loci for sagittal NSC and suggest that BMP2 plays a role in the genetic etiology of sagittal craniosynostosis.

P12.265

Improving genetic counselling in carriers of spinal muscular atrophy with two copies of the SMN1 gene.

L. Alías[1], *S. Bernal*[2], *M. Barceló*[2], *R. Martínez-Hernández*[2], *C. Vázquez*[3], *A. Santana*[3], *J. Salazar*[1], *L. González-Quereda*[1], *M. Baiget*[1], *E. F. Tizzano*[1];
[1]Hospital Sant Pau, CIBERER U-705, Barcelona, Barcelona, Spain, [2]Hospital Sant Pau, Barcelona, Barcelona, Spain, [3]Hospital Materno Infantil de Las Palmas, Gran Canaria, Spain.

Autosomal recessive spinal muscular atrophy (SMA) is caused by mutations in the Survival Motor Neuron1 gene (*SMN1*) leading to loss of motor neurons of the spinal cord. Carrier frequency is around 1/50. Detection of carriers of *SMN1* deletions is crucial to define couples at risk for SMA offspring. One of the pitfalls in quantitative SMA carrier diagnosis is the presence of two SMN1 genes in cis (2/0 carriers). We analysed 2827 individuals (810 parents and 2017 other relatives) for SMA carrier diagnosis. In the group of parents, 786 (97%) showed one SMN1 copy. The remaining 24 showed two copies and based on the inheritance of the at-risk alleles and quantitative analyses of their parents or siblings, 18 individuals were considered 2/0 carriers (2.25%) and 6 "de novo" cases (0.75%). In the group of relatives we detected 600 carriers with one copy, 1362 two copies, 50 three copies and 5 four copies. Using the same criteria as in the parent group, 27 of the cases with two SMN1 copies (4.3%) were considered 2/0 carriers. In 414 individuals of the general population (partners of possible or confirmed carriers) 15 (3.6%) showed one copy, 342 two copies, 36 three copies and 4 four copies. We conclude that 2/0 carriers are detected using both, marker and quantitative SMN1 analyses. For better genetic counselling, cases from the general population can be identified after quantitative analyses of their parents when one parent show 3 SMN1 copies and the other one SMN1 copy (Supported by CIBERER/FIS 11-2606).

Metabolarray®: targeted array-CGH for the detection of copy number changes in inherited metabolic disease

*B. Pérez[1,2,3], E. Vallespin[4,3], J. Nevado[4,3], F. Santos[4,3], P. Rodríguez-Pombo[1,2,3], B. Merinero[2,3], C. Pérez-Cerdá[2,3], P. Lapunzina[4,3], M. Ugarte[2,3], **L. R. Desviat**[1,2,3];*
[1]Centro de Biologia Molecular Severo Ochoa CSIC-UAM, Madrid, Spain, [2]Centro de Diagnóstico de Enfermedades Moleculares (CEDEM), Madrid, Spain, [3]CIBERER, Madrid, Spain, [4]INGEMM-Hospital La Paz, Madrid, Spain.

Clinical molecular testing in inherited metabolic disease (IMD) is currently PCR-based precluding the identification of deletions which account for a variable fraction (1-25%) of mutant alleles depending on the gene involved. We have developed a high-resolution comparative genomic hybridization array (Metabolarray®) for the detection of CNV in 205 genes involved in IMD which are currently diagnosed in the laboratory. The array consists of 62,979 oligos spread genome wide, with 40,555 hybridizing to target genes with an average spacing of about 250 bp and 26,678 covering the rest of the genome. For validation, we have retrospectively analyzed a series of IMD patients carriers of exonic deletions previously genotyped by different methods (MLPA, SNP-arrays). All the heterozygous and homozygous deletions even of a single exon were detected using the Metabolarray®. We are applying this tool prospectively to a series of patients with incomplete genotype. In one propionic acidemia patient with discordant Mendelian inheritance, we have identified a novel 2 Kb deletion in the PCCB gene encompassing exons 4 and 5. Our results show the clinical utility of this new molecular tool in the genetic diagnosis of IMD, allowing the detection of CNV at the resolution of individual exons.

Association of non-alcoholic fatty liver disease and hypercholesterolemia with mutations on the genes LEP, UGT1A1, ATP7B.

***A. Zarina**[1], L. Piekuse[1], Z. Steinberga[1], M. Kreile[1], A. Krumina[2], J. Keiss[3], V. Sondore[3];*
[1]Riga Stradins university Scientific laboratory of molecular genetics, Riga, Latvia, [2]Latvian Biomedical Research and study center, Riga, Latvia, [3]Infectology Center of Latvia, Riga, Latvia.

Introduction: Leptin (Lep), a polypeptide hormone probably have been implicated in pathogenesis of non-alcoholic fatty liver disease (NAFLD) (Swellam M, et al, 2012). Wilson's disease (WD) is a severe disorder of copper misbalance, caused by mutations in a gene ATP7B and is accompanied by accumulation of copper in tissues, especially in the liver, that can manifest as liver pathology (including NAFLD). Gilbert syndrome could be involved in lipid metabolism
Aim: To determine whether the polymorphisms and mutations, mentioned below are associated with dyslipidemia in patients with steatohepatitis (non-alcoholic fatty liver disease).
Material and methods: The study population included 39 patients who had been screened for hypercholesterolemia (total cholesterol >5mmol/l) and steatohepatitis, that liver biopsy revealed. Determinants were the mutation *H1069Q* in ATP7B gene, $(TA)_7$ in gene *UGT1A1,* I and D alleles in *LEP* gene 3'UTR region. In control population there were 56 individuals.
Results: $(TA)_7$ allele frequency in affected individuals 0.5303 (p=0.47, OR 0.85, CI95% 0.46 - 1.58) - Deletion allele 0.39 (p=0.12, OR 0.63, CI 95% 0.35-1.14). *H1069Q* allele frequency 0.01, in control group it was not found. After linear regression analysis there were not found significant asssociation (p>0.05) with any of biochemical marker.
Conclusions: There have to be done larger study to evaluate genetic reason to find association for NAFLD and hypercholesterolemia.

P13.03

Deletion of *NT5E* promotes dislipidemia, intramyocellular lipid accumulation and results in peripheral insulin resistance

***S. Burghoff**[1], U. Flögel[2], S. Bongardt[2], V. Burkart[3], H. Sell[4], S. Tucci[5], K. Ikels[6], D. Eberhard[7], J. Eckel[4], J. Schrader[2];*
[1]Institute of Human Genetics, Halle, Germany, [2]Institute of Molecular Cardiology, Düsseldorf, Germany, [3]Institute of Clinical Biochemistry, Leibniz Center for Diabetes Research, Düsseldorf, Germany, [4]Paul-Langerhans-Group "Integrative Physiology", Leibniz Center for Diabetes Research, Düsseldorf, Germany, [5]Department of General Pediatrics – University Children´s Hospital, Düsseldorf, Germany, [6]Institute for Animal Development and Molecular Biology, Düsseldorf, Germany, [7]Institute of Metabolic Physiology, Düsseldorf, Germany.

Mutations in *NT5E* are the cause of nonfunctional CD73 in humans and subsequently result in calcification of lower-extremity arteries and hand and foot joint capsules. CD73 converts extracellular AMP to adenosine, which is known to inhibit lipolysis. It is unknown, however, whether adenosine formed by CD73 is functionally relevant in lipid homeostasis. We therefore explored the effect of CD73-derived adenosine on lipid metabolism of transgenic mice lacking CD73 ($CD73^{-/-}$) at the age of 6-8 months. Using ^{1}H MRI we found significantly decreased superficial fat content in $CD73^{-/-}$ mice (WT: 2.6±0.9 a.u.; $CD73^{-/-}$: 1.4±0.5 a.u.) accompanied by increased serum free fatty acids (WT: 203±65 µM; $CD73^{-/-}$: 354±141 µM), triglycerides (WT: 4.2±4.9 mg/dl; $CD73^{-/-}$: 15.4±12.2 mg/dl), blood glucose (WT: 111±14 mg/dl; $CD73^{-/-}$: 146±24 mg/dl) and serum insulin levels (WT: 1.20±1.15 µg/l; $CD73^{-/-}$: 7.06±5.51 µg/l). Consistent with insulin resistance, intramyocellular lipid levels as measured with localized ^{1}H MR spectroscopy were significantly increased (WT: 1.01±0.31 a.u.; $CD73^{-/-}$: 1.52±0.61 a.u.; n=10 each). Insulin-induced Akt phosphorylation was reduced in skeletal muscle of $CD73^{-/-}$ mice. Islets from WT mice did not express CD73 at the mRNA and protein level, and glucose-stimulated insulin release from pancreatic islets was not different between WT and $CD73^{-/-}$ mice. In contrast, high fat diet almost completely downregulated the expression of CD73 in WT mice, which was also observed in adipose tissue from ob/ob mice. Our findings suggest that adenosine generated by *NT5E*/CD73 is an important insulin independent modulator of lipid metabolism *in vivo*, whereas non-functional *NT5E*/CD73 results in peripheral insulin resistance.

P13.04

A novel cardiomyopathy syndrome due to dolichol kinase deficiency

***E. Morava**[1], L. Kapusta[1], H. Mandel[2], D. Lefeber[1], R. Wevers[1];*
[1]UMC Nijmegen, Nijmegen, Netherlands, [2]University of Rambam, Rambam, Israel.

Congenital disorders of glycosylation are a growing group of inborn errors of protein glycosylation.Cardiac involvement is frequently observed in the most 14 common form, PMM2-CDG, especially hypertrophic cardiomyopathy. Dilated cardiomyopathy, however, has been only observed in a few CDG subtypes, usually with a lethal outcome. We report on cardiac pathology in nine patients from three unrelated Israeli families, diagnosed with dolichol kinase deficiency, due to novel, homozygous DK1 gene mutations. The cardiac symptoms varied from discrete, mild dilation to overt heart failure with death. Two children died unexpectedly with acute symptoms of heart failure before the diagnosis of DK1-CDG and heart transplantation could take place. Three other affected children with mild dilated cardiomyopathy at the time of the diagnosis deteriorated rapidly, two of them within days after an acute infection. They all went through successful heart transplantation; one died unexpectedly and 2 others arecurrently (after 1-5 years) clinically stable. The other 4 children diagnosed with mild dilated cardiomyopathy are doing well on supportive heart failure therapy. In most cases, the cardiac findings dominated the clinical picture, 33 without central nervous system or multisystem involvement, which is unique in CDG syndrome. We suggest to test for DK1-CDG in patients with dilated cardiomyopathy.Patients with discrete cardiomyopathy may remain stable on supportive treatment while others deteriorate rapidly. Our paper is the first comprehensive study on the phenotype of DK1-CDG and the first successful organ transplantation in CDG syndrome.

P13.05

Determing clinical revelance of gene conversion CYP21A2 and CYP21A1P

***S. Herbst**, B. Eichorn, R. Fahsold;*
Mitteldeutscher Praxisverbund Humangenetik, Dresden, Germany.

Congenital Adrenal Hyperplasia (CAH) is a common autosomal recessive disorder caused mainly by mutations in the 21-hydroxylase gene (CYP21A2). The CYP21A2 is located at 6p21.3 about 30 kb apart from its pseudogene CAP21A1P, which encodes for an inactive protein due to the presence of 15 mutations. Gene and pseudogene are part of a tandemly repeated structure;

hence they are often targets of intergenic recombinations causing small lesions, deletions, duplications and gene conversions. Latter comprises fused genes with its 5`end and 3`end corresponding to CYP21A1P and CYP21A2 respectively, which are known to be pathogenic.

However, here we demonstrate three patients with a fusion between CYP21A2 and CYP21A1P observed by a suspicious MLPA result. In all patients exons 1-3 of the gene are duplicated whereas the corresponding region of the pseudogene is deleted. Direct sequencing reveals that a part of the gene (from upstream of the promoter to intron 3) indeed replaced the corresponding region of the pseudogene. Even if the gene promoter is present, the stop mutation in exon 7 of the pseudogene part generates a truncated protein. In addition two intact CYP21A2 copies are present.

In conclusion, the described chimeric gene CYP21A2/CYP21A1P is not disease causing, while at least one intact copy of the CYP21A2 gene is present. We recommend performing a long-range PCR in combination with direct sequencing subsequent to the observation of aberrant MLPA pattern to validate whether an intact gene copy is available.

P13.06

Defect of cobalamin intracellular metabolism (cblC, cblD and cblF defects) masquerading as diabetic ketoacidosis

S. Sharda, *S. Angurana, M. Walia, S. V. Attri;*
Post Graduate Institute of Medical Education and Research, Chandigarh, India.

Inborn errors of metabolism, especially aminoacidopathies, manifesting as diabetic ketoacidosis or hyperglycemia are rare, only a few cases have been reported. We report a 13-month-old boy who presented with vomiting, dehydration, coma, hyperglycemia, high anion gap metabolic acidosis, and ketosis mimicking diabetic ketoacidosis (DKA). Treatment with parenteral fluid, electrolyte and insulin infusion lead to an improvement in hyperglycemia but persistence of metabolic acidosis and lack of improvement of neurologic findings led us to suspect an inborn error of metabolism. Urinary organic acid analysis revealed increased methylmalonic acid levels. In addition to this, he also had increased plasma and urine homocystine tested by high performance liquid chromatography (HPLC). There was some improvement in neurologic status and metabolic parameters after treatment with low-protein diet, vitamin B12, and L-carnitine but he ultimately succumbed to nosocomial sepsis. Methylmalonic aceidemia presenting with DKA like symptoms has been reported. But to the best of our knowledge, this is probably the first case report of late-onset combined methylmalonic acidemia and homocytinuria (cblC, cblD and cblF defects) masquerading as diabetic ketoacidosis. The early diagnosis of IEM is of utmost importance for the treatment, prognosis as well as genetic counseling for the family. High index of suspicion even in varied clinical presentation is the only way to diagnose these disorders in places where newborn screening is still not a routine practice.

P13.07

Genetic analysis of congenital disorders of glycosylation patients using candidate gene genomic capture and next generation sequencing

C. Medrano[1], C. Pérez-Cerdá[1], P. Gómez-Puertas[2], L. R. Desviat[1], M. Ugarte[1], ***B. Pérez***[1]*;*
[1]Centro de Diagnóstico de Enfermedades Moleculares-Centro de Biología Molecular, CIBERER, IDIPAZ, Madrid, Spain, [2]Centro de Biología Molecular,, Madrid, Spain.

Congenital disorders of glycosylation are a heterogeneous group of disorders caused by genetic defects in the protein glycosylation pathway. The clinical and subsequent biochemical diagnosis allow to classify the affected patients as CDG type I caused by defects in cytoplasmic and endoplasmic reticulum proteins or CDG type II caused by defects in the Golgi apparatus. Genetic diagnosis is required to identify the affected gene using a high-time consuming approach to sequence gene by gene. The aim of this study was to improve molecular diagnosis for congenital disorders of glycosylation by developing a customized array.We present the initial results obtained by combination of a targeted in solution capture from Agilent and subsequent next generation sequencing using the Solid platform. In this work 16 barcoded patients have been analyzed (seven CDGI and nine CDGII). On average, coverage was 45 to 60 fold and we have detected close to one-hundred SNV per patient. The SNV were filtered excluding common variants and also excluding synonymous, deep intronic variants and also UTR changes. The initial results have allowed the identification of pathogenic mutations in DPAGT1, RTF1 and COG7 genes. In summary the development of next generation sequencing panels in the genetic diagnostic laboratory allows a most efficient genetic diagnosis compared with the conventional gene-by-gene sequencing.

P13.08

Cystic fibrosis related diabetes-risk factors

I. M. CIUCA[1]*, L. Pop[1], Z. Popa[1], I. Velea[1], L. Tamas[2], I. Popa[1];*
[1]Pediatric II Department, Timisoara, Romania, [2]Biochemistry Department, Timisoara, Romania.

Background: Cystic fibrosis related diabetes (CFRD) is frequent in female with pancreatic insufficiency, carriers of so-called severe mutations . While risk factors for type 1 diabetes are well-known, CFRD risk factors who could be influenced are still looking. **Objectives**: Evaluate the risk factors for the development of CFRD in our patients. **Methods**: We performed retrospective seven years cohort study; 81 patients were evaluated. For all CFRD patients were obtained data about familial history of diabetes, positive antecedent of rickets and early diet. Biannual biochemical evaluation was completed in addition to clinical examination. **Results**: CFRD was diagnosed in eight patients (9.8%), 50% carriers of class I mutations. Prevalence was significantly higher in girls (75%) compared to boys. Median age at CFRD debut was 13.37 years and the mean age at CF diagnosis 7.27 years. We did not noticed positive family history for diabetes in any of patients. Five patients (62.5%) had rickets as toddlers, although vitamin D was given for prophylaxis . All of CFRD patients were nourished with cow`s milk formulas, one was breast fed for 2 months. Early introduction of gluten cereals (at 4 months) was documented in 7 patients (87.5%). Unfortunately 50% of CFRD patients died from pulmonary disease. **Conclusion**: Girls diagnosed late with CF, fed with cow`s milk and gluten nourishment in the early infancy, with positive history of vitamin D deficiency are more prone to develop CFRD. Early dietary intervention especially in female patients with "severe" genotype might be helpful.

P13.09

Metabolic characterization of common variants of the FTO and TCF7L2 loci by nutritional challenge tests

S. Wahl[1]*, S. Krug[2], C. Then[3], T. Brand[2], K. Ehlers[2], M. Claussnitzer[2], T. Skurk[2], A. Lechner[3], H. Wichmann[4], C. Huth[5], C. Meisinger[5], C. Prehn[6], F. Stückler[7], G. Kastenmüller[7], J. Adamski[6], K. Suhre[7,8], T. Illig[9,1], H. Grallert[1], H. Laumen[2,10], J. Seissler[3], H. Hauner[2,10];*
[1]Research Unit of Molecular Epidemiology, Helmholtz Zentrum Muenchen, Neuherberg, Germany, [2]EKFZ, Chair for Nutritional Medicine, Technical University Muenchen, Freising, Germany, [3]Diabetes Center, Medical Clinic Innenstadt, Ludwig Maximilians University, Munich, Germany, [4]Institute of Epidemiology I, Helmholtz Zentrum Muenchen, Neuherberg, Germany, [5]Institute of Epidemiology II, Helmholtz Zentrum Muenchen, Neuherberg, Germany, [6]Institute of Experimental Genetics, Helmholtz Zentrum Muenchen, Neuherberg, Germany, [7]Institute of Bioinformatics and Systems Biology, Helmholtz Zentrum Muenchen, Neuherberg, Germany, [8]Department of Physiology and Biophysics, Weill Cornell Medical College, Education City, Qatar, [9]Hanover Unified Biobank, Hanover Medical School, Hannover, Gabon, [10]ZIEL, Research Center for Nutrition and Food Sciences, Technical University Muenchen, Freising, Germany.

Common single nucleotide polymorphisms in the FTO and TCF7L2 gene loci have been consistently associated with obesity and type 2 diabetes mellitus, respectively. The mechanisms underlying these associations remain poorly understood. Measuring metabolite response profiles by metabolomics during nutritional challenges may help to unravel how the interaction of genetic variants with lifestyle influences metabolism. We present an approach combining detailed phenotyping, nutritional and intravenous interventions and metabolomics analyses to investigate early metabolic alterations in healthy risk allele carriers. 77 non-obese male participants of the KORA S4/F4 cohort, aged 34 to 67 years, were recruited. 19/24 homozygous carriers of the FTO locus risk allele rs9939609, 16/17 carriers of the TCF7L2 locus risk allele rs7903146 and 20/24 homozygous controls performed nutritional and intravenous challenge tests, respectively. Nutritional challenges comprised an oral glucose tolerance test after overnight fasting, a standardized fast food meal, and a lipid tolerance test within a two-day study period. The intravenous challenge consisted of an intravenous glucose tolerance test and a subsequent euglycemic hyperinsulinemic glucose-clamp test. For metabolomics analysis, blood was sampled at three time points for each participant during each challenge and concentrations of 163 metabolites were determined using the AbsoluteIDQTM p150 kit (Biocrates Life Sciences AG). We show the initial analyses of metabolite-response profiles to the different challenges. The presented approach intends to functionally characterize genetic variants in the FTO and TCF7L2 loci and to identify novel markers of prediabetes. The presented design provides a framework for further analysis of additional risk variants.

P13.10
Investigation of CAT gene C1167T polymorphism in diabetic nephropathy

*C. Grauntenau[1], A. Cimpoeru[1], D. Clenciu[1], E. Cioboata[1], M. Bacu[1], S. Serban-Sosoi[1], M. Stavarachi[2], M. Ioana[1], **N. M. Panduru**[3], M. Mota[1], E. Mota[1];*
[1]University of Medicine and Pharmacy, Craiova, Romania, [2]Genetics Department of Bucharest University, Bucharest, Romania, [3]"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania.

Diabetic nephropathy (DN) is the most severe diabetic complication. Oxidative stress may play a role in its pathogenesis. Antioxidant defense seems to be modulated by genetic variability. The aim of this study was to investigate the association of CAT gene C1167T (rs769217) polymorphism with DN in type 1 diabetes.

Clinical data and blood samples were collected from 269 Romanian patients with type 1 diabetes. They were divided in two groups according to the presence of DN - 108 patients without DN and 161 patients with DN. Genomic DNA was extracted from peripheral blood leucocytes using commercial kits and the rs769217 polymorphism was assessed by TaqMan SNP assay on the ViiA7 Real-Time PCR system. Statistical analysis was performed using PLINK v1.07 software.

The sample population was in Hardy-Weinberg equilibrium. The frequency of minor allele (T) was 0.21 in DN group and 0.26 in the controls without DN. In raw analysis neither T allele (OR=0.762, [95%C.I. 0.512-1.135], p=0.18) or C allele (OR=1.312, [95%C.I. 0.881-1.954], p=0.18) conferred risk or protection for DN. We performed adjustment for a minimal additive model (age, sex, duration of diabetes and glycated hemoglobin A1c), but the results remained concordant with the raw analysis (ORT=0.773, [95%C.I. 0.5073-1.178], p=0.23].

In summary, CAT gene C1167T (rs769217) polymorphism does not seems to confer risk for DN in patients with type 1 diabetes.

P13.11
Type V Hyperlipoproteinemia with Neonatal Onset

***C. Cladovan**[1], D. Dubau[2], A. Szilagyi[2], C. Jurca[2];*
[1]University of Oradea, Faculty of Medicine and Pharmacy, Oradea, Romania, [2]University of Oradea, Faculty of Medicine and Pharmacy, Oradea, Romania.

Introduction. Familial hyperlipoproteinemias in neonates are rarely encountered in clinical practice. The incidence of Frederickson type V familial hypertriglyceridemia is not estimated in childhood. The pattern of inheritance is autosomal dominant. **Case report**. We present a case of sixteen days old newborn admitted in our department for milky plasma detected in Maternity and association of severe bleeding disorders. Physical examination revealed pallor, dysmorphic face with xanthomas, mucosal bleeding, abdominal distension. Laboratory findings identified extremely high values for triglycerides (2500 mg/dl), cholesterol (1276 mg/dl initially then 336 mg/dl with HDLc 19 mg/dl, LDLc 3,87 mg/dl), total fats (5317 mg/dl), the test for chylomicrons positive, severe alteration of coagulation tests without proof of clotting factors deficiency, transitory thrombocytosis. Echocardiography revealed non-compaction cardiomyopathy. First -degree relatives have evidence of dyslipidemia above 90th percentile. **Conclusion.** Our case presented a rare familial hyperlipoproteinemia type V with neonatal onset associated with severe bleeding disorder and non-compaction cardiomyopathy.

P13.12
Development of a cell-based reporter assay for the analysis of regulatory interactions between FGF23/KLOTHO/FGFR1, small inhibitors and downstream targets

***S. Diener**[1], B. Lorenz-Depiereux[1], T. M. Strom[1,2];*
[1]Helmholtz Zentrum München, German Research Center for Environmental Health, Institute of Human Genetics, Neuherberg, Germany, [2]Klinikum Rechts der Isar der Technischen Universität München, Institute of Human Genetics, Munich, Germany.

The analysis of rare genetic disorders affecting phosphate homeostasis led to the identification of several proteins essential for the renal regulation of phosphate homeostasis: PHEX (XLH [MIM 307800]), FGF23 (ADHR [MIM 193100]), SLC34A3 (HHRH [MIM 241530]), DMP1 (ARHR1 [MIM 241520]), ENPP1 (ARHR2 [MIM613312]), GALNT3 (FTC [MIM 211900]), and KLOTHO (FTC [MIM 211900]). A key regulator of phosphate homeostasis is the fibroblast growth factor 23 (FGF23). It is mainly secreted from osteocytes, circulates in the blood, and binds to receptor heterodimers composed of FGF receptor 1 (FGFR1) and KLOTHO in the kidney. FGF23 activates KLOTHO/FGFR1 to inhibit renal phosphate reabsorption and to suppress 1,25-dihydroxyvitamin D3 synthesis. As a key signalling pathway mitogen-activated protein kinase (MAPK) pathway is employed. To analyse regulatory interactions between FGF23/KLOTHO/FGFR1, small inhibitory compounds and further downstream targets, we have developed FGF23-inducible HEK293 cells that stably express KLOTHO (HEK293-KL). Stable cell clones were picked, expanded, and expression of KLOTHO was confirmed by Western blot analysis. By investigating the activation of MAPK pathway we could show that HEK293-KL cells are FGF23-inducible. Moreover, we could inhibit the induction with FGF23 by the use of two small inhibitory molecules: (1) SU5402, an inhibitor of FGFR1 and (2) U0126, an inhibitor of MAPK pathway. Taken together, we have established a potent cell-based reporter assay, which can now be used to investigate FGF23/KLOTHO/FGFR1 receptor signalling and receptor complex inhibition in more detail. We will try to identify novel downstream targets which may be candidates for regulatory compounds involved in phosphate homeostasis.

P13.13
A novel splice mutation and a novel exon deletion in the AGL gene in a patient with Forbes-Cori disease (GSD III)

***M. Kuhn**[1], C. Distler[1], F. Wegner[2], D. Glaeser[1];*
[1]Genetikum, Neu-Ulm, Germany, [2]Pediatrics, St. Marien-Hospital, Dueren, Germany.

Glycogen storage disease type III (GSD III) is an autosomal recessive disorder characterized by excessive accumulation of glycogen in the liver and in skeletal / cardiac muscles. The typical symptoms are hepatomegaly, hypoglycaemia and muscles weakness, also shown in our 4 years old male patient. GSD III is caused by a deficiency of the glycogen debranching enzyme (AGL). We performed screening for mutations in the AGL gene by sequencing all exons including flanking intronic sequences. The analysis revealed a heterozygous mutation at the donor splice site of exon 10. Considering the autosomal recessive inheritance pattern of GSD III, this mutation cannot solely be responsible for the present phenotype in the patient. So it was appropriated to search for possible deletions in the AGL gene. A gross deletion was excluded by Array-CGH. As there is no commercial MLPA kit for AGL available, we designed our own MLPA probes. Having established the assay we analyzed DNA from the patient. We found a heterozygous novel single exon deletion in the AGL gene. This result was confirmed by junction fragment analysis using flanking primers. Sequence analysis of the junction fragment revealed a 2.3 kb deletion and the intronic break points. The deletion could also be detected in paternal DNA and the splice mutation in maternal DNA. This demonstrates the compound heterozygosity of the two detected genetic alterations. Our results show that home-made MLPA tests are an appropriate method to detect causative exon deletions in genes since there is no commercial MLPA kit available.

P13.14
Efficacy of enzyme replacement therapy with velaglucerase alfa in patients with type 1 Gaucher disease and marked thrombocytopenia or splenomegaly

***A. Zimran**[1], D. E. Gonzalez[2], M. Kabra[3], E. A. Lukina[4], P. Giraldo[5], I. Kisinovsky[6], M. Ben Dridi[7], D. Elstein[1], D. Zahrieh[8], E. Crombez[8], H. Ben Turkia[7];*

Background. The responses of type 1 Gaucher disease (GD)-related thrombocytopenia and splenomegaly to enzyme replacement therapy (ERT) are linked to their pretreatment severity.

Methods. TKT032 and HGT-GCB-039 were parallel-group trials; eligible patients were ≥2 years old with untreated type 1 GD. In both trials, 1 treatment arm was allocated to velaglucerase alfa 60 U/kg ERT every other week (EOW). Patients completing either trial could enrol in a combined extension study, HGT-GCB-044.

Results. 27 type 1 GD patients received velaglucerase alfa 60 U/kg EOW in TKT032 or HGT-GCB-039 and HGT-GCB-044 over 24 months. 15/27 patients had a pretreatment (Baseline) platelet count <100×10^{9}/L; 6 of these 15 had a platelet count <60×10^{9}/L. All 15 had an intact spleen. 6/27 patients had severe Baseline splenomegaly (splenic volume >15 multiples of normal); all 6 had a platelet count <100×10^{9}/L. At 24 months, 14/15 (93%) patients had reached the platelet count therapeutic goal and 6/6 with severe Baseline splenomegaly had reached the splenic goal. 5/6 (83%) patients with a Baseline platelet count <60×10^{9}/L had a normal platelet count (≥120×10^{9}/L), including 2 with severe Baseline splenomegaly (Table).

Table. Individual platelet and splenic responses: 24 months of study drug

Base-line age, y	Gender	Platelet count, ×10⁹/L				Splenic volume, multiples of normal

*Patients with spleens >15 multiples of normal in volume at Baseline.
†Below goal.
Therapeutic goals by 2 years: splenic volume must decrease 50-60%; Baseline platelet count 60-120×10⁹/L must be ≥100×10⁹/L; Baseline platelet count <60×10⁹/L must increase 2-fold.

Conclusion. Clinically significant improvements in platelet count and splenic volume occurred in the first 24 months of velaglucerase alfa treatment among patients with type 1 GD and severe Baseline splenomegaly and/or a platelet count <100×10⁹/L (including those with a platelet count <60×10⁹/L).

P13.15

The genetic origin of glutaric aciduria type I in Belarus

A. Zinovik, S. Miasnikov, N. Gusina;
National Research and Applied Medicine Centre "Mother and Child", Minsk, Belarus.

Glutaric aciduria type I (GA-I) is a rare organic aciduria caused by inherited deficiency of glutaryl-CoA dehydrogenase which is involved in the catabolic pathways of L-lysine, L-hydroxylysine and L-tryptophan. From 1975 more than 500 patients were diagnosed worldwide. More than 200 disease-causing mutations of GCDH gene (19p13.2) are known thus far, most mutations are unique to individual families. In some countries GA-I is included in the panel of diseases identified by expanded newborn screening.
In Belarus the possibility to diagnose GA-I appeared after the beginning of acylcarnitine analysis by tandem mass spectrometry (MS/MS). From 2007 4120 patients passed selective screening by MS/MS, and four unrelated patients, aged 7 months - 2 years, were diagnosed as having GA-I. The analysis of GCDH gene revealed one common mutation, p.R402W, covering 75% (6 from 8) of all mutant alleles. High prevalence of p.R402W also among Russian GA-I patients indicates possible Slavic origin of this mutant allele and suggests that screening for this mutation may be appropriate for the confirmation of biochemical and clinical diagnostic, identification of carrier status and prenatal diagnosis of GA-I in this region.

P13.16

Association of HFE gene mutations with HLA-A and -B alleles in patients with idiopathic hepathobiliar disorders

O. Bilevych, D. Zastavna, H. Makukh, O. Terpylyak;
Institute of Hereditary Pathology, NAMS of Ukraine, Lviv, Ukraine.

Hereditary hemochromatosis (HH) is an autosomal recessive disease characterized by abnormal accumulation of iron in parenchymal organs leading ultimately to organ dysfunction. This is the most common inherited liver disease. HH gene (*HFE*) is located within the human leukocyte antigen (HLA) class I region on chromosome 6. It is suggested linkage disequilibrium between these genomic regions which results in certain clinical features of HH. The aim of the study was to establish the distribution of HLA-A and -B alleles in patients with idiopathic hepathobiliar disorders (IHD) in association with C282Y and H63D mutations in *HFE* gene.
The presence of *HFE* mutations was established in 70 patients with IHD (chronic idiopathic hepatitis, liver cirrhosis, hepatomegaly) and in 60 healthy controls. HLA typing was performed in 25 *HFE* mutation carriers and 20 non-carriers. *HFE* mutations were screened for by RFLP performed on PCR products. HLA alleles were detected using allele-specific PCR.
Heterozygous C282Y mutation found in 14.3% of patients with IHD was significantly higher than in control group (χ^2=4.625, P<0.05). The differences in H63D mutation frequencies were not reliable. An expected significant association between *HFE* mutations and HLA-A3 allele was established (χ^2=3.902, P<0.05). 4 out of 5 patients with chronic idiopathic hepatitis were HLA-A3/B7, HLA-A3/B62 and HLA-A3/B14 genotype carriers in association with both C282Y and H63D mutation.
We suggest that heterozygous status for C282Y mutation may be a risk factor for IHD. HLA-A3 allele and HLA-A3-containing genotypes in combination with *HFE* mutations may play important role in susceptibility to chronic idiopathic hepatitis.

P13.17

Diagnostic tests for the genetic defects of urate transporters

I. Sebesta[1], B. Stiburkova[2];
[1]Inst Med Biochem and Lab Dg,Inst of Inher Metab Dis, First Faculty of Medicine, Prague, Czech Republic, [2]Inst of Inher Metab Dis, First Faculty of Medicine,Charles University, Prague, Czech Republic.

Introduction: Primary hereditary renal hypouricemia is a genetic disorder affecting renal uric acid (UA) reabsorption with clinical features such as nephrolithiasis and exercise-induced acute renal failure. The known causes are: defects in the SLC22A12 gene, encoding the human urate transporter 1 (hURAT1), and also impairment of voltage urate transporter (URATv1), encoded by SLC2A9 (GLUT9) gene. Diagnosis is based on hypouricemia (< 119 µmol/l) and increased fractional excretion of UA (> 10%). To date more than one hundred Japanese patients with mutations in hURAT1 gene have been described. Hypouricemia is sometimes overlooked, therefore we have set up the flowchart for this disorder.
Methods**:** The patients were selected for molecular analysis from 640 Czech hypouricemic patients. These cases were found in 3 700 blood and urine samples. Serum and urinary UA and creatinine were determined. The sequence analysis of SLC22A12 and SLC2A9 genes were performed.
Results: Other secondary causes of hyperuricosuric hypouricemia were excluded. The estimations of : 1) serum UA, 2) excretion fraction of UA, 3) and analysis of hURAT1 and URATv1 genes follow. We have found 3 transition, 4 deletions in SLC22A12 gene and one nucleotide insertion in SLC2A9 gene in overall 7 Czech patients. Three patients had acute renal failure and urate nephrolithiasis.
Conclusions: Our finding of the defects in URATv1 gene gives further evidence that SLC2A9 is a causative gene of primary renal hypouricemia. Hereditary renal hypouricemia is still unrecognized disorder and probably not wide spread in East Asia only. (Supported by project PRVOUK, MOLMED of Charles University).

Identification of two novel isoforms of the HNF1A gene

D. Fernández García[1,2], E. González Ruano[1], C. Cieza Borrella[1,2], I. Rodríguez Hernández[1,2], J. Miralles García[3], R. González Sarmiento[1,2];
[1]Unidad de Medicina Molecular-Departamento de Medicina e IBMCC. Universidad de Salamanca., Salamanca, Spain, [2]IBSAL, Salamanca, Spain, [3]Servicio de Endocrinología. Hospital Universitario de Salamanca, Salamanca, Spain.

Background
HNF1A is a transcription factor that plays a central role in the regulation of pancreatic beta cells. It controls the transcription of key genes such as insulin and GLUT2. Their mutations cause deregulation of certain processes leading to the onset of MODY3 diabetes. So far it has been described three HNF1A isoforms. We have identified two new isoforms in liver cells.
Methods
HNF1A cDNA was synthesized in HepG2, Capan 1, Hek and MCF7 cells (negative control). The reaction products were cloned to analyse the isoforms activity by luciferase assay in COS1 and HepG2 cells. We carried out a predictive analysis of the structures of two new isoforms and their location was determined by immunofluorescence in both cell types.
Results
We found two unreported transcripts: HNF1AΔ2, which lost exon 2 and the reading frame, and HNF1AinsIVS8, who never missed the reading frame and inserts 31 amino acids in the protein. Luciferase analysis show a 77% reduction in expression levels of isoform HNF1AΔ2 and a twofold increase in the activity of the isoform HNF1AinsIVS8 with respect to the Wt. The structure prediction shows a significant change in the case of isoform HNF1AinsIVS8. Immunofluorescence analysis shows that this isoform maintain the nuclear localization. This isoform is expressed in Hepg2 cell line but not in Capan1, HEK293T, JURKAT or MCF7. Analysis of HNF1AΔ2 isoform is underway.
Conclusion
We report two novel isoforms cloned by HNF1A gene that are expressed in HepG2 cell line and could help to better understand HNF1A activity.

P13.19
Molecular genetic analysis in patients with congenital hyperinsulinism of infancy: Identification of novel mutations in *ABCC8* and *KCNJ11* and implementation of genetic diagnosis in disease management

I. Wieland[1], *K. Mohnike*[2], *S. Empting*[2], *T. Meissner*[3], *M. Lindner*[4], *W. Barthlen*[5], *M. Zenker*[1];
[1]Universitätsklinikum, Institut für Humangenetik, Otto-von-Guericke Universität, Magdeburg, Germany, [2]Universitätsklinikum, Universitätskinderklinik, Otto-von-Guericke Universität, Magdeburg, Germany, [3]Universitätsklinikum, Zentrum für Kinder- und Jugendmedizin, Heinrich-Heine Universität, Düsseldorf, Germany, [4]Universitätsklinikum, Zentrum für Kinder- und Jugendmedizin Angelika-Lautenschläger-Klinik, Ruprecht-Karls Universität, Heidelberg, Germany, [5]Kinderchirurgie Universitätsmedizin, Greifswald, Germany.

Congenital hyperinsulinism (CHI) causes persistent hypoglycemia due to uncontrolled insulin secretion in newborns and infants. Since patients are at increased risk of neurological sequelae, a rapid diagnosis and disease management is mandatory. CHI is a heterogenous condition at the clinical and genetic level. Mutations in several genes including *ABCC8*, *KCNJ11*, *GLUD1*, *GCK*, *HADH*, *SLC14A1*, *HNF4A* and *UCP2* have been identified in approximately half of the patients in several patient cohorts. The most severe forms of CHI are caused by loss of function of the *ABCC8* and *KCNJ11* genes encoding subunits of the ATP-sensitive K(+) channel. They are usually associated with unresponsiveness of pancreatic ß-cells to medical treatment. Recently, it has been suggested to implement rapid genetic analysis of *ABCC8* and *KCNJ11* in newborns with diazoxide unresponsive CHI to improve patient management. We report sequence analysis in 37 CHI patients referred to us within one year. Mutations in *ABCC8* and *KCNJ11* were observed in 7/17 patients aged less than one year and in 5/20 patients at age of more than one year. Seven patients harbored homozygous or compound heterozygous mutations that cause diffuse form of CHI and five patients had paternally transmitted single heterozygous mutations predicted to cause focal form of CHI. Together, 14 different mutations were identified and 12 were novel with one recurrent mutation in two consanguineous families of Turkish descent. In conclusion, genetic analysis of *ABCC8* and *KCNJ11* in CHI newborns and infants revealed mutations in about one third of the patients and contributed to further patient management.

P13.20
Clinical signs of autosomal dominant inherited hypophosphatasia

J. Engel[1], *S. Rost*[1], *F. Jakob*[2], ***E. Kunstmann***[1];
[1]Human Genetics University of Wuerzburg, Wuerzburg, Germany, [2]Muskuloskelettales Centrum Wuerzburg, Wuerzburg, Germany.

Hypophosphatasia (HPP) is a hereditary metabolic disorder of the bone. It is caused by impaired activity of the tissue-nonspecific isoenzyme of alkaline phosphatase. Five clinical forms are distinguished depending on the patient's age when clinical symptoms occur. Early onset of the disease normally accompanies a severe clinical course, in this case HPP is normally transmitted as an autosomal recessive trait. HPP due to a single mutation in the ALPL gene and inherited as an autosomal dominant trait can cause milder forms without clearly defined symptoms so far.

Results: Here we present clinical data of 9 families and 22 individuals with one mutation in the ALPL gene. Stress fracture and impaired healing of fractures are leading symptoms of dominant HPP. The majority of mutation carriers show signs of odontohypophosphatasia like premature tooth loss, tooth decay and caries. One third of the patients complained about joint pain, followed by pain of the muscles. Approximately a quarter of patients reported impaired physical fitness. Only few patients suffered from ostealgia.

The majority of patients showed decreased activity of the alkaline phosphatase. Eight missense mutations in the ALPL gene and no nonsense mutation were found.

Conclusion: The clinical signs of dominant HPP are not well known and despite of decreased activity of the alkaline phosphatase diagnosis of dominant HPP is rarely made. Therefore, these patients are often not treated in an appropriate way.

P13.21
The inherited metabolic diseases of liver in genetic practice

N. Gusina, *E. Budzeika*, *T. Zimovina*, *T. Dzemidovitch*, *S. Dubovik*, *A. Zinovik*, *S. Miasnikov*, *O. Pechkurova*;
National Research and Applied Medicine Centre "Mother and Child", Minsk, Belarus.

Objectives: To investigate the role of inborn errors of metabolism (IEM) as a cause of liver disease and their mutation spectrum.

Patients and Methods: A group of 2837 patients with hepatomegalia/hepatosplenomegalia or jaundice of unknown etiology was investigated. The diagnosis of IMD was based on the results of biochemical investigation. The DNA assays included restriction analysis, allele-specific hybridization or direct sequencing.

Results and Conclusions: The IMD appeared the cause of liver disease in 68% (1929/2837) of investigated patients. The following IMD were detected: galactosemia - 20 cases (mutant alleles Q188R and K285N - 64%), inherited fructose intolerance - 2, glycogen storage disease type Ia - 2 (R43C - 50%), Ib - 4, III - 1, VI-1, alfa-1-antitrypsin deficiency - 43 (PiZZ- 13, PiMZ - 28, PiMS - 2), Wilson disease - 55 (H1069Q, 2299insC, I1102T, 3400delC - 76%), Nieman-Pick type C - 4, CESD - 3 (E8SJM - 50%), hereditary hemochromatosis - 5 (C282Y - 2, C282Y/H63D - 3), Gaucher disease type I - 8 and III - 2 (N370S, L444P, RecNciI - 77%), methylmalonic aciduria - 3, LCHAD deficiency - 3, VLCAD deficiency - 1, syndrome HHH - 3, CDG-syndrome -1, tyrosinemia - 3, Alpers syndrome - 1 (A467T/G268A), hepatocerebral mitochondrial depletion syndrome - 2, Zelweger syndrome - 2, citrullinemia type 1 - 1, Gilbert's syndrome - 1759. IEM are the frequent cause of liver disease and should be kept in mind working with such groups of patients.

P13.22
Maternally inherited Leigh syndrome in a Hungarian patient with the G13513A mutation

K. Komlósi[1], *P. Kisfali*[1], *K. Hadzsiev*[1], *L. Sztriha*[2], *L. Kaizer*[3], *K. Brinyiczki*[3], *I. Bódi*[4], *E. Pál*[5], *B. Melegh*[1];
[1]Department of Medical Genetics, University of Pécs, Pécs, Hungary, [2]Department of Pediatrics, Faculty of Medicine, Albert Szent-Györgyi Clinical Center, Szeged, Hungary, [3]Department of Pathology, Faculty of Medicine, Albert Szent-Györgyi Clinical Center, Szeged, Hungary, [4]Neuropathology Research Group, Clinical Neuroscience Department, King's College, London, United Kingdom, [5]Department of Neurology, University of Pécs, Pécs, Hungary.

Leigh syndrome (LS) is a progressive neurodegenerative disorder with symmetrical lesions in the brainstem and/or basal ganglia in infancy and childhood. Mutations in nuclear and mitochondrial genes of the energy metabolism have been associated with LS. The G13513A mutation in ND5, one of the 7 mtDNA encoded subunits of Complex I, was originally reported in MELAS, but later identified in children with LS.

We present the first Hungarian documented case of LS associated with the G13513A mtDNA mutation in a 3,5 year-old girl. Psychomotor delay was noted at the age of 1 year, unaided walking developed at 17 months, bilateral ptosis at 21 months, ataxia and intention tremor at 3 years of age. Elevated blood and CSF lactate, multiple lesions in the cerebellum, brain stem, caudate nucleus, internal capsule and thalami pointed to LS. Progressive deterioration from age 3 years on lead to death at age 3,5 years due to aspiration. Mutation analysis from blood showed a 60% heteroplasmy of the G13513A mutation, postmortem muscle and liver tissue revealed 70% mutation loads. No mutation was detected in blood from the mother.

The G13513A mutation has not been detected in the 350 Hungarian mitochondrial encephalomyopathy patients from our Biobank so far. Despite the variable phenotype, the course of disease and the absence of cardiologic manifestations differentiate our case from previous reported ones. Since the A13513G mutation is often observed as a de novo change it is important to carefully examine multiple tissues from the mother before genetic counseling can be given.

P13.23
Leigh Syndrome with mild neonatal Complex IV deficiency

S. Seneca[1,2], *K. Van Campenhout*[2], *J. Smet*[3], *R. Van Coster*[3], *L. Dom*[4], *U. Ullmann*[1,5], *W. Lissens*[1,2], *S. Van Dooren*[1,2], *L. De Meirleir*[6,2];
[1]UZ Brussel, CMG, Brussels, Belgium, [2]Vrije Universiteit Brussel (VUB), Brussels, Belgium, [3]Ghent University Hospital, Division of Pediatric Neurology and Metabolism, Ghent, Belgium, [4]ZNA Koningin Paola Ziekenhuis, Department of Child Neurology, Antwerp, Belgium, [5]Institut de Pathologié et de Génétique, Gosselies, Belgium, [6]UZ Brussel, Department of Child Neurology, Brussels, Belgium.

Isolated complex IV deficiency is a frequent cause of respiratory chain impairment and mitochondrial disease. Onset, nature and severity of the clinical presentation or the genotype of these patients are heterogeneous.

Here, we report clinical, biochemical and genetic data of a male infant with pathogenic mutations in *COX15*. The patient was born as the 2nd child to healthy, not related parents and has an healthy brother. He was hypotonic and presented with feeding difficulties, failure to thrive, psychomotor retardation, lactic acidosis and cardiomyopathy. His MRI was suggestive for Leigh Disease. The cardiomyopathy progressed rapidly and the patient died of heart failure at five months of age.

Oxidative phosphorylation (OXPHOS) enzyme activities were measured using spectrophotometrical analysis. Biochemical analysis of the COX activity showed a very mild decrease in fibroblasts and a low normal range value in muscle tissue. Other respiratory chain activities were normal. Functional integrity of the five complexes was evaluated using blue native polyacrylamide gel electrophoresis followed by in-gel activity staining in muscle tissue, and showed a decreased amount of fully assembled CI, CII, CIII and CIV, and the presence of subassembly products of CV.

Sequencing analysis of the coding exons of the *COX15* genes revealed that the patient is compound heterozygous p.Ser151X/p.Pro302Leu. Although the number of reported *COX15* mutant patients is limited to four, the p.Ser151X mutation was previously seen in two unrelated families with a predominant clinical presentation of cardiomyopathy. This mutation might represent a hot spot location in the *COX15* gene.

P13.24

Recurrent LMNA mutation in patients with familial partial lipodystrophy Dunnigan-type

D. Mitter[1], *C. Gläser*[2], *K. Miehle*[3], *J. Porrmann*[2], *F. Stock*[1], *M. Fasshauer*[3], *K. Hoffmann*[2];
[1]*Institut für Humangenetik, Universitätsklinikum, Leipzig, Germany,* [2]*Institut für Humangenetik, Universitätsklinikum, Halle, Germany,* [3]*Department Innere Medizin, Universitätsklinikum, Leipzig, Germany.*

Familial partial lipodystrophy (FPLD) Dunnigan type is an autosomal dominant disorder with abnormal distribution of adipose tissue. After puberty, patients show excess fat on their face, neck, back, and absence of subcutaneous fat of the extremities, trunk and gluteal region resulting in a muscular appearance. Metabolic abnormalities include insulin-resistant diabetes mellitus, abnormal serum lipoproteins, and hypertension. FPLD is a heterogeneous disorder with mutations in LMNA and other genes including PPARG, AGPAT2, and PLIN1. We compared clinical and molecular findings in 15 patients presenting with FPLD. Sequencing of LMNA identified a heterozygous missense mutation in exon 8 (p.R482Q) in 5 female patients from 3 families. All 5 carriers of p.R482Q show a characteristic muscular habitus with abnormal fat distribution. Of note, 3 of 5 patients complained about muscle pain, which seems to be an additional characteristic feature. 3/5 patients had mild elevated HbA1c (mean 6.2 %). One patient only required insulin therapy since the age of 47 years. Patients showed dyslipoproteinaemia with hypertriglyceridemia (3/5), elevated cholesterol (4/5), low HDL (3/5), and elevated LDL (3/5). Additional features included hypertension (4/5), hepatic steatosis (2/5). None of the p.R482Q carriers but 8/10 of the other patients without LMNA mutations had pancreatitis. The overlap of metabolic features in FPLD and metabolic syndrome and the overrepresentation of female patients raise the possibility of significant under diagnosis of FPLD among patients with the reported metabolic changes. Especially men with a muscular habitus and less prominent metabolic changes may be suspected to have metabolic syndrome instead of FPLD.

P13.25

Is histidinemia always a “non-disease”? and why truncating mutations in the HAL gene appear so rare?

A. Piton[1], *C. Redin*[1], *F. Feillet*[2], *L. Faivre*[3], *M. Alice*[3], *O. Chris*[4], *J. Mandel*[1];
[1]*IGBMC, Strasbourg, France,* [2]*Centre de Référence des Maladies Héréditaires du Métabolisme, Service de Médecine Infantile I, CHU Brabois Enfant, Vandoeuvre les Nancy, France,* [3]*Centre de Génétique, Centre de Référence Maladies Rares, Dijon, France,* [4]*Unité de Biochimie métabolique, Hôpital Necker-Enfants Malades, Paris, France.*

Histidinemia is an autosomal recessive defect with an incidence of 1/12000-20000, due to a deficient activity of histidine-ammonia-lyase (HAL gene). Initial studies in the 1970s suggested that it might be associated to intellectual deficiency, epilepsy, autism or ataxia. Later assessment of cases identified through neonatal screening, who did not suffer from developmental delay or ID, led to consider histidinemia as a non-disease. A recent study has suggested however that it may be a risk factor for autism (Miyachi et al. 2009). Because of this lack of established clinical impact, interest in this trait has subsided and a single mutation study in the HAL gene revealed only 4 different missense mutations in a minority of tested cases ascertained through neonatal screening. Following the identification of histidinemia in a girl with developmental delay and ataxia, we initiated a mutation study. Preliminary results on 3 patients with ID revealed 5 different missense mutations, and one splice site mutation. In another case with no reported neurological phenotype, another homozygous missense variant was found, not predicted pathogenic by SIFT or Polyphen2. Up to now, truncating mutations appear underrepresented (one detected compared to 10 different missenses). The spontaneous histidinemic mouse mutant (with no obvious neurologic phenotype) is also due to a missense mutation. One may wonder whether phenotype in histidinemia depends on the level of residual activity, and whether total loss of function may be lethal or very severe. We are looking for collaborations to extend this study to other cases with or without neurological involvement.

P13.26

GI microbiota and epigenetic markers in metabolic syndrome and caloric restriction

A. G. Haslberger, *M. Remely, E. Aumueller, Y. Cen, B. Hippe;*
Univ. of Vienna, Vienna, Austria.

Microbial diversity, abundance and metabolic activities contribute to a highly individual GI tract microbiota. The metabolic syndrome is one condition, where host genetic factors, microbiota composition and microbiota-directed regulation of gene expressions combined contribute to pathogenesis. Intestinal symbiosis is maintained via the signaling activities of short chain fatty acids (SCFAs), bacterial LPS mediated immune reactions, but also via epigenetic mechanisms, e.g. causing a hyporesponsiveness of toll-like receptors (TLRs) towards the symbiotic and commensal constituents of the microbiota.

We analyzed changes in microbiota and epigenetic regulation of inflammatory mediators in type 2 diabetic (n = 25) volunteers under caloric restriction in comparison to lean (n = 18) and obese (n = 8) healthy controls. The abundance of bacteria and bacterial subgroups we measured in fecal samples with quantitative PCR (qPCR) of 16S rRNA coding regions.

Lactobacilli and Clostridium cluster XIVa differed significantly in type 2 diabetics compared to lean controls before intervention and after weight loss. Obese individuals had a higher Firmicutse to Bacteroidetes ratio than lean controls. In type 2 diabetics with weight loss the ratio of Firmicutes to Bacteroidetes increased throughout the study period.

In addition to changes in the microbiota composition, we also report that epigenetic mechanisms regulate gene promoters with relevance to inflammation, antioxidation and DNA-repair in type 2 diabetes and that diet and caloric restriction have epigenetic regulatory effects.

P13.27

High endocannabinoid levels are genetically determined and are associated with obese phenotype

A. Prossomariti[1], *F. Fanelli*[2], *E. Marasco*[1], *C. Fazio*[1], *I. Belluomo*[2], *V. Di Lallo*[2], *M. Mezzullo*[2], *A. Aquilano*[1], *P. Garagnani*[3], *U. Pagotto*[2], ***V. Mantovani***[1];
[1]*Center for Applied Biomedical Research (CRBA), S.Orsola-Malpighi Hospital, Bologna, Italy,* [2]*Unit of Endocrinology, S.Orsola-Malpighi Hospital, Bologna, Italy,* [3]*Department of Experimental Pathology, Bologna University, Bologna, Italy.*

The endocannabinoid system (ECS) is involved in energy homeostasis and food intake. It was suggested that ECS hyperactivation may contribute to obesity development, however conflicting data are reported.

Aim of this study was to investigate the association of variants in the ECS receptor (CNR1) and degrading enzyme (fatty acid amide hydrolase, FAAH) genes with the obese phenotype and the plasma level of ECS mediators. 736 randomly selected subjects were submitted to SNPs genotyping and measurement of EC plasma levels. Seven SNPs in CNR1 region (rs12720071, rs806368, rs806370, rs1049353, rs806381, rs6454674, rs10485170) and the coding variant c.385C>A in FAAH gene (rs324420) were genotyped by MassARRAY platform. Circulating ECs, AEA, 2-AG, PEA and OEA were measured by an LC-MS/MS method validated according to FDA's guidance. Genotypes were compared to EC levels and to body mass index (BMI; kg/m^2), waist circumference and waist-to-hip ratio.

EC circulating levels were significantly higher in overweight and obese (BMI>25,0) compared to normal weight subjects (AEA, PEA, OEA p=0,00001; 2AG p=0,008). FAAH 385A allele carriers showed significantly increased EC levels, particularly OEA ($p=8x10^{-11}$) and PEA ($p=5x10^{-7}$), but they showed no significant association to obesity indexes. Coexistence of FAAH-predisposing genotype and increased EC levels also did not correlate with obesity. None of CNR1 SNPs showed association with obesity indexes, nor with EC increased levels. In conclusion, our data show that the FAAH 385A allele has a direct effect on EC elevated plasma levels, and that the detected hyperactivation of ECS may be a novel biomarker of obesity.

P13.28

Efficiency of metformin treatment for obesity and metabolic syndrome in children and adolescents depends on TCF7L2 genotype

O. S. Glotov[1,2,3], *I. A. Makchrova*[4,3], *M. A. Glebova*[1,2], *I. V. Pugacheva*[1,3], *T. E. Ivashchenko*[1], *N. P. Shabalov*[5], *V. S. Baranov*[1,2];
[1]*Ott's Institute of Obstetrics and Gynecology RAMS, Saint-Petersburg, Russian Federation,* [2]*Saint-Petersburg State University, Saint-Petersburg, Russian Federation,* [3]*BioGlot Company Limited, Saint-Petersburg, Russian Federation,* [4]*Mechnikov North-Western State Medical University, Saint-Petersburg, Russian Federation,* [5]*S.M. Kirov Military Medical Academy, Saint-Petersburg, Russian Federation.*

Despite a large body of research, currently there is no common strategy for drug therapy of obesity and metabolic syndrome (MS) in children and adolescents. At present, Metformin is the drug of choice for treating children with MS over 8 years old. However, a number of patients remain refractory to Metformin. We investigated the contribution of TCF7L2 IVS3 C>T polymorphism to response to Metformin in children with MS. 38 of 200 children with obesity in the age of 10 - 17 enrolled in this study were treated with Metformin. Patients were diagnosed with MS in accordance with guidelines developed by International Diabetes Federation in 2007.Among 38 of 200 children treated with Metformin, one (2.6%) was diagnosed with MS, and in another 37 abdominal-type obesity with concurrent abnormalities was manifested. Abnormalities included impaired glucose tolerance (in 35.1% of children), hyperinsulinemia (in 32.4%), atherogenic dyslipidemia (in 45.9%), hypertension (in 10.8%). 20 children taking Metformin were genotyped as C/C, 13 as C/T, and 5 as T/T. Postprandial glucose level in children with C/T and T/T genotypes was higher than in children with C/C genotype. During the treatment, the most pronounced improvements were observed for children with C/T genotype, namely, reduction in body weight ($p<0.001$), body mass index ($p<0.001$), waist circumference ($p<0.001$), fasting plasma ($p=0.017$) and postprandial ($p=0.003$) glucose levels, uric acid level ($p=0.05$), atherogenic index ($p=0.029$). Our data suggest that Metformin treatment efficiently promotes body weight reduction and normalization of carbohydrate metabolism in children, suffering from obesity and MS, with TCF7L2 C/T genotype.

New probable pathogenic mutations in 22 tRNA mitochondrial genes in Iranian cytopathy patients

A. Arastehkani[1,2], *F. Keshavarzi*[3], *V. Ghodsinejadkalahroudi*[1], *M. Dehghan Manshadi*[1,2], *O. Aryani*[2], *M. Ashrafi*[4], *M. Houshmand*[2,5]*;*

[1]*Department of Biology, Science and Research branch, Islamic Azad University, Kurdestan, Islamic Republic of Iran,* [2]*Special Medical Center, Dep. of Medical Genetics, Tehran, Islamic Republic of Iran,* [3]*Department of Biology, Sanandaj branch, Islamic Azad University, Kurdestan, Islamic Republic of Iran,* [4]*Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran,* [5]*National Institute of Genetic Engineering & Biotechnology, Dep. of Medical Genetics, Tehran, Islamic Republic of Iran.*

Mitochondrial tRNA (*MTT*) gene mutations are an important cause of human morbidity and are associated with a wide range of pathology, from isolated organ-specific diseases such as myopathy, hearing loss, MELAS, MERRF, CPEO, Leigh syndrome through to multisystem disorders with encephalopathy. The aim of this study was to detect any type of mutations, polymorphisms and possible pathogenic variations in blood samples of Iranian cytopathy patients. We describe the result of extensive sequence analysis for tRNA genes in 18 patients selected according to several criteria. The result included: reported mutation as T5543C in tRNA^{Trp}, A8344G in tRNA^{Lys} , G12236A in tRNA^{Ts} and Several

known polymorphism such as A12308G were observed. These findings are besides to novel transitions, m.15930G>A in tRNA^{Thr} , m.5790C>A in tRNA^{Cys} and m.10467 in tRNA^{Arg}, in different patients who were negative for reported mtDNA mutations. These nucleotide were moderated and they were absent in 100 control suggesting its pathogenicity . So further investigation includes familial study, functional assay and nuclear genes analyses are needed.

P13.30

Large-scale deletions on 22q13.33 and 12q24.33 detected in patients with mitochondrial disorders

M. Tesarova[1], *A. Vondrackova*[1], *K. Vesela*[1], *K. Vinsova*[1], *T. Honzik*[1], *V. Stranecky*[2], *H. Hansikova*[1], *J. Zeman*[1]*;*

[1]*Department of Pediatrics and Adolescent Medicine, First Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Prague 2, Czech Republic,* [2]*Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Prague 2, Czech Republic.*

Mitochondrial disorders (MD) represent a group of clinically and genetically heterogeneous diseases whose molecular-genetic diagnosis is challenging. The standard diagnostic approach is direct DNA sequencing of candidate genes. Nevertheless, this technique does not enable to detect large heterozygous deletions. SNP arrays with high marker density may be utilized. The **aim** of this study is to analyze large-scale deletions in group of 15 patients with MD of unknown etiology. Genome-Wide Human SNP 6.0 array (Affymetrix) was used for genotyping of DNA isolated from leucocytes of patients. In 20% of patients, large deletions as a cause of MD were found. In 2 of them, 175-kb, 87-kb resp. heterozygous deletions on 22q13.33 affecting *SCO2* and *TYMP* genes were detected. Missense point mutations in *TYMP*, *SCO2* genes resp. were identified on the other allele. Patient 1 with MNGIE phenotype inherited c.261G>T in *TYMP* from father and 175-kb deletion from mother. A novel *SCO2* mutation c.667G>A was found on maternal allele of patient 2 in combination with 87-kb deletion inherited from father. Interestingly, 175-kb deletion on 22q13.33 partially overlaps with two described copy-number variations (CNV; variation_5192 and variation_4139). In patient 3, homozygous 5-kb deletion on 12q24.33 affecting exon 4 of *PUS1* gene was revealed. **Conclusions:** Genome-Wide Human SNP 6.0 Array allowing detection of deletions larger than 700 bp was successfully used to determine genetic diagnosis in 3 out of 15 patients. *Supported by research project PRVOUK of the Charles University in Prague-First Faculty of Medicine (program MOL-MED) and grant IGA NT 11186-5/2010.*

Molecular modifications and bioenergetics in relation to phenotype of MILS-NARP syndrome

D. Lin[1], *H. L. Liu*[2], *N. C. Chiu*[1], *C. S. Ho*[1]*;*

[1]*Dept. of Pediatric Genetics, Mackay Memorial Hospital, Taipei, Taiwan,* [2]*Chemical engerineering and Biotechnology, National Taipei University of Technology, Taipei, Taiwan.*

Objectives: Mitochondrial DNA mutations at m.8993T>G of the mtDNA ATPase 6 gene typically cause the Maternal Inherited Leigh Syndrome (MILS) and neurogenic muscle weakness, ataxia, retinitis pigmentosa (NARP). To elucidate the molecular-clinical correlations in MILS-NARP syndrome, the phenotype, biochemical parameters, mtDNA mutant loads, and bioenergentics were investigated in three generations of a pedigree harboring m.T8993G mutation.

Methods: Detailed neurological and ophthalmological phenotypes, biochemical and metabolic status, mutant load, cellular bioenergentic and molecular modification were investigated in members of three generations of pedigree with MILS-NARP syndrome.

Results: The ATP6 mutation was ubiquitously distributed in various tissues of the affected individuals. A remarkable high mutation load was demonstrated in individuals with MILS and Retinitis Pigmentosa (RP), respectively. While a mutant load ranging from 5% to 97% was noted in those individuals with mild or absent clinical symptoms. Interestingly, the individual affected with MILS showed remarkable elevation in the levels of lactate, pyruvate, and alanine, and deficiency of carnitine, impaired cellular bioenergetics, and molecular compensation with glycolysis. While the fibroblasts from RP showed molecular modification through the nuclear respiratory chain complex pathway.

Conclusion: The correlation between the mutant load in tissues and the severity of phenotype in MILS-NARP is very complex, and the genetic background may play an important role in modulating the bioenergetics, biochemical defects and clinical outcome. Our results emphasizes the complexity of mechanism contributing in the phenotypic expression of the m.8993T>G mutation and the need for caution in predictive counseling in such patients.

A constant and similar assembly defect of mitochondrial respiratory chain complex I allows rapid identification of NDUFS4 mutations in patients with Leigh syndrome

Isolated complex I deficiency is a frequent cause of respiratory chain defects in childhood. In this study, we report our systematic approach with Blue native PAGE (BN-PAGE) to study mitochondrial respiratory chain assembly in skin fibroblasts from patients with Leigh syndrome and CI deficiency. We describe five new NDUFS4 patients with a similar and constant abnormal BN-PAGE profile and present a meta-analysis of the literature. All NDUFS4 mutations that have been tested with BN-PAGE result in a constant and similar abnormal assembly profile with a complete loss of the fully assembled complex I usually due to a truncated protein and the loss of its canonical cAMP dependent protein kinase phosphorylation consensus site. We also report the association of abnormal brain MRI images with this characteristic BN-PAGE profile as the hallmarks of NDUFS4 mutations and the first founder NDUFS4 mutations in the North-African population.

P13.33

Mutations in the *GCK* gene are the most common cause of MODY-Diabetes in a cohort of over 600 patients in Germany

P. J. Laitinen-Forsblom, *S. Bingemann, C. Bayerl, D. Strohmayer, C. Nevinny-Stickel-Hinzpeter;*

synlab MVZ Humane Genetik München, Munich, Germany.

Maturity Onset Diabetes of the Young (MODY) is an autosomal dominant form of diabetes mellitus. The clinical phenotype is mild in comparison to type 1 Diabetes but diabetic complications can occur. In patients with MODY the insulin production or blood glucose level sensing is impaired. According to the literature, mutations in *HNF1A* are the most common causes of MODY. Here we describe the results of a diagnostic mutation screening in MODY genes conducted in the years 2008-2011 in a cohort of over 600 patients.

Material and methods: 619 probands mostly of Caucasian origin with clinical suspicion of MODY were referred to our laboratory for molecular genetic analysis. The analysis was performed stepwise, beginning with the genes known to be more commonly involved in the pathophysiology of MODY. Based on the proband's clinical picture some clinicians delineated the diagnostics to specific MODY subtypes.

The causative genes for MODY subtypes HNF4A, GCK, HNF1A, IPF1 and HNF1B were directly sequenced. MLPA-analysis was performed to detect large deletions and duplications.

Results and discussion: In the 619 patients, altogether 163 mutations were identified (Table). These data show that in our patient cohort mutations in the *GCK* gene are the most common cause of MODY. These results differ from published data and are likely to be more widely applicable to the German population.

Gene	Patients analysed (N)	Mutations detected (N)	% of all mutation-positive samples
HNF4A	238	10	6%
GCK	494	88	54%
HNF1A	489	52	31%
IPF1	76	1	0,5%
HNF1B	208	12	7%

P13.34

Clinical features in 17 patients with Mucopolysaccharidosis

*B. G. Nur[1], A. Toylu[2], **O. A. Clark**[2], E. Mihci[1,2];*
[1]Akdeniz University School of Medicine, Department of Pediatric Genetics, Antalya, Turkey, [2]Akdeniz University School of Medicine, Department of Medical Genetics, Antalya, Turkey.

The mucopolysaccharidosis (MPS) are a large group of inherited lysosomal storage disorders. Each mucopolysaccharidosis subtype is caused by a deficiency in the activity of a single specific lysosomal enzyme which required for glycosaminoglycan degradation. The deficiency of these enzyme results in the storage of the glycosaminoglycans in several tissues.

The clinical presentation and the natural course of the patients with MPS may be different among subtypes which are influenced by the presence of the genetic background including functional polymorphisms and environmental problems. The general features are course facies, corneal clouding, developmental delay, mental retardation, skeletal and joint abnormalities, and cardiac abnormalities.

We report frequency of the clinical symptoms of the MPS patients of our pediatric genetic clinic. Between January 1995 and December 2011, aged 2-18 years, seventeen children (11 boys, 6 girls) were examined. The MPS III, MPS IV, and MPS I were the most frequent subtypes amongst the MPS patients, respectively. The patients were most frequently representing coarse facies, skeletal abnormalities, mental retardation and hepatomegaly.

Although MPS is a rare disorder, it is important to consider the MPS in the differential diagnosis of patients presenting coarse facies, skeletal abnormalities, neurodevelopmental disabilities and hepatomegaly. We could not forget the importance of the screening for oligosaccharides in children with neurodevelopmental delay with mild phenotypic symptoms. Early diagnosis and effective medical management in some types can improve patient outcomes and may reduce the disease burden on patients and caregivers. Furthermore, it allows genetic counseling.

P13.35

Cystic fibrosis mutation detection- difficulties and traps

__L. Pop__[1], I. Ciuca[1], Z. Popa[1], L. Tamas[2], I. Popa[1], A. Anghel[2];
[1]Pediatric II Department, Timisoara, Romania, [2]Biochemistry Department, Timisoara, Romania.

Background: A characteristic aspect for Romania is the CF mutations heterogeneity which leads to a reduced percentage of genotype identification. **Objective:** Assessment of a mixed panel efficacy for CF mutation detection in Romanian patients. **Methods**: We evaluated retrospectively 40 patients (pts) with typical CF, registered in the National CF Center Timisoara. The genetic tests were performed using a mixed panel - (29 mutations) - ARM and another kit for 38 mutations-PCR. 18 mutations were common to the two kits; the total number of identifiable alleles was 49. **Results:** The first panel identified in order of frequency: ΔF508, G542X, N1303K, 621 + 1 G>T, I148T, representing 17.2% from panel 1 mutation. We found the following patients genotypes: 21 pts homozygous for F508del, 10 pts with F508del/ x , 5 pts F508del/G542X , 1 patient F508del/ N1303K . In 3 patients with compound genotype non-F508del , the other alella could not be identified, complementary genetic testing done in parents have ruled out the possibility of homozygous non-F508del genotype. In 13 patients (32.5%) we could not fully identify the genotype, thus they were further tested with panel 2. **Conclusions:** Superposition of kits with identified mutations in CF Romanian patients is low, although kits contain the most frequent mutations used in Europe. Genetic heterogeneity in Romania limits significantly the possibility of detection of both alleles, the diagnosis rate of heterozygote being reduced. The question of using additional kits or methods like CF gene sequencing raises the issue of a high cost.

P13.36

Niemann-Pick type C disease: mutation analysis and genetic counselling in Czech and Slovak families

__L. Dvorakova__, H. Vlaskova, M. Hnizdova-Bouckova, H. Treslova, L. Stolnaya, V. Dostalova, H. Jahnova, K. Peskova, M. Elleder, M. Hrebicek;
Instit. of Inherited Metabolic Disorders, General University Hospital in Prague and First Faculty of Medicine, Charles University in Prague, Praha 2, Czech Republic.

Niemann-Pick type C disease (NPC, OMIM #257220, #607625) is a severe autosomal recessive neuro-visceral disorder characterized by progressive neurological deterioration and hepatosplenomegaly. The most prominent biochemical feature is complex lipid storage of free cholesterol and glycolipids. Molecular defects in two late endosomal/lysosomal proteins (NPC1 or NPC2) cause symptoms of NPC.

Fifty four Czech and Slovak NPC patiens were diagnosed by histochemical and biochemical methods. Prevalence based on these data is 1:109,000, significantly higher than the reported pan-ethnic prevalence of 1:150,000. Probands from 37 families were available for molecular genetic analysis. Mutations in NPC2 gene were proved only in one family. Thirty nine patients from 36 families belonging to NPC1 complementation group had highly variable clinical manifestations - from infantile neurological form to adult solely visceral form. By Sanger sequencing we have identified 32 different mutations on 69 NPC1 alleles, 14 of them being novel. MLPA method did not reveal any deletion in NPC1 gene of three patients, in which only one mutation was identified by sequencing. The most common mutations were p.R1186H, p.S954L and p.P1007A (16, 10 and 7 alleles, respectively).

In one family an unrelated partner of a carrier was tested during the preconception genetic counselling for mutations in four exons (18, 19, 20, 23) which encompassed 60% of all identified mutations. Unexpectedly, recurrent mutation p. P1007A (exon 20) was identified. This case shows that molecular genetic analysis of unrelated partners may be important also in very rare disorders.

Clinical, Biochemical and Molecular Diagnosis of Niemann-Pick Disease type C, in three Iranian Patients, and two Novel Mutation in the NPC1 gene

__Y. Shafeghati__[1,2], A. Hamidieh[3], F. Hadipour[2];
[1]Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran, [2]Medical Genetics Department, Sarem Women Hospital, Tehran, Islamic Republic of Iran, [3]BMT and SCT Unit, Pediatric Hematology and Oncology Department, TMSU,, Tehran, Islamic Republic of Iran.

Niemann-Pick type C is a rare autosomal recessive neurometabolic disorder, characterized by progressive neurodegeneration. It is a pan-ethnic disease with estimated prevalence of around 1 in 120 000 to 150 000 worldwide. Age of onset may vary from the perinatal period to adulthood. Two different genes, *NPC1 or NPC2,* have been identified to cause disease, 95% is due to the *NPC1* gene (18q11), its product is a large membrane glycoprotein that consists of 1278-amino-acids, and 5% have mutations in the *NPC2 gene (14q24.3)* which encodes a small protein that consists of 132-amino-acid a binds to cholesterol with high affinity. Clinical characteristic is hily variable. In the classic form, patients appear to be normal in the first 1 to 2 years, they gradually develop neurologic abnormalities (ataxia, grand mal seizures, and myoclonic jerks), dystonia, vertical supranuclear gaze palsy, dementia, and psychiatric manifestations, hepatosplenomegaly is less striking than NP-A/B.

Diagnosis based on clinical suspicions and foamy histiocytes in BM aspirates, white matter involvement on MRI scanning, formal esterification studies. Diagnosis would be confirmed by performing filipin staining on skin fibroblast cell cultures and mutation analysis in NPC1 and NPC2 genes.

Here we report 3 Iranian affected cases that were confirmed by filipin staining and mutation analysis. We detected mutations in NPC1 gene in all of them, in two patients the mutations were novel and have not been reported before. Two of the patients are under treatment with Miglustat and now their general conditions are stable especially with amelioration of visceromegaly.

Evaluation of the innate immunity in mucopolysaccharidosis: analysis of the functional activity of phagocytes

*L. C. Torres[1,2], C. R. D. C. Quaio[3], J. F. S. Franco[3], I. Gomy[3], D. R. Bertola[3], L. D. Kulikowski[3,4], M. Carneiro-Sampaio[5], **C. A. Kim**[3];*
[1]Translational Research Laboratory Prof. C. A. Hart, Instituto de Medicina Integral Prof. Fernando Figueira (IMIP), Recife, Brazil, [2]LIM36 - Instituto da Criança da FMUSP, São Paulo, Brazil, [3]Genetics Unit, Instituto da Criança da FMUSP, São Paulo, Brazil, [4]LIM3 - Hospital das Clínicas da FMUSP, São Paulo, Brazil, [5]Instituto da Criança da FMUSP, São Paulo, Brazil.

Mucopolysaccharidoses (MPS) are a group of inherited metabolic disorders characterized by the deficient activity of catabolic enzymes in the lysosomes and its consequent abnormal accumulation of deposits of glycosaminoglycans (GAGs). The lysosomal dysfuction caused by this irregular storage is responsible for the clinical manifestations seen in MPS.
Once the lysosome is also important for normal functioning of the immune system, playing a key role in the expression of cellular membrane receptors, the presentation of antigens, the secretion of cytokines and phagocytosis, we presume that these processes may be impaired in patients with MPS. The presence of recurrent respiratory infections in these individuals may be a clinical clue of the immune dysregulation in MPS.
We studied the leukocyte oxidative burst activity and chemotactic function of neutrophilic granulocytes and phagocytic activity and expression of mieloperoxidase in phagocytes by flow cytometric immunoassay of 15 patients with MPS types I, II, IV and VI.
All patients demonstrated normal phagocytic activity and normal chemotactic function of neutrophilic granulocytes. Normal levels of reactive oxygen metabolites after the stimulation with PMA and opsonized *Escherichia coli* and normal expression of myeloperoxidase by granulocyte and monocytes. In our *in vitro* tests using widely available commercial kits, we were not able to find either quantitative deficiency or functional defects of granulocytes and monocytes. This is the first study in the literature of evaluation of the innate immunity in patients with MPS.

P13.39

The mutant phenylalaninhydroxylase gene is more often found out in alcoholics

***S. Khalchitsky**[1], A. Shaposhnikov[1], I. Nikiforova[1], I. Bulycheva[2];*
[1]Laboratory of Medical Genetics CPHS LD, Saint-Petersburg, Russian Federation.
[2]Interdistrict narcological clinic, Saint-Petersburg, Russian Federation.

It has been investigated 156 patients with alcoholism of both sexes at the age of 25-60 years on presence of mutation in the PAH gene. By PCR method the R408W mutation is established in 11 out of 156 alcoholic patients (7,05%) and 10 out of 417 volunteers of the same age (2,39%). Metabolism of Phe appeared to be impaired in chronic alcoholism as shown by an increase in concentration of Phe in blood serum as well as by elevation urinary excretion of Phe and phenylpyruvic acid. The most distinct impairment in Phe metabolism was observed in alcohol withdrawal syndrome (delirium tremens). This study aimed to investigate whether the mayor (about 60%) R408W mutation in phenylalaninehydroxylase (PAH) gene influences chronic alcoholism and delirium tremens cases. The data obtained indicate that decreased by R408W mutation activity of PAH and development of alcoholism and especially delirium tremens are impaired. So, genetic rearrangements in PAH are the contributing factor to development of alcoholism.

P13.41

Genome-wide association study identified MEP1A in relation to insulin metabolism in Polycystic Ovary Syndrome

***U. Lam**[1], E. Lerchbaum[1], N. Schweighofer[1], O. Trummer[1], B. Genser[2], E. Katharina[3], A. Groselj-Strele[3], T. Pieber[1], B. Obermayer-Pietsch[1];*
[1]Division of Endocrinology and Metabolism, Department of Internal Medicine, Medical University of Graz, Graz, Austria, [2]BG Statistical Consulting, Graz, Austria, [3]Center for Medical Research, Medical University of Graz, Graz, Austria.

There is a clear association between polycystic ovary syndrome (PCOS) and cardiovascular events, which might be based on disorders of glucose metabolism. Accumulating evidence suggests that insulin resistance and hyperinsulinemia affect 65-70% of PCOS patients. Vitamin D has been shown to influence both insulin resistance and other symptoms of PCOS. In a genome-wide association study (GWAS) of cardiovascular patients, we found MEP1A as a potential candidate gene in PCOS.MEP1A variants were replicated in 586 PCOS women and 105 controls. Metabolic, hormonal, functional and anthropometric parameters were determined. In cell culture experiments, human hepatocellular carcinoma (HepG2) cells were treated with insulin, vitamin D and parathyroid hormone (PTH) for the expression of MEP1A. In the replication cohort, MEP1A variants were not associated with the incidence of PCOS per se. However, the SNPs showed a significant association with insulin metabolism in overweight/obese PCOS. MEP1A GG-carriers showed a significantly increased HOMA index ($p = 0.005$), elevated fasting insulin ($p = 0.006$), and stimulated insulin after 30min ($p = 0.003$), 1h ($p = 0.003$) and 2h ($p = 0.009$). HepG2 cell experiments showed a relation of MEP1A to the expression of bone genes and vitamin D. MEP1A is a possible target for disease modifying in PCOS and potential new therapeutic options. It might contribute to the involvement of vitamin D deficiency in abnormalities of glucose metabolism and insulin sensitivity. Whether MEP1A is a potential risk factor for PCOS and how it is associated with gene function will be further investigated.

P13.42

Homozygous 669-698del in exon 12 of HMBS gene in a Spanish patient with acute intermittent porphyria

***A. Zuñiga**, C. Merino, L. Pedrola, Y. Bello;*
Hospital de la Ribera, Alzira (Valencia), Spain.

Acute intermittent porphyria (AIP, MIM # 176000) is an autosomal dominant disease caused by a partial deficiency of hydroxymethylbilane synthase (HMBS; EC 4.3.1.8). It is characterized by acute attacks of neurovisceral dysfunction, often precipitated by several factors. Early detection of AIP carriers is very important for the prevention of acute attacks. The diagnosis of AIP is based on clinical symptoms and increased urinary porphyrin precursors, δ-aminolevulinic acid (ALA) and porphobilinogen (PBG), in combination with the HMBS activity assay.
We report a case of a female patient of 35 years old who came from a southeastern region of Spain, with abdominal pain, neurospsyquiatric symptoms, hyponatraemia and tachycardia. Neurological checkup showed axonal polyneuropathy with proximal afectation in all the four limbs. In the past, she had two episodes of muscular weakness of limbs. Abdominal examination did not reveal any abnormality. There was no sensory impairment. Laboratory investigations showed the TLC of 6,300/cmm with a DLC of P-52%, L-33%, M-13% and E-2%; hemoglobin was 7,9 g/dL. Urine was strongly positive for ALA (172 mg/24h) and PBG (3,3 mg/24h).
Genomic DNA was isolated from PBL, and all 15 exons and flanking regions of the HMBS gene were amplified by PCR and sequenced in an ABIPRISM 3100 Genetic Analyzer. Patient was carrier of a homozygous 30 pb deletion in exon 12 of HMBS gene. This mutation, 669-668del, causes a mutant protein that lacks of 10 amino acids (p.Glu223-Leu232) and has been described previously in Spanish AIP of southern ancestral origin with a possible founder effect.

P13.43

Novel variants in the *CYP51* gene found in Caucasian mothers and neonates with potential to contribute to spontaneous preterm birth

***M. Lewinska**[1], D. Rozman[1], J. C. Murray[2];*
[1]Center for Functional Genomics and Bio-Chips, Institute of Biochemistry, Faculty of Medicine, Univer, Ljubljana, Slovenia, [2]Department of Pediatrics, University of Iowa, Iowa City, Iowa, United States of America, Iowa City, IA, United States.

Cholesterol is an essential component of cellular membranes, a precursor of steroid hormones, oxysterols, and bile acids. It is involved in many signaling pathways including the sonic hedgehog (Shh) pathway. Sterols play crucial role in maintaining pregnancy, and a large amount of cholesterol is required during ontogenesis and embryogenesis. Defects in cholesterol synthesis or intracellular transport result in serious malformations and mutations in some cholesterol synthesis genes are associated with preterm delivery (PTD).
Here we investigated for the first time variants in fetal and maternal lanosterol 14α-demethylase (*CYP51A1)*, a key gene of post-squalene cholesterol synthesis, and we examined their contribution to PTD. Ten amplicons covering exons, untranslated regions (UTR) and intron-exon borders have been investigated in 188 Caucasian women who had a spontaneous preterm delivery and 188 unrelated preterm infants born at a gestational age <37 weeks. The study included neonates from singleton pregnancies, 94 of each gender.
We identified 22 polymorphisms, where 11 represent rare, novel variants. Three novel variants are heterozygous missense mutations in exons 1, 3 and 4. According to PolyPhen2 the mutation in exon 3 causes a probably dama-

ging amino acid substitution in the substrate recognition site, resulting in a T/G change causing a Y145D transversion. This amplicon was sequenced further in 1000 premature infants. The low frequency of the novel *CYP51* polymorphism suggests that this polymorphism has little contribution to PTD. TaqMan genotyping of common variants in larger population is in progress, together with further sequencing of the 5' and 3'-UTRs.

P13.44

Yeast, a simple and effective tool to study COQ gene mutations causing primary CoQ10 deficiency

M. Doimo[1], C. Santos-Ocaña[2], P. Navas[3], F. Hildebrandt[4], L. Salviati[1], ***E. Trevisson**[1];*
[1]Clinical Genetics, Department of Pediatrics, Univeristy of Padova, Padova, Italy, [2]Centro Andaluz de Biología del Desarrollo, Universidad Pablo de Olavide-CSIC and CIBERER, ISCIII, Seville, Seville, Spain, [3]Centro Andaluz de Biología del Desarrollo, Universidad Pablo de Olavide-CSIC and CIBERER, ISCIII, Seville, Sevilla, Spain, [4]Department of Human Genetics, University of Michigan, Ann Arbor, Ann Arbor, MI, United States.

Primary coenzyme Q10 (CoQ) deficiency is associated to different phenotypes mainly affecting SNC, skeletal muscle or kidney and it is caused by mutations in genes involved in CoQ biosynthesis. Mutations in COQ6, encoding a monooxygenase required for CoQ biosynthesis, have been reported in patients affected by early-onset steroid-resistant nephrotic syndrome (SRSN) with sensorineural deafness.

We employed a yeast model to evaluate the role of different isoforms of COQ6 and to study the functional consequences of the mutated alleles on protein function. Human COQ6 encodes for at least two isoforms. In yeast there is only one COQ6 isoform and its deletion causes the loss of the ability to grow in non-fermentative carbon source (glycerol).

We proved that human isoform a but not isoform b can complement the deleted yeast. We then modeled the "human" mutations on the corresponding residues of the yeast gene that are conserved throughout evolution.

The yeast model proves to be simple and effective to validate COQ6 mutations. All alleles, except for a nonsense mutation, show some residual activity (as shown both by growth and CoQ6 content analysis); analysis of the CoQ/DemetoxyCoQ ratio in the mutants did not detect an altered ratio (as in the case of COQ2 mutations) suggesting that the mutations affect only COQ6 catalytic activity but not the structure of the entire CoQ biosynthetic complex.

Together these data show that all patients thus far identified still retain some residual endogenous CoQ biosynthesis, supporting the notion that complete lack of CoQ biosynthesis is embryonically lethal.

P13.45

Characterisation of a novel metabolic defect in prolin synthesis and pathomechanism in autosomal recessive cutis laxa syndrome type 2B

***T. Gardeitchik**[1], B. Fischer[2], D. Kouwenberg[1], M. Mohamed[1], U. Kornak[2], L. Nijtmans[1], E. Morava[1];*
[1]UMC Nijmegen, Nijmegen, Netherlands, [2]Max Planck Institute, Berlin, Germany.

Mutations in the Pyrroline-5-carboxylate reductase 1 (PYCR1; EC 1.5.1.2) gene have been recently discovered as the underlying etiology of patients diagnosed with autosomal recessive cutis laxa syndrome (ARCL-2B). Intriguingly this unique metabolic defect in proline synthesis, leading to a recognizable dysmorphology syndrome, appears to be a mitochondrial disorder as well, based on careful evaluation of the phenotype.

PYCR1 is a mitochondrial enzyme, catalyzing the NAD(P)H-dependent conversion of pyrroline-5-carboxylate to proline. This disease is closely linked with P5CS deficiency, caused by mutations in *ALDH18-A1*, a gene coding for an enzyme catalyzing an earlier step in de novo proline synthesis. Both disorders are associated with progeroid features, lax joints, dysmorphic features, microcephaly, intrauterine growth retardation and developmental delay.

While patients diagnosed with P5CS deficiency have variable hyperammonemia and abnormal amino acid levels no obvious metabolic abnormalities have been described so far in *PYCR1* patients. Here we report on the phenotypic and metabolic characteristics of 5 novel patients with cutis laxa syndrome diagnosed with recessive *PYCR1* mutations. Mitochondrial function, respiratory complex activity and oxygen consumption have been evaluated in patient cell lines and in HeLa cells after knockdown of *PYCR1*. Proline synthesis and its metabolic consequences were studied in different body fluids of patients by NMR analysis and in fibroblast cell culture media. Our results suggest that *PYCR1* mutations lead to a metabolic defect altering the intracellular endogenous proline buffer, changing the balance in NAD(H) concentration and mitochondrial membrane gradient, leading to early apoptosis.

P13.46

MECP2-related disorders and molecular investigation: Iranian aspect

***J. Dadgar**[1], A. Arastehkani[1], S. Dadgar[1], O. Aryani[1], M. Houshmand[1,2];*
[1]Genetic Department of Special Medical Center, Tehran, Islamic Republic of Iran, [2]National Institute of Genetic Engineering & Biotechnology, Pazhohesh Blv. 17th Km Tehran-Karaj Highway, Tehran, Iran, Tehran, Islamic Republic of Iran.

MECP2-related disorders include classic Rett syndrome, variant or atypical Rett syndrome, and mild learning disabilities in females and neonatal encephalopathy and mental retardation syndromes in males. Classic Rett syndrome is a progressive neurologic disorder in girls characterized by normal birth and apparently normal psychomotor development during the first six to 18 months of life. The girls then enter a short period of developmental stagnation followed by rapid regression in language and motor skills. Females with classic Rett syndrome typically survive into adulthood, but the incidence of sudden, unexplained death is significantly higher than in controls of similar age. Atypical Rett syndrome is increasingly observed as MECP2 mutations have been identified in individuals previously diagnosed with autism, mild learning disability, clinically suspected but molecularly unconfirmed Angelman syndrome, or mental retardation with spasticity or tremor.

In this study PCR and whole MECP2 gene sequencing was performed in 57 cases clinically suspected to RETT syndrom. The result showed five reported mutations in 7 patients. Two of them had C>T (Arg 168 Term), the other two patients showed C>T (Gln 406 Term) and each of these alterations C>T (Arg 106 Trp), C>T (Arg 270 Term), G>A (Val 288 Met) were found in 1 patients, respectively. Investigation about the new alterations which have been seen in 12 patients without any reported mutations was under reviewed. The rest of our cases showed no alteration related to disease.

P13.47

High frequency of common mutation g.1541G>A in SCO2 gene responsible for cytochrome c oxidase deficiency in Polish population.

***S. Łuczak**, D. Piekutowska-Abramczuk, J. Trubicka, P. Kowalski, E. Ciara, M. Borucka-Mankiewicz, D. Jurkiewicz, A. Tańska, M. Pelc, M. Krajewska-Walasek, E. Pronicka;*
The Children's Memorial Health Institute, Warsaw, Poland.

Mutations in the *SCO2* gene (22q13) lead to severe COX deficiency observed mainly in muscles, heart and brain. SCO2 is one of the ancillary proteins necessary for correct assembling and functioning of cytochrome c oxidase (COX). It is involved in the transport and incorporation of the copper ions to the CuA enzymatic site on COXII subunit. A common substitution, g.1541G>A (p.E140K), is identified at least on one allele in all reported patients.

The aim of this study was to ascertain the frequency of g.1541G>A mutation in Polish population.

We examined 3080 anonymous newborn's samples (dry blood spots - Guthrie cards). Genotyping with Taqman's probe (based on Real Time equipment) was used to identify of the specific mutation. Presence of the mutation in selected samples were confirmed by direct sequencing. The study revealed the presence of the common mutation in 21 carriers coming from 13 provinces (out of 16). The mean frequency was determined as 1:147 life birth with the highest result in lodzkie voivodeship.

The obtained data enabled us to establish the high frequency of the common mutation (g.1541G>A) in Poland and assess its regional variety. We hope for that our study increase awareness of the severe clinical consequences of cytochrome c oxidase deficiency.

The study was supported by the National Science Centre project no. 1154/B/P01/2011/40.

P13.48

Frequency distribution of *NQO1*2* and *SULT1A1*2* alleles in Polish population

***O. Zakerska**[1,2], E. Ciemniejewska[2], M. Skrzypczak-Zielinska[3], A. Mikstacki[4], B. Tamowicz[4], R. Slomski[2,3];*
[1]The NanoBioMedical Centre, Poznan, Poland, [2]Department of Biochemistry and Biotechnology, University of Life Sciences, Poznan, Poland, [3]Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland, [4]Department of Anaesthesiology and Intensive Care Medicine, Poznan, Poland.

The *SULT1A1* gene encodes a phenol sulfotransferase, which belongs to the enzyme superfamily involved in the sulfonation of xenobiotics, hormones and drugs. Quinone oxidoreductase encoded by *NQO1* gene is a detoxification enzyme that catalyses the reduction of a wide range of substrates. Both enzymes participate in the biotransformation pathway of popular anaesthetic drug - propofol, catalyzing the secondary step of its metabolism. Changes in this metabolism step, related to variations in *SULT1A1* and *NQO1* genes may lead to adverse effects after propofol use. Large interindividual variability in these enzymes activity has been shown and several polymorphisms in genes coding these enzymes have been described. Most of this variability is related to the polymorphism P187S in *NQO1* gene and R213H amino acid substitution in *SULT1A1* gene, which are responsible for decreased enzyme activity. The aim of our study was to determine the frequency distribution of these two alleles *SULT1A1*2*, *NQO1*2* in Polish patients under propofol anaesthesia. We analyzed 232 alleles using pyrosequencing as a rapid genotyping method. The frequency of the *SULT1A1*2* allele was 19,3% and *NQO1*2* was 14,2%. Disturbed enzyme activity in biotransformation pathway may lead to increased risk of propofol toxicity. The current analysis is an important initial step in bringing these polymorphisms into an optimal planning of anaesthesia based on the modified pharmacodynamic response of propofol.

P13.49

ATP7B expression measurement improves detection rate of newly diagnosed patients with Wilson Disease

A. Stalke[1,2], *E. Pfister*[2], *V. Wittig*[1], *T. Krech*[3], *M. Bredt*[3], *B. Schlegelberger*[1], *U. Baumann*[2], *N. von Neuhoff*[1];
[1]*Hannover Medical School, Institute of Cell and Molecular Pathology, Hannover, Germany,* [2]*Hannover Medical School, Paediatric Gastroenterology and Hepatology, Hannover, Germany,* [3]*Hannover Medical School, Institute of Pathology, Hannover, Germany.*

Background: Wilson Disease (WD) is an autosomal recessive disorder leading to toxic accumulation of copper mainly in liver tissue. Currently, more than 370 mutations are known in the disease-related *ATP7B* gene (OMIM#606882). However, standard investigations to diagnose WD occasionally fail, e.g. disease-causing *ATP7B*-mutations sometimes remain undetected by direct sequencing.
We therefore aimed to evaluate quantification of *ATP7B* mRNA as a new tool to improve WD diagnostics.
Methods: Total RNA was extracted from snap-frozen and from FFPE liver tissue. After cDNA synthesis, real-time PCR was performed using HybProbes and TATA Box-binding protein (TBP) as reference gene. Expression determination was done by calibrator-normalized relative quantification with efficiency correction. *ATP7B*-expression of 12 snap-frozen liver specimens from WD-patients was compared to that of 22 patients with hepatocellular carcinoma (HCC), 9 patients with biliary atresia, 8 clinically healthy donors and 12 patients with other liver diseases. Furthermore, *ATP7B*-expression in FFPE liver tissue from 8 WD-patients was compared to that of 4 hepatitis B and 5 biliary atresia patients.
Results: *ATP7B* mRNA expression in snap-frozen liver tissue from WD-patients was significantly lower (median 1.7) than in the control groups (median: HCC 5.3; biliary atresia 4.9; healthy 7.4; other 6.5). Comparable results were found in FFPE tissue (median: WD 1.08; hepatitis B 3.50; biliary atresia 2.65).
Conclusion: Our findings suggest that quantification of *ATP7B* mRNA provide a novel tool for the diagnosis of WD in patients where no *ATP7B* mutation is found. Prospective studies in larger patient cohorts are necessary to validate our results for clinical practice.

P14. Therapy for genetic disorders

Background: Agalsidase alfa (agalα) effect and tolerability were assessed in patients with Fabry disease (FD; treatment-naïve or previously agalsidase beta-treated [switch]).
Methods: An ongoing, multicenter, open-label, treatment protocol (HGT-REP-059) evaluated estimated glomerular filtration rate (eGFR), left ventricular mass index (LVMI), biomarkers (globotriaosylceramide [Gb3]; globotriaosylsphingosine [lyso-Gb3]), and tolerability after 1-year intravenous agalα (0.2mg/kg every other week).
Results: 29 naïve (14 male/15 female; median age [range] 38.7yrs [12-74]) and 62 switch patients (33 male/29 female; 47.0yrs [5-84]) were assessed. Baseline median years since FD diagnosis were numerically lower in naïve (1.1 [0.1-27.4]) versus switch patients (7.1 [0.9-49.3]), suggesting lower naïve patient disease burden.
12-month change from baseline
Mean (95%CI)
Naïve Switch
eGFR, mL/min/1.73m2 -1.3 (-10.2, 7.6) -3.2 (-6.6, 0.2)**
LVMI, g/m2.7 2.2 (-1.2, 5.6) 0.0 (-4.7, 4.7)
Plasma Gb3, nmol/mL -6.7 (-9.1, -4.3)** -2.6 (-3.6, -1.6)**
Creatinine-normalized urine Gb3, nmol/mg -2.1 (-4.2, 0.0)* -0.9 (-1.6, -0.1)**
Plasma lyso-Gb3, nM -37.8 (-58.1, -17.4)** -3.0 (-7.3, 1.2)
*p<0.05, **p<0.01
28 (96.6%) naïve and 56 (90.3%) switch patients experienced ≥1 treatment-emergent adverse events (AEs; mostly mild/moderate; possibly/probably drug-related: 12 [41.4%] naïve, 26 [41.9%] switch). 7 (24.1%) naïve and 19 (30.6%) switch patients had serious AEs (1 possibly drug-related: transient ischemic attack). 2 naïve patients discontinued agalα (possibly/probably drug-related); 1 switch patient died (not drug-related).
Conclusion: After 12-months agalα, no statistically significant change in LVMI (naïve/ switch) or eGFR (naïve) occurred. Switch patients showed an eGFR drop of -3.2 mL/min/1.73m2. Plasma and creatinine-normalized urine Gb3 (naïve/switch) and lyso-Gb3 (naïve) dropped significantly. Agalα was generally well tolerated.

P14.04

Generating a Mouse Model for Familial Dysautonomia Disease

R. Bochner, *Y. Ziv*, *R. Ashery-Padan*, *G. Ast*;
Department of Human Molecular Genetics and Biochemistry, Sackler Faculty of Medicine, Tel-Aviv University, Ramat Aviv, Israel.

Familial Dysautonomia (FD) is an autosomal recessive congenital neuropathy that occurs almost exclusively in the Ashkenazi Jewish population. The major mutation leading to FD is a T to C mutation at position 6 of intron 20 of the *IKBKAP* gene; this mutation causes aberrant splicing of the *IKBKAP* gene product in a tissue-specific manner and reduces production of the IKAP protein in the nervous system. The aim of this study was to establish a humanized *IKBKAP* knock-in mouse model that exhibits some of the characteristics of the human FD disease such as alternative splicing of exon 20 of *IKBKAP* gene. We established two homozygous humanized mice strains carrying human exon20 and its two flanking introns: one possesses the FD mutation and the other one lacks it. The IKBKAP$^{\mathrm{FD}\mathit{loxP}/\mathrm{FD}\mathit{loxP}}$ mouse demonstrates a unique tissue-specific alternative splicing pattern of the *IKBKAP* gene.
We also generated two other humanized knock-in mice strains similar to the strain described above except that they contain a *Neomycin* cassette in intron 20. The IKBKAP$^{\mathrm{FD}\mathit{loxPNeo}/+}$ mice were supplemented with phosphatidylserine (PS), a food supplement that was previously shown in our lab to increase mRNA and protein levels of *IKBKAP* in cell lines generated from FD patients. We demonstrated that PS treatment increased *IKBAKP* mRNA levels in various tissues of the IKBKAP$^{\mathrm{FD}\mathit{loxPNeo}/+}$ mice.
Here we show that the IKBAKP$^{\mathrm{FD}\mathit{loxP}/\mathrm{FD}\mathit{loxP}}$ mice have great potential for use as a model to evaluate the effects of PS and other potential therapeutic agents on the mRNA and protein levels of *IKBKAP*. Hence, this mouse model provides a medical breakthrough in the research of FD for preliminary evaluation of drugs that may improve the clinical status of FD patients.

P14.05

Polymorphism in gene encoding drugs and xenobiotic metabolizing enzyme CYP2D6 as a risk factor for drug response in colchicine unresponsive FMF patients

S. Atik[1], *F. Ozen*[2], *S. Gur*[3], *A. Uludag*[1], *C. Silan*[4], *F. Silan*[1], *O. Ozdemir*[1];
[1]*Department of Medical Genetics, Faculty of Medicine, Canakkale Onsekiz Mart University, Canakkale, Turkey,* [2]*Department of Medical Genetics, Faculty of Medicine, Cumhuriyet University, Sivas, Turkey,* [3]*Department of Internal Medicine, Faculty of Medicine, Canakkale Onsekiz Mart University, Canakkale, Turkey,* [4]*Department of Pharmacology, Faculty of Medicine, Canakkale Onsekiz Mart University, Canakkale, Turkey.*

Familial Mediterranean Fever (FMF) is a recessively inherited autoinflammatory disorder characterized by recurrent attacks of fever and serositis. Although colchicine is the standard therapy for preventing attacks and suppressing inflammation, 5%-10% of compliant patients are colchicine-resistant. We report the effect of *CYP2D6* in FMF with colchicine unresponsiveness. The genetic polymorphism results in different *CYP2D6* xenobiotic metabolisms phenotypes namely extensive metabolizers (EM), intermediate metabolizers (IM), and poor metabolizers (PM). Total genomic DNA samples from 60 FMF patients of colchicine unresponsiveness were used for *MEFV* and *CYP2D6* genes profile analyses. Target genes were genotyped by multiplex PCR based reverse hybridization stripAssay method. 12 (20 %) patients were poor metaboliser, 48 (80 %) were intermediate metaboliser for *CYP2D6* gene. Every one patient of five was poor metaboliser and was also colchicine unresponsive. Our results indicate that *CYP2D6* polymorphisms were associated with colchicine resistance in nonresponder FMF patients during the common therapy protocol.

P14.06

The Metabotropic Glutamate Receptor Theory in Fragile X Syndrome: testing the safety and efficacy of AFQ056/Mavoglurant in adults and adolescents

T. Jaecklin[1]*, A. Angelov*[2]*, B. Koumaras*[2]*, C. Collober*[1]*, J. Lee*[2]*, F. N. Hossain*[2]*, J. Lustig*[1]*, S. Satija*[3]*, M. Brinkman*[4]*, G. Apostol*[1]*, A. Graf*[1]*, F. von Raison*[1]*;*
[1]*Neuroscience Development, Novartis Pharma AG, Basel, Switzerland,* [2]*Neuroscience Development, Novartis Pharmaceutical Corporation, East Hanover, NJ, United States,* [3]*Neuroscience Development, Novartis Healthcare Pvt. Ltd., Hyderabad, India,* [4]*Neuroscience Clinical Research, Novartis Pharma GmbH, Nuremberg, Germany.*

Fragile X syndrome is the most common cause of inherited mental retardation and is associated with behavioral problems including hyperactivity, attention deficit disorder and autism. It is caused by the expansion of a CGG repeat in the *FMR1* gene, leading to hypermethylation and transcriptional silencing of *FMR1*, and absent or reduced levels of the translational repressor FMR1 protein (FMRP). The metabotropic glutamate receptor (mGluR) theory hypothesizes that without FMRP, uncontrolled protein synthesis occurs in response to activation of synaptic mGluRs and may lead to the clinical symptoms of FXS.

Randomized controlled data suggest that the mGluR5-antagonist AFQ056/Mavoglurant might improve behavioral symptoms of FXS, especially in patients with fully-methylated FMR-1 promoter regions *(*30 points improvement on Aberrant Behavior Checklist-Community edition (ABC-C) vs. placebo, n=7).

Novartis currently conducts the largest clinical development program in FXS, testing the efficacy and safety of AFQ056/Mavoglurant. It is the first program conducted in Europe (Denmark, France, Germany, Italy, Spain, Switzerland, Sweden, UK) and across multiple languages and cultures. Adults (18-45 years) and adolescents (12-17 years) are randomized in two separate studies to up to 4 months treatment with AFQ056/Mavoglurant or placebo. ABC-C (primary outcome), other behavioral scales and safety parameters are measured. After completing these studies, patients can enroll into open-label, long-term studies with AFQ056/Mavoglurant for ≥24 months.

In summary, the AFQ056/Mavoglurant program is testing the mGluR theory in FXS and attempts to replicate the promising results seen previously. It is actively recruiting patients worldwide. Studies in smaller children and over longer treatment periods are planned.

P14.07

The mGluR5 antagonist AFQ056 does not affect methylation and transcription of the mutant FMR1 gene in vitro

E. Tabolacci[1]*, F. Pirozzi*[1,2]*, B. Gomez-Mancilla*[3]*, F. Gasparini*[3]*, G. Neri*[1,2]*;*
[1]*Institute of Medical Genetics, Rome, Italy,* [2]*Catholic University, Rome, Italy,* [3]*Novartis Institutes for BioMedical Research, Basel, Switzerland.*

Fragile X syndrome (FXS), the leading cause of inherited mental retardation, is due to expansion and methylation of a CGG sequence in the FMR1 gene, which result in its silencing and consequent absence of FMRP protein. This absence causes loss of repression of metabotropic glutamate receptor 5 (mGluR5)-mediated pathways resulting in the behavioral and cognitive impairments associated with FXS. In a randomized, double-blind trial it was recently demonstrated a beneficial effect of AFQ056, a selective inhibitor of metabotrobic glutamate receptor type 5 (mGluR5), on fully methylated FXS patients respect to partially methylated FXS ones. To determine whether AFQ056 may have secondary effects on the methylation and transcription of FMR1, here we treated three FXS lymphoblastoid cell lines and one normal control male line. A quantitative RT-PCR was performed to assess transcriptional reactivation of the FMR1 gene. To assess the methylation status of the FMR1 gene promoter it was carried out a bisulphite sequencing analysis. Both FMR1-mRNA levels and DNA methylation were unmodified with respect to untreated controls. These results demonstrate that the AFQ056 effect on fully methylated FXS patients is not due to a secondary effect on DNA methylation and consequent transcriptional activation of FMR1.
Supported by FRAXA Foundation and Telethon Onlus.

P14.08

A phase II randomized placebo-controlled double-blind pilot clinical trial to test the safety and effectiveness of Ascorbic acid and Alpha-tocopherol on behavioral and learning problems in the Fragile X syndrome

I. Fernandez Carvajal[1]*, L. Perez Costillas*[2]*, C. Quintero*[3]*, R. Calvo Medina*[4]*, R. Heredia Farfan*[5]*, L. Sanchez Salido*[5]*, E. Lima Cabello*[5]*, Y. de Diego Otero*[5]*;*

Hospital Carlos Haya, Málaga, Spain,* [5]*Laboratorio de investigación. Fundación IMABIS. Hospital Carlos Haya, Valladolid, Spain.*

Introduction and Objectives:
Fragile X Syndrome (FXS) is a neurodevelopmental disorder affecting intelligence and behaviour.The treatments available today are unable to normalize these symptoms. We demonstrated that an excess of oxidative stress is present in FXS-mouse brain and a treatment with antioxidants could reverse hallmarks of the FXS-mouse phenotype. We propose a combination of ascorbic acid and alpha-tocopherol to improve learning abilities in young male patients.

Material and Methods:
Phase II randomized placebo-controlled double-blind pilot clinical trial to treat 30 selected FX male patients(15 treated patients and 15 in placebo) in two groups: A:6 to 12 and B:13 to 18 year olds. Mean age (SD) 11.67 (4.20) [treated subgroup: 12.13 (3.44); placebo subgroup: 11.71 (4.86)].
A questionnaire to evaluate clinical data and neuropsychological tests was performed at the beginning of the trial (T0) and at 12 weeks of placebo versus treatment (T1). The principal variable: the Wechsler Intelligence Scale for Children (WISC-R) tested by simple linear regression ($p<0.05$).

Results:
Significant improvements in direct scores in total manipulative and total verbal subscales were observed in young patients compared to the placebo group only when they were not taking psychoactive medication.

Conclusions:
Clinical trials for Fragile X Syndrome are necessary due to the absence of effective therapies and the side effects of available psychopharmacological treatments. We present our positive results about improvement in learning problems measured with the WISC-R scale after 12 weeks of treatment with a combination of two well known vitamins with a potent antioxidant capability, ascorbic acid and alpha-tocopherol.

P14.09

Current efforts towards population screening and therapeutic drug discovery for Friedreich Ataxia

D. Oglesbee[1]*, C. Kroll*[1]*, O. Gakh*[1]*, J. Solberg*[2]*, E. Deutsch*[3]*, D. Lynch*[3]*, K. Raymond*[1]*, D. Gavrilov*[1]*, S. Tortorelli*[1]*, P. Rinaldo*[1]*, D. Matern*[1]*, D. Hook*[2]*, G. Isaya*[1]*;*
[1]*Mayo Clinic, Rochester, MN, United States,* [2]*University of Minnesota, Minneapolis, MN, United States,* [3]*Childrens Hospital of Philadelphia, Philadelphia, PA, United States.*

Background: Friedreich ataxia (FRDA) is a neurodegenerative disease characterized by progressive ataxia and cardiomyopathy with an incidence of 1:50,000. FRDA is typically diagnosed by identifying GAA-repeat expansions, or mutations, in FXN that cause reduced frataxin expression. We describe a Luminex immunoassay to measure frataxin in whole blood (WB) and dried blood spots (DBS) for population screening and therapeutic monitoring of FRDA. In addition we adapted this assay to a MesoScale Discovery platform and completed an initial screen of a Library of Pharmogologically Active Compounds (LOPAC 1280) in FRDA patient cells. Results: Recovery for frataxin is 99% from WB and DBS. Intra-assay imprecision is 4.9-13% CV and inter-assay imprecision is 9.8-15.8% CV. The LOD is 0.07 ng/mL and reportable range is 2-200 ng/mL. The reference range for adult and pediatric normals is 15-82 ng/mL (median: 33) for DBS and WB. FRDA carriers (n=30) have frataxin levels of 12-30 ng/mL (median: 18) and FRDA patients (n=82) of <26 mg/mL (median: 6). Frataxin was stable for over 6 months at 22°C, 4°C and -70°C. An initial screen of LOPAC 1280 has yet to uncover a positive hit but it also has not provided evidence that EPO, pentamidine, or bisbenzimide enhance frataxin expression as observed by others in different experimental settings. Conclusions: We validated a high-throughput assay for frataxin that is applicable to diagnosis and population screening and modified the method for FRDA drug discovery. Ongoing work includes expanding the drug screen beyond LOPAC 1280.

Two-year efficacy and safety of velaglucerase alfa in patients with type 1 Gaucher disease switching from imiglucerase: Phase III trial HGT-GCB-039 and extension

P. Giraldo[1], *E. Crombez*[2], *N. Wang*[2], *P. S. Kishnani*[3], *H. Ben Turkia*[4], *D. E. Gonzalez*[5], *A. Zimran*[6], *M. Kabra*[7], *E. A. Lukina*[8], *I. Kisinovsky*[9], *A. Bavdekar*[10], *M. Ben Dridi*[4], *N. Gupta*[7];
[1]Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER) and Hospital Universitario Miguel Servet, Zaragoza, Spain, [2]Shire Human Genetic Therapies, Inc., Lexington, MA, United States, [3]Duke University Medical Center, Durham, NC, United States, [4]La Rabta Hospital, Tunis, Tunisia, [5]Sanatorio Español, Asunción, Paraguay, [6]Shaare Zedek Medical Center and Hebrew University-Hadassah Medical School, Jerusalem, Israel, [7]All India Institute of Medical Sciences, New Delhi, India, [8]Hematology Research Center, Moscow, Russian Federation, [9]Your Health SA, Buenos Aires, Argentina, [10]KEM Hospital Research Centre, Pune, India.

Objective: To determine the efficacy and safety of velaglucerase alfa in type 1 Gaucher disease (GD1) patients switched to velaglucerase alfa in an open-label extension study (HGT-GCB-044 [ClinicalTrials.gov, NCT00635427]) after receiving imiglucerase in a double-blind, randomized, Phase III trial (HGT-GCB-039 [NCT00553631]).
Methods: In HGT-GCB-039, treatment-naïve GD1 patients aged ≥2 years received velaglucerase alfa or imiglucerase as a continuous 60-minute intravenous infusion (60 U/kg every other week [EOW]; 9 months). Imiglucerase-treated patients completing HGT-GCB-039 could enroll in ongoing extension study HGT-GCB-044, switching to velaglucerase alfa (60 U/kg EOW). Assessments were conducted after 15 months in HGT-GCB-044 (total of 2 years' enzyme replacement therapy).
Results: Sixteen patients receiving imiglucerase in HGT-GCB-039 entered HGT-GCB-044 (median age, 27 years; male, n=7; splenectomized, n=10). Mean changes from baseline (HGT-GCB-039 entry) at 9 months and 2 years, respectively, were 1.40 g/dL and 1.98 g/dL for hemoglobin concentration, 149×10^9/L and 164×10^9/L for platelet count, −1.18% and −1.67% bodyweight for liver volume, and −2.79% and −3.63% bodyweight for spleen volume. Adverse events (AEs) reported by ≥20% patients: arthralgia and influenza in HGT-GCB-039; headache and upper respiratory tract infection in HGT-GCB-044. Three serious AEs occurred in 3 patients (none study drug-related or life-threatening). Anti-velaglucerase alfa antibodies were not detected in any patient receiving velaglucerase alfa, including 3 patients who developed anti-imiglucerase antibodies in HGT-GCB-039.
Conclusions: GD1 patients continued to improve across 4 key clinical parameters after switching from imiglucerase (9 months' treatment) to velaglucerase alfa (15 months' subsequent treatment). No patient exposed to velaglucerase alfa developed anti-velaglucerase alfa antibodies.

P14.11

Evaluating the effects of olesoxime, a mitochondria-targeting drug on the behavioral and neuropathological phenotype of a Huntington Disease rat model

H. Nguyen[1], *L. Clemens*[1], *T. Wlodkowski*[1], *M. Michaud*[2], *L. Yu*[1], *A. Redensek*[1], *E. Portal*[1], *J. Magg*[1], *C. Calaminus*[3], *B. Pichler*[3], *T. Bordet*[2], *R. Pruss*[2], *O. Rieß*[1];
[1]Department of Medical Genetics, Tuebingen, Germany, [2]Trophos, Parc Scientifique de Luminy, Marseille, France, [3]Laboratory for Preclinical Imaging and Imaging Technology of the Werner Siemens-Foundation, Tuebingen, Germany.

Olesoxime, a cholesterol-oxime is a neuroprotective compound and was found to exert its beneficial effects by an improvement of mitochondrial function. Since mitochondrial dysfunction also plays a prominent role in Huntington disease (HD), we evaluated its effects on the behavioral and neuropathological phenotype of the BACHD rat, a full-length mutant huntingtin (mhtt) model of HD. Behavioral observations were carried out during a 12-months study period and neuropathology was investigated subsequently. BACHD rats displayed clasping behavior and had severe problems to run on a rotating rod already at 6 weeks of age, indicating early-onset motor dysfunction. A simple swimming test carried out at 8 months of age revealed a deficit in reversal learning. Furthermore, BACHD rats showed metabolic abnormalities, deteriorating with disease progression. However, no difference was found between rats treated with olesoxime and untreated rats. NMRI revealed a specific reduction in cerebral and not cerebellar volume in the BACHD rats. Immunostaining of brain slices further showed cytoplasmic aggregation and intranuclear accumulation of mhtt in most cerebral brain regions as well as a decreased width of axonal bundles within the corpus striatum. Treatment with olesoxime increased overall brain volume in BACHD but also in wild type rats, and by trend reduced nuclear mhtt accumulations within the prelimbic cortex. It remains unclear, how olesoxime exerts these effects and whether there is an interaction between olesoxime and mhtt. However, the beneficial effects found ex vivo did not lead to an improvement of the behavioral phenotype of the BACHD rat.

P14.12

The investigation of the ITPA and XDH genes variants in Polish IBD patients treated with thiopurine drugs

M. Skrzypczak-Zielinska[1], *J. Widomska*[2], *O. Zakerska*[3,2], *L. Jakubowska-Burek*[4], *M. Szalata*[1,2], *A. Dobrowolska-Zachwieja*[4], *R. Slomski*[1,2];
[1]Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland, [2]Department of Biochemistry and Biotechnology, University of Life Sciences, Poznan, Poland, [3]The NanoBioMedical Centre, Adam Mickiewicz University, Poznan, Poland, [4]Department of Gastroenterology, Human Nutrition and Internal Diseases, University School of Medical Sciences, Poznan, Poland.

Thiopurine drugs are widely used in the treatment of inflammatory bowel disease (IBD). However, even among patients treated with azathioprine (AZA) or 6-mercaptopurine varied responses to treatment were observed. Thiopurines in as many as 30% of patients are not effective and in 20 % of patients side effects occur. Identification of genetic factors is essential in optimizing the individual treatment in IBD patients. In the metabolism of thiopurines besides well-established thiopurine methyltransferase, also other enzymes as inosine triphosphate pyrophosphohydrolase (ITPase) and xanthine oxidase (XO) are involved, which are encoded by ITPA and XDH genes. Two sequence variations in the ITPA gene have been described as associated with ITPase deficiency (P32T, IVS2+21A>C). Changes R149C and T910L in the XDH gene are the most common alleles responsible for a decreased enzyme activity. The aim of our study was to determine the frequency of these 4 sequence variations. We established pyrosequencing method. We tested 91 of Polish IBD patients treated with thiopurine drugs, where 11 did not have any therapeutic effect of thiopurine treatment and where adverse drug reactions existed. Allele frequencies estimated in our study for ITPA gene were lower to the determined in other Caucasian populations. Allele P32T was identified with frequency of 4.95%. The frequency of IVS2+21A>C allele was 8.24%. Investigated alleles in the XDH gene were not observed in this study group of Polish IBD patients and in 200 healthy Polish individuals additionally, what suggested probably no role of this alleles on thiopurine metabolism in the Polish population.

P14.13

The effect of losartan on the TGF-beta pathway in vascular smooth muscle cells of patients with bicuspid and thoracic aortic aneurysms

G. Belge[1], *A. Radtke*[2], *R. Nimzyk*[1], *M. Kirkgoez*[2], *J. Bullerdiek*[1], *H. Sievers*[2], ***S. Mohamed***[2];
[1]Center for Humangenetics, Bremen, Germany, [2]Department of Cardiac Surgery, University of Schleswig-Holstein Campus Luebeck, Luebeck, Germany, Luebeck, Germany.

Introduction The renin-angiotensin system is believed to participate in the development of thoracic aortic aneurysms (TAA) by targeting the TGF-beta pathway. Blockade of the renin-angiotensin system by the angiotensin II Type 1 receptor (AT_1) antagonist, losartan, has been shown to prevent aneurysm growth in Marfan syndrome. We therefore aimed to investigate the effect of losartan on the TGF-beta pathway in vascular smooth muscle cells (VSCM).
Methods and Results Aortic cells were cultivated and characterized as VSCM. The cells were grown to 80 percent confluency and incubated in serum-free media for 24 h. Next, 1 µM losartan was added to the media followed by incubation for 24 h. The cellular RNA was extracted, reverse transcribed into cDNA, and the expression of 84 genes related to the TGF-beta pathway quantified using the RT^2 Profiler PCR Array from Qiagen. Several genes related to the TGF-beta pathway demonstrated significant changes in expression after losartan treatment, although none of these changes were above two fold. Among these were *Edoglin* (-1.14, p = 0.005), *SOX4* (-1.25, p = 0.006), and *CDC25A* (-1.24, p = 0.0008).
Discussion Our study revealed the complex relationship between the renin-angiotensin system and the TGF-beta pathway in aortic smooth muscle cells. The relatively mild changes in gene expression may indicate that the losartan dosage used is not sufficient to fully antagonize the AT_1 receptor in VSMC obtained from bicuspid aneurysmal tissue.

P14.14

Losartan therapy in operated patients with Marfan syndrome after aortic aneurysm: prevention of re-dissection of the aorta

R. Zhuraev;
Lviv National Medical University after Danylo Halytski, Lviv, Ukraine.

Background. Aortic root dilation, dissection and rupture are major clinical problems in Marfan syndrome. Marfan patients require specialized interdisciplinary care for optimal out-come and life quality. We study the efficacy and tolerability of angiotensin II receptor blockade Losartan to prevent progressive dilation of aortic root and dissection in other parts of the aorta in patients with Marfan syndrome operated on aneurysms of ascending aorta.
Methods. We examined 41 patients with Marfan syndrome after aortic valve-

replacing root operations. All patients are meeting strict diagnostic criteria for Marfan syndrome based on the original Ghent nosology and underwent aortic valve-replacing root operations. We collected clinical data, biological samples (DNA/blood samples, aorta/valve tissues), and echocardiographic. We make two groups: one treated and one non-treated with losartan.
Results. In the 20 patients who received losartan experienced better control of blood pressure during the day, previously normalized clinical parameters, quality of life, none of the patients did not require repeat surgery. The changes in aortic distensibility and cross-sectional compliance were similar between the two groups. Mean aortic diameter increased 0.5 mm/year, while in patients who have not received losartan 1.6 mm/year. Left ventricular function was better in patients treated with losartan.
Conclusions. The results of this clinical study could lead to profound modification of the management of aortic risk and complications in patients with Marfan syndrome. The uniqueness in our study is related to the fact that the additive effect of losartan evaluated in patients with Marfan syndrome who have already undergone surgery.

P14.15
The differentiation of human mesenchymal stem cell in to neural cells

S. Karimian[1], S. Kaviani[2], M. Soleimani[2], M. Hashemi[3];
[1]Departemen of Genetics , Faculty of Basic Sciences , Olum Tahghighat Branch , Islamic Azad University ,, Tehran, Islamic Republic of Iran, [2]Department of Hematology and Blood Banking , Faculty of Medical Sciences , Tarbiat Modares University, Tehran, Islamic Republic of Iran, [3]Departemen of Genetics , Tehran Medical Branch , Islamic Azad University, Tehran, Islamic Republic of Iran.

The differentiation of human mesenchymal stem cell to neuron like cell on engineered nanofibrous scafolds have a great potential for bionanomaterial- cell transplautation therapy of neuro degenerative disease and injuries of the nerous system.
We investigated the potential of human bone marrow derived mesenchymol stem cell (MSCS) for neural differentiation in vitro on polycaprolacton (PCL) nanofibrons scaffolds.Studies in this fild have led to the realization that invivo cells intract with the extra cellular matrix , composed of nanofibrous at sub- micron scale , which not only provides the mechanical support to the cells but also plays akey role in regulation of cellular behavior with stem cells is emeraging as an important tool in the development of tissue engineering and regenerative medicine.
PCL characterizations were carried out using SEM , contact angle and tensile instrument.
The differentiation of MSC was carried out using neural inducing factors including Retinoic acid , epidermal growth factor (EGF) and fibroblast growth factor (FGF-2) and Ibmx in DMEM/F12.
Scaning electron microscopy results showed normal morphology and proli fration of Mesenchymal cell on PCL nanofibrous scaffolds.
The expression of neural protein markers was analyzed by immunocytochemistry. The differentiated Mesenchymol cell on nanofibre scaffold were found to express the neural protein , - tubulin III and Map2 ,On day 14 a fter culture by immuno- fluorescent.
Our studies on the differentiation of MSC to Neural cells on nanofibrous scaffold suggest their potentioral application towards nerve regeneration.

P14.16
Partial mechano-sensoric blindness to micrometer topography in *NF1* haploinsufficient cultured fibroblasts indicates a new function of neurofibromin in mechanotransduction

D. Kaufmann[1], J. Hoesch[1], L. Deeg[1], K. Mellert[1], S. Biela[2], S. Jungbauer[2], Y. Su[2], J. Spatz[2], R. Kemkemer[2];
[1]Institute of Human Genetics, Ulm, Germany, [2]Max Planck Institute for Intelligent Systems, Stuttgart, Germany.

Cells sense their physical environment and translate geometries into biochemical signals enabling them to adapt to cues in their surroundings. In this study, cell responses to surface topography of micro-structured polydimethylsiloxane substrates were investigated in cultured human cells differing in *NF1*. Age matched dermal fibroblasts from five patients with Neurofibromatosis type 1 (*NF1*+/-) and five controls (*NF1*+/+) were tested. As response indicator the mean cell orientation along micro-structured grooves with heights of 175 or 200 nm and distance of 2 µm was systematically examined by analysis of microscopy images using ImageJ. The tested *NF1* haploinsufficient fibroblasts were significantly less affected by the topography than those from healthy donors. Incubation of the *NF1*+/- fibroblasts with the farnesyltransferase inhibitor FTI-277 disrupting constitutive H-Ras-specific activation of MAP kinase ameliorates significantly the cell orientation. These data indicate that the response to surface topography can be altered by *NF1* haploinsuffiency resulting in a partial mechano-sensoric blindness in cultured fibroblasts. In further studies this new function of Neurofibromin in mechanotransduction will tested in more detail.

P14.17
Artificial over expression of NT3 and its receptor TrkC in bone marrow stromal cells

Z. Hajebrahimi[1], M. Movahedin[2], S. J. Mowla[3];
[1]Department of Physiology, Aerospace Research Institute, Tehran, Islamic Republic of Iran, [2]Department of Anatomy, School of Medical Sciences, Tarbiat Modares University, Tehran, Islamic Republic of Iran, [3]Department of Molecular Genetics, School of Biological Sciences, Tarbiat Modares University, Tehran, Islamic Republic of Iran.

The adult mammalian nervous system has a very limited capacity to replace neurons lost following an injury. In the last few decades, transplantation of neural-like cells derived from stem cells has been carried out as a potential treatment for neurodegenerative diseases. The potential success of the transplantation process, however, depends on the functional activity of the grafted cells in their new environment. Bone marrow stromal cells (BMSCs) which are capable of differentiating into neural cells, has been employed for cell and gene therapy of neurodegenerative diseases. Neurotrophin-3 (NT-3) is a member of the neurotrophin family of growth factors, best characterized by its survival- and differentiation-inducing effects on developing neurons.Our previous studies revealed that BMSCs do not express NT-3 and its receptor, TrkC, either before or after differentiation into neural like cells. Since during the development of the brain, NT-3 expresses earlier than other NTs, we used electroporation technique to introduce NT-3 and TrkC genes into the BMSCs by pDsRed-N1 and pCMV vector, respectively. PDsRed-N1 is a mammalian expression vector that encodes a variant of red fluorescent protein. Vectors transformed into E coli DH5α. Expression of NT-3 and TrkC confirmed using fluorescence microscopy and RT-PCR method. Our results showed that BMSCs have the potential for being genetically manipulated and electroporation can serve as a fast, easy, and efficient method for it. We successfully obtained cells could express RFP, NT3 and TrkC. Due to the expression of RFP, the fate of cells can be easily traced after transplantation into tissues.

P14.18
Induction of embryonic microRNA (miR) cluster 302 and pluripotency genes in human mesenchymal stroma cells under hypoxic culture conditions

S. Foja[1,2], M. Jung[3], O. Pelz-Ackermann[4], I. Schroeder[5];
[1]Department of Human Genetics, Halle/Saale, Germany, [2]Translational Centre for Regenerative Medicine, Leipzig, Germany, [3]Translational Centre for Regenerative Medicine, Leipig, Germany, [4]BD Biosciences GmbH, Heidelberg, Germany, [5]Department of Anatomy and Cell Biology, Halle/Saale, Germany.

Multiple ways and cells sources for the generation of induced pluripotent stem (iPS) cells using for analysis of pathogenesis and personalized treatment are currently under investigation. We hypothesized that due to their multipotency human mesenchymal stroma cells (hMSC) could be more easily reprogrammed than other somatic cells. Therefore, we investigated whether cultivation of MSCs under hypoxic culture conditions, known to support pluripotency in embryonic stem (ES) cells, would suffice to induce pluripotency in MSCs. In particular we analysed the expression of pluripotency-associated genes and the microRNAs (miRs) 302, specific for pluripotent embryonic stem cells, as parameter for reprogramming. Therefore primary human MSCs obtained from bone marrow aspirates and the MSC cell line L87 were cultured under hypoxic (5%O$_2$) and normoxic (20%O$_2$) culture conditions with and without FGF2 supplementation. We found that under hypoxic culture condition in the presence of FGF2, MSCs showed higher proliferative capacities and decreased senescence. FGF2 induced *OCT4* and *NANOG* analyzed by real-time-RT-PCR. In combination with hypoxia this effect was potentiated. If not already present, *KLF4* and *c-MYC* were likewise induced. Most importantly, in contrast to many retroviral methods, the combination of hypoxia and FGF2 led to an induction of the miR302 cluster similar to that found in ES cells leading to the repression of their predicted targets at day 14. In summary, we showed that hypoxia is a safe, easily applicable and sufficient tool to induce pluripotency-associated genes and miRs in multipotent MSCs. This may serve as a first step to generate clinical-grade iPS-cells.

P14.19

Bezafibrate as treatment option in patients with mitochondrial complex I deficiency

B. M. Haberberger[1,2], P. Freisinger[3], V. Strecker[4], K. Heim[2], U. Ahting[5], B. Rolinski[6], T. Haack[1], J. Mayr[7], W. Sperl[7], E. Wilichowski[8], M. Schuelke[9], T. Klopstock[10], M. Zeviani[11], I. Wittig[4], T. Meitinger[1,2], H. Prokisch[1,2];

Mitochondriopathies are inherited metabolic disorders with a severe clinical phenotype affecting different organ systems. A majority of them affect the respiratory chain and the cellular ATP production but even these clinical manifestations are highly variable, extending from early childhood encephalopathies to adult-onset myopathies. In spite of rapid progress identifying the molecular cause, curative therapeutic options are barely available. Bastin et al. (2008) and Wenz at al. (2008) provided evidence from in vitro studies and mouse models that activation of the PPAR/PGC-1-alpha pathway with bezafibrate could be a new therapeutic approach. In order to verify this effect, we collected 28 fibroblast cell lines from patients with isolated complex-I deficiency and a defined molecular diagnosis. The complex I activity in patient fibroblasts ranged from 10% to 80% compared to controls. Bezafibrate treatment led to significant improvement of complex I activity in more than 50% of the cell lines. In a subgroup of 13 cell lines, the treatment effect was additionally analyzed on genome-wide expression levels, revealing increased expression of genes involved in lipid and fatty acid metabolism and transport. In 5 cell lines which responded to bezafibrate treatment with significant increase of complex I activity, we found increased amounts of complex I assembled in supercomplexes by two-dimensional blue native SDS-PAGE experiments. These results support bezafibrate as a promising treatment option in a well defined subgroup of patients. They have to be verified in other mitochondrial disorders like COX-deficiency.

P14.20

Vascular malformations and soft tissue tumours in segmental overgrowth disorders respond to mTOR inhibitors, in spite of normal PTEN and AKT1 function

E. Lausch[1], R. Keppler[1], E. Maas[2], B. Zabel[1], C. Niemeyer[1], J. Rössler[1];
[1]University of Freiburg, Freiburg, Germany, [2]Olgahospital, Stuttgart, Germany.

Vascular malformations are common among patients with segmental overgrowth disorders. Very recently, a recurrent activating AKT1 mutation was identified in Proteus syndrome lesions and loss-of-function mutations of PTEN are known to cause SOLAMEN syndrome. Genetically, both aberrations are predicted to increase downstream phosphoinositide 3-kinase (PI3K) signalling pathway activity. A significant number of patients, however, do not show mutations in either PTEN, or AKT1, and the pathogenesis of hamartomatous tumours and associated vascular malformations remains unresolved. Over the past years, we provided clinical care and molecular diagnosis for patients affected by vascular and hamartomatous tumours. No constitutive PTEN mutation was detected in a cohort of eleven children with segmental overgrowth disorders, mainly classifiable as Proteus, or Proteus-like syndrome. Molecular analyses of tumour tissues failed to demonstrate somatic activation of AKT1. Mosaic mutations were neither found in dermal fibroblasts derived from affected regions, nor in vascular malformations, nor in soft tissue tumours. Nevertheless, experimental therapy with mTOR inhibitors was able to induce rapid remission in three of three treated patients, proving efficacy against diverse lesions, including intestinal haemangioma, intra-thoracal lipomatosis, and retro-orbital lymphangioma. In view of the poor outcome and high complication rate of surgical approaches, mTOR inhibition therefore holds the promise of a well-tolerated first line medical alternative for this group of disorders, regardless of mutational status of proven disease genes. Our results provide clear evidence for genetic heterogeneity in segmental overgrowth disorders, especially in Proteus, and Proteus-like syndrome. Preliminary molecular data suggest a common pathogenic mechanism involving the PI3K/PTEN/AKT/mTOR pathway.

P14.21

Testing Riluzole in a conditional mouse model of SCA3

***J. Schmidt**, A. Kaiser, O. Rieß, T. Schmidt;*
University of Tuebingen, Tuebingen, Germany.

Spinocerebellar ataxia type 3 (SCA3) or Machado-Joseph disease (MJD) is an inherited neurodegenerative disorder caused by the expansion of a CAG repeat within the *MJD-1* gene resulting in a polyglutamine repeat in the encoded protein ataxin-3. SCA3/MJD therefore belongs to the group of polyglutamine diseases. Up to now, no treatment is available for this disease. In a recent study, a positive effect of riluzole (benzothiazol, Rilutek), was observed in a heterogenous group of patients suffering from different types of cerebellar ataxias after just eight weeks of treatment with riluzole. However, in the mentioned study, only short-term effects were analyzed which may be just symptomatic. In order to analyze whether riluzole may also be beneficial for SCA3 and whether also long-term effects of riluzole treatment can be observed, we treated our recently generated inducible mouse model of SCA3 with riluzole. This mouse model allows us not only to measure a possible effect of riluzole on disease progression but also to quantify this effect by comparison with an “optimal treatment” (i.e. turning off the expression of ataxin-3). We started the treatment once significant deficits in the rotarod performance were obvious in the generated mice and followed the outcome of the treatment using Rotarod and measurement of home cage activity. Mice were sacrificed at different time points and brain tissue was analyzed for inclusions and neuropathology using Western-Blot and immunohistochemistry. Tissue was also analyzed on RNA level to exclude that riluzole influences the expression of the transgenic ataxin-3.

P14.22

The prevalence of VKORC1 1639 G>A and CYP2C9*2*3 genotypes in patients that requiring anticoagulant therapy in Turkish population

***C. Silan**[1], O. T. Dogan[2], F. Silan[3], F. M. Kukulguven[4], H. F. Asgun[5], S. Ozdemir[6], A. Uludag[3], S. Atik[3], B. Gungor[1], S. Akdur[1], H. E. Aksulu[1], O. Ozdemir[3,7];*
[1]Department of Pharmacology,Faculty of Medicine,Canakkale Onsekiz Mart University, Canakkale, Turkey, [2]Department of Chest Diseases,Faculty of Medicine,Cumhuriyet University, Sivas, Turkey, [3]Department of Medical Genetics, Faculty of Medicine, Canakkale Onsekiz Mart University, Canakkale, Turkey, [4]Department of Emergency,Faculty of Medicine, Cumhuriyet University, Sivas, Turkey, [5]Department of Cardiovascular Surgery,Faculty of Medicine,Canakkale Onsekiz Mart University, Canakkale, Turkey, [6]Department of Nuclear Medicine, Faculty of Medicine, Canakkale Onsekiz Mart University, Canakkale, Turkey, [7]Department of Medical Genetics, Faculty of Medicine, Cumhuriyet University, Sivas, Turkey.

The VKORC1 and CYP2C9 genotypes were investigate in anticoagulant therapy requiring patients in two different Turkish populations. Cohort included 292 patients that need anticoagulant therapy with the history of deep vein thrombosis and/ or pulmonary artery thromboembolism.Genomic DNA was isolated from peripheral blood samples and StripAssay reverse hybridization technique was used for genotype analysis. Genotypes for CYP2C9 were detected as; 165 (56.5%) for CYP2C9*1/*1, 67 (23.0%) for CYP2C9*1/*2, 25 (8.6%) for CYP2C9*1/*3, 9 (3.0%) for CYP2C9*2/*2, 21 (7.2%) for CYP2C9*2/*3, 5(1.7%) for CYP2C9*3/*3 for CYP2C9 and the allele frequencies were; 0.723 for allele*1, 0.182 for allele*2 and 0.095 for allele*3 respectively. Genotypes for VKORC1 were detected as; 64 (21.9%) for GG, 220 (75.4%) for GA and 8 (2.7%) for AA alleles. The G allele frequency was detected as 0.596 and A allele frequency was 0.404. The VKORC1 1639 G>A and CYP2C9 mutation prevalence and allele frequency of current results showed similar great variable profiles when compared to the other results from Turkish population.

P14.23

Sodium butyrate and Valproic acid as a splicing restoring agents in erythroid cells of β-thalassaemic patients

***S. M. Derakhshan**, M. S. khaniani, M. tagizade;*
Tabriz university of Medical Science, Tabriz, Islamic Republic of Iran.

β-thalassaemia is a common autosomal recessive disorder in humans caused by a defect in β-globin chain synthesis . Over two hundred different mutations have been found to cause β-thalassaemia, with the most common being splicing mutations (1). Most of these mutations activate aberrant cryptic splicing of 5’ or 3’ splice sites without abolishing completely normal splicing. Some mutations allow a significant level of normal splicing (e.g. IVSI-6), leading to thalassaemia intermedia, while others reduce normal splicing to low (e.g. IVSI-110) or very low levels (e.g. IVSI-5 and IVS2-654) and lead to blood transfusion dependency in the homozygote forms. In most of these cases, the normal splicing sites are not mutated, resulting in competition between the normal and aberrant splice sites and the production of variable amounts of normal mRNA . Modulation of splicing can be achieved by activation or suppression of transacting factors such as SR proteins and hnRNPs through drugs. Here, we demonstrate restoration of IVSI-110 mutation obtained by sodium butyrate, iso butyramide and valproic acid, histone deacetylase inhibitors, known to upregulate the expression of splicing factors. These results highlight the therapeutic potential of splicing modulation for genetic diseases caused by splicing mutations.

A novel StripAssay for the detection of genetic factors modulating the risk of developing AA amyloidosis

S. Németh[1], *L. Obici*[2], *S. Grandemange*[3], *I. Touitou*[4], *H. Lachmann*[5], *C. Oberkanins*[1];
[1]*ViennaLab Labordiagnostika GmbH, Vienna, Austria,* [2]*Biotechnology Research Laboratories, IRCCS Fondazione Policlinico San Matteo, Pavia, Italy,* [3]*Inserm U844, Montpellier, France,* [4]*Unité médicale des maladies auto-inflammatoires, Hôpital Arnaud de Villeneuve, Montpellier, France,* [5]*National Amyloidosis Centre, London, United Kingdom.*

Systemic reactive (AA) amyloidosis represents the most important complication within TNF receptor associated periodic syndrome (TRAPS), familial Mediterranean fever (FMF) and other autoinflammatory syndromes, progressively leading to endstage renal failure. The homozygous condition of the serum amyloid A (SAA) variant SAA1.1 is significantly associated with the occurrence of AA amyloidosis in TRAPS patients (unpublished results). Likewise in FMF patients the *MEFV* mutation c.2080A>G (M694V) correlates with amyloidosis and the presence of a SAA1.1 / SAA1.1 genotype increases the clinical severity (age at disease onset, amyloidosis, arthritis). An association between mannose-binding lectin 2 (*MBL2*) alleles and AA amyloidosis in TRAPS patients is not conclusively established, but the analysis of *MBL2* variants is of considerable diagnostic interest also in closely related fields, including rheumatoid arthritis or innate immunity. Still under discussion of being a modulating risk factor for TRAPS, the *TNFRSF1A* intron 4 polymorphism c.473-33C>T is involved in *TNFRSF1A* expression.

We developed and validated a reverse-hybridization assay (StripAssay) for detection of genetic factors modulating the risk of developing AA Amyloidosis. *MBL2* and *TNFRSF1A* variants can be identified as well, but their role within amyloidosis needs to be cleared. Our panel of markers encompasses c.473-33C>T (*TNFRSF1A*); c.2080A>G (*MEFV*), c.209C>T, c.224T>C (*SAA1*); g.4447 C>G, g.4776 C>G, g.5000 C>T, c.154C>T, c.161G>A, c.170G>A (*MBL2*).

The StripAssay is based on multiplex PCR and reverse-hybridization of biotin-labeled amplification products to a parallel array of allele-specific oligonucleotides immobilized on membrane teststrips. The test follows a simple protocol and requires only small amounts of DNA for comprehensive genetic analysis.

P15.02

Accreditation of cytogenetic laboratories

K. Miller;
Institute of Human Genetics, Hannover, Germany.

The accreditation of a laboratory is the formal recognition of its competence to perform specific tests. It requires regular inspections by qualified external assessors. In medical laboratories, the usual standard is ISO 15189.

This report presents the experience of 75 inspections in 40 cytogenetic laboratories in Germany. The requirements concern: technical aspects such as accommodation, equipment, methods, pre- and post-examination procedures, reporting, quality control, and competence of staff.

In total, 226 non-conformities were found. On average, 5.6 (range 0-12) non-conformities were reported at first accreditation and 2.4 and 3.2 at subsequent second and third controls, respectively.

The highest number of non-conformities (26.6%) was reported for examination procedures. Of these, 33% concerned validation, 28% documentation and 23% procedure itself.

Laboratory equipment was the reason for 25.6% of non-conformities; insufficient documented or expired consumables accounted for 28%, maintenance and surveillance for 26% and data security for 19% of these.

About 19% of the observations concerned accommodation and environment, of which almost 40% concerned security aspects and 23% inadequate storage.

Inadequate reporting was the reason for 16.8% of the non-conformities of which 55% were due to incorrect use of ISCN.

Staff, pre- and post-examination procedures, and quality control were found only rarely among the non-conformities.

The observations show an improvement of the performance of accredited laboratories. The laboratories with a high number of non-conformities in the first inspection profited from the external evaluation to improve their organisation.

(The study includes data that have been reported earlier: Chromosome Res. 2009; 17: 23-24).

P15.03

Comparing Ion Torrent's PGM™ Sequencer and the 5500 SOLiD™ System with Sanger sequencing: Next generation resequencing of the *CFTR* gene using PCR and sample multiplexing

R. Achmann[1], *R. Greither*[2], *A. Rico*[2], *L. He*[2], *A. Sartori*[2], *M. Wenz*[3], *S. Berosik*[3], *N. Rieber*[4], ***B. Auber***[1];
[1]*MVZ genteQ GmbH, Hamburg, Germany,* [2]*Life Technologies GmbH, Darmstadt, Germany,* [3]*Life Technologies, Foster City, CA, United States,* [4]*Deutsches Krebsforschungszentrum, Heidelberg, Germany.*

Almost 2000 mutations have been described in the Cystic Fibrosis (CF) associated CFTR gene. In a few populations the mutation spectrum is well defined and screening tests for the most frequent mutations exist. Sequencing of the entire CFTR gene would be preferable especially in less well characterized populations, but Sanger sequencing is expensive and tedious. Thus, we tested two next generation sequencing (NGS) platforms (Ion Torrent Personal Genome Machine™ (PGM™) and 5500 SOLiD™ System) concerning their throughput, ease of use and analytical sensitivity.

Testing of 20 human samples with different known CFTR genotypes (validated by Sanger sequencing on 3500xL Genetic Analyzer, Applied Biosystems), using a Multiplicom™ multiplexing assay for the CFTR gene, sample barcoding and subsequent NGS with the 5500 SOLiD™ System and the semiconductor-based IonTorrent PGM™ Sequencer.

Sanger sequencing identified a total of 33 mutations and 53 SNPs in the 20 samples. Using the SeqNext software module (JSI medical systems GmbH), all mutations except one insertion/deletion mutation were identified correctly with data from both NGS systems. The SNP detection rate was highly dependent on the coverage reached for a particular region of interest. For sequence coverage of 100-fold or higher the detection rate reached 100% for both NGS systems.

If a sufficiently high coverage can be realized, Ion Torrent and Solid NGS sequencing produce reliable data. Bioinformatic analysis of more complicated variants still needs to be improved.

The products referred to in this abstract are for Research Use only, not intended for animal or human therapeutic or diagnostic use.

P15.04

Scanning and genotyping of CFTR mutations and common SNPs using snapback primers

L. Zhou[1], *F. Ye*[1], *J. Chen*[1], *B. Palais*[2], *C. T. Wittwer*[1];
[1]*Department of Pathology, University of Utah School of Medicine, Salt lake City, UT, United States,* [2]*Department of Mathematics, University of Utah, Salt lake City, UT, United States.*

Complete genotyping of CFTR mutations is currently performed exclusively by sequencing, a costly and time-consuming procedure. High-resolution melting analysis with snapback primers can be used to genotype all common mutations and scan for rare mutations more rapidly and economically. There are 23 common mutations listed by the American College of Medical Genetics and 7 common SNPs in the CFTR gene. Twenty seven CFTR gene exons were amplified in 39 exon/intron fragments due to length considerations for some of the exons. High-resolution melting was performed on all 39 fragments on the LightScanner® to scan the intramolecular amplicon melting curves for common and rare mutations or SNPs. The twenty exon/intron fragments that may contain common mutations or SNPs were amplified using snapback primers. After scanning, these amplicons were then diluted in H2O to favor intermolecular hybridization, denatured by heating, cooled, then melted again on the LightScanner®. The resulting snapback probe melting peaks detect intra-molecular hybridization and identify the genotype at the loci all of common mutations or SNPs. Twenty six CFTR mutation cell lines from Coriell, 25 pretested CF patient and 80 none patient samples were used for blinded testing. All of the loci of common mutations and SNPs were genotyped correctly by high-resolution melting with snapback primers. The method genotyped all but 0.3% samples require sequencing. Genotyping CFTR mutations by using snapback primer with high-resolution melting analysis is reliable, rapid and inexpensive. The fewer than 1% amplicons that were not directly genotyped by the method were detected for subsequent sequencing.

P15.06

Pyrosequencing Assay Panels For Genotyping Disease-Associated Polymorphisms/Mutations

D. Ciglidag Dungul[1], *B. Metin*[1], *E. Sakalli*[1], *B. Torun*[1], *S. Richardt*[2], *F. Narz*[2];
[1]*ATQ Biotechnology, Ankara, Turkey,* [2]*Qiagen GmbH, Hilden, Germany.*

Background: Molecular diagnostics are increasingly used to guide diagnosis and therapy of human diseases. The detection of key polymorphic variants/ mutations in human genes provides valuable information about diagnosis, risks or therapeutic regimens.

Familial Mediterranean Fever (FMF) is an autosomal-recessive disease which affects Armenian, Arab, Jewish, Greek, Turkish and Italian populations. Beta thalassemia (BTAL) is a blood disorder that reduces the production of hemoglobin. BTAL is common in Mediterranean countries such as Greece, Italy, Spain, Cyprus, but occurs as well in North Africa, the Middle East, India, and Eastern Europe. Thrombosis is a blood clot inside a blood vessel, obstructing or stopping the flow of blood through the circulatory system. Thrombotic diseases are one of the main causes of mortality worldwide.

Methods: Pyrosequencing assays were developed targeting key mutations/ polymorphisms in genes associated with thrombosis (*Factor II, Factor V, MTHFR, PAI-1*), FMF (*MEFV*) and BTAL (*HBB*). The important disease related deletions, insertions, point mutations and polymorphisms in these genes were determined by pyrosequencing. Plasmids coding for FMF, BTAL and thrombosis variants were used to study assay precision.

Results: All assays allow flexible, fast and reliable genotyping of the mutations in DNA isolated from whole blood with excellent concordance to Sanger sequencing.

Conclusions: Pyrosequencing was shown to be highly suitable to detect, identify and quantify important polymorphisms/mutations in human disease-associated genes. The newly developed assays have a significant lower turn-around time and are easier to interpret raw-data compared to the current gold standard Sanger sequencing and maintain the flexibility of a sequencing-based method.

P15.07

Guidelines for the genetic diagnosis of hereditary recurrent fevers

Y. Shinar[1], *L. Obici*[2], *I. Aksentijevich*[3], ***I. Touitou***[4];
[1]*1FMF Molecular Diagnostics Lab, Sheba Medical Center, Tel HaSomer, Israel,* [2]*Amyloid Center, Biotechnology Research Laboratories, Fondazione IRCCS, Pavia, Jersey,* [3]*National Human Genome Research Institute, Bethesda, MD, United States,* [4]*UMAI laboratoire de génétique, Montpellier, France.*

Hereditary recurrent fevers (HRFs) are a group of monogenic autoinflammatory diseases characterized by recurrent bouts of fever and serosal inflammation that are caused by pathogenic variants in genes important for the regulation of innate immunity. The discovery of the molecular defects responsible for these diseases has initiated genetic diagnostics in many countries around the world including the Middle East, Europe, USA, Japan and Australia. However, diverse testing methods and reporting practices are employed, and there is a clear need for consensus guidelines for the HRF genetic testing.

Draft guidelines were prepared based on current practice deduced from previous HRF External Quality Assurance (EQA) schemes and data from the literature. The draft document was disseminated through the EMQN (European Molecular genetics Quality Network) for broader consultation and amendment. A workshop was held in Bruges (Belgium) on September 18 and 19, 2011 to ratify the draft into a final consensus document.

An agreed set of best practice guidelines was proposed for genetic diagnostic testing of HRFs, for reporting the genetic results, and for defining their clinical significance.

Supported by EU projects EuroGentest (FP6-512148), Eurotraps (FP7-2008-200923), la Région Languedoc-Roussillon, Eurofever (EAHC, Project 2007332).

Automated analysis by using real-time PCR assays of mutations: Factor V Leiden, *F12C46T* and rs7025486 of DAB2IP gene

I. Tirado, *I. Coll, B. Cuevas, E. Martínez-Sánchez, J. Mateo, J. Fontcuberta;*
Hospital Sant Pau.Unitat d'Hemostàsia i Trombosi, Barcelona, Spain.

Several genetic factors implicated in the pathogenesis of venous thromboembolism have been reported in the literature. The aim of this study was to automate the methods of genetic analysis of mutations: Factor V Leiden, and *F12C46T* and rs7025486 of *DAB2IP* gene. Methods: DNA extraction was performed by MagnaPure Compact (Roche). We designed an assay of TaqMan allelic discrimination by real-time PCR 7500 (Applied Biosystem). Were selected DNA samples from patients (n=50) from whom the mutations were previously genotyped by other assays. Factor V Leiden and *F12C46T* mutations were performed by real-time PCR with allele-specific probes with the Light Cylcer 2.0 analyzer (Roche). The rs7025486 mutation of *DAB2IP* gene (c.18554G>A) was performed by direct sequencing with Analyzer Genetic 3500 (Applied Biosystems). Results: We designed assays using real-time PCR 7500 with allele-specific *Taqman* probes in 96-well plate format samples. In all samples we obtained the same genotype for each mutation with both methods (sensitivity and specificity of 100 %). However, the automated process by real-time PCR genotyping plate allows us to analyze a large number of samples in each run (n = 92) including matched controls (n = 4). If this protocol were employed using automated DNA extraction, the full process would last 2 hours until the report of the results. Conclusion: T*aqMan* allelic discrimination assay provides a good alternative tool in detection of SNPs associated with venous thrombosis. Red RECAVA RD 06/0014/0016. Generalitat de CatalunyaAG-AUR 20095GR1147.

P15.10

Quality assurance practices in Europe: a survey of molecular genetic testing laboratories

S. Berwouts[1,2], *K. Fanning*[1,2], *M. A. Morris*[3,2], *D. E. Barton*[4,2], *E. Dequeker*[1,2];
[1]*Department of Public Health, Biomedical Quality Assurance Research Unit, Leuven, Belgium,* [2]*EuroGentest, Leuven, Belgium,* [3]*Molecular Diagnostic Laboratory, Service of Genetic Medicine, University Hospitals, Geneva, Switzerland,* [4]*National Centre for Medical Genetics, UCD School of Medicine & Medical Sciences University College Dublin, Our Lady's Children's Hospital, Crumlin, Dublin, Ireland.*

In the 2000s, a number of initiatives were taken internationally to improve quality in genetic testing services. To contribute to and update the limited literature available related to this topic, we surveyed 910 human molecular genetic testing laboratories, of which 291 (32%) from 29 European countries responded. The majority of laboratories were in the public sector (81%), affiliated with a university hospital (60%). Only a minority of laboratories were accredited (23%), and 26% were certified. 22% of laboratories did not participate in external quality assessment and 28% did not use reference materials. The main motivations given for accreditation were to improve laboratory profile (85%) and national recognition (84%). Nearly all respondents (95%) would prefer working in an accredited laboratory. In accredited laboratories, participation in external quality assessment ($p<0.0001$), use of reference materials ($p=0.0014$) and availability of continuous education on medical/scientific subjects ($p=0.023$), specific tasks ($p=0.0018$), and quality assurance ($p<0.0001$) were significantly higher than in non-accredited laboratories. Restriction of the development of new techniques ($p=0.023$) and the improvement of work satisfaction ($p=0.0002$) were significantly overestimated by non-accredited laboratories. By using a quality implementation score, we showed that accredited laboratories (average score 92) comply better than certified laboratories (average score 69, $p<0.001$), and certified laboratories better than other laboratories (average score 44, $p<0.001$), with regard to the implementation of quality indicators. We conclude that quality practices vary widely in European genetic testing laboratories. This leads to a potentially dangerous situation in which the quality of genetic testing is not consistently assured.

P15.11

Quality assurance of PCR based molecular genetic tests through elimination of thermocycler variability during assay validation

M. Span[1], *M. A. W. Verblakt*[2], *M. T. M. Hendrikx*[1];
[1]*CYCLERtest BV, Landgraaf, Netherlands,* [2]*GENOtronics BV, Landgraaf, Netherlands.*

Validation and verification of PCR methods and procedures before their use in clinical molecular genetic testing is essential for producing correct and clinically relevant results.

Over the past decades many validation studies and external quality assessments have addressed the difficulties of producing and reproducing PCR, qPCR and HRM molecular diagnostic results. Non consistent PCR results are often attributed to different purities of template DNA and reagents used, but seldomly to variations in thermocycler performance as thermocyclers are perceived as a constant rather than a variable.

In this study the thermal performance of over 10.000 thermocyclers has been evaluated. The temperature calibration data show a large spread, both between and within thermocyclers. This variability is expressed in inconsistent, false negative, lower positive or incorrect PCR results.

Typically, thermocyclers can not be adjusted and therefore solutions must be sought to deal with this variability in the design and validation of PCR assays. Currently, accredited laboratories consider PCR assays as sufficiently validated when an empirical validation study on a limited number of thermocyclers has produced comparable results. However, the large variability as measured during this study reveals the severely underestimated risk of using limited numbers of thermocyclers for empirical validation studies. Through this detailed study we have generated guidelines for easy, straightforward, analytical validation of PCR based molecular genetic tests. These guidelines are accepted by auditors around the world.

Since the introduction of high-throughput DNA genotyping and sequencing technologies, the number of DNA samples analyzed for genetically complex phenotypes has tremendously increased. Furthermore it has become very important to combine samples from different sites to further increase statistical power to detect small genetic effects. This has led to serious challenges concerning the individual sample coding. Often encountered problems which hamper the unambiguous identification of individual samples include samples having the same identifier by chance as well as spelling errors in the sample identifier.

To address these problems we have developed an universal sample coding system the Unified Sample Identifier (USI) over the last years. The USI is based on the ISO certified IBAN system which is used in the international banking system since more than 30 years. The USI includes a checksum making it very resistant to spelling errors and data about project, study, sample type and aliquot, but does not include any information on the affection status, diagnosis, gender and ethnicity.

Here we present data on the implementation of the USI in our database system, the use of automatically generated barcodes and the evaluation of the checksum system. We especially analyzed the probable risk of collisions - different lab codes sharing the same check sum - in the normal lab context. We checked for random one letter changes first and focused on common human letter recognition issues in a second analysis. Based on these results we are further optimizing the algorithms for automatic correction of coding errors.

P15.13

About sequence quality: impact on clinical applications

T. Noguchi[1], *V. Bourdon*[1], *H. Sobol*[1,2];

[1]*Institut Paoli-Calmettes, Marseille, France,* [2]*Faculté de Médicine, Aix-Marseille Université, Marseille, France.*

Advance of sequencing technologies is accelerating with a surprisingly fast rhythm, and it is clear that next-generation sequencing (NGS) should be in clinic in near future. Recent survey shows that the introduction of desktop sequencers like Ion Torrent PGM and Illumina MiSeq will be a primary growth driver for this new market.

Nevertheless, it doesn't necessary mean the end of Sanger sequencing: recent comparative studies show that performance of NGS platforms varies considerably and different NGS instruments produce different types of errors. In short, the current NGS workflows are too heterogeneous for their technical characteristics to conceive any standardized clinical platform. Also several surveys show a recent development of new markets for Sanger sequencing instruments designed for diagnosis, especially in China and one can imagine easily potential weight of this market.

Sanger sequencing remains the sequencing "gold-standard" for accuracy, reliability and easy of use: used to validate the results of NGS.

However, even in Sanger sequencing the sequence quality definition remains fuzzy and too empirical for clinical applications.

We realized a heuristic analysis of more than 31 000 sequence traces generated in the clinical diagnosis and demonstrated that the sequence traces qualities are inherently variable in routine practices and the most commonly used criterion "average quality value" alone is too inaccurate and not sufficient for clinical uses.

We demonstrated that with a combination of three parameters (average quality value, relative sequence intensity and electropherogram profile), it is possible to determine accurately the quality of any sequence.

P15.14

SNPflow - A laboratory information system for automated data processing and quality management of SNP genotyping results

H. Weißensteiner[1], *M. Haun*[1], ***S. Schönherr***[1,2], *M. Neuner*[2], *L. Forer*[1], *G. Specht*[2], *A. Kloss-Brandstätter*[1], *F. Kronenberg*[1], *S. Coassin*[1];

[1]*Division of Genetic Epidemiology, Department for Medical Genetics, Molecular and Clinical Pharmacology, Medical University Innsbruck, Innsbruck, Austria,* [2]*Research group Databases and Information Systems, Institute of Computer Science, University of Innsbruck, Innsbruck, Austria.*

High-throughput genotyping projects in large epidemiological study populations require sophisticated laboratory information management systems (LIMS). Small to medium sized genotyping facilities often lack such LIMS and thus have to rely on basic R or VBA scripts for the quality control of their genotyping experiments. Since modern genetic epidemiological studies often comprise >10,000 individuals, automated workflows are, however, required to handle and review the large amount of genotypic data generated by modern multiplex genotyping approaches such as Sequenom iPLEX. To address this issue, we developed the web application "SNPflow". This solution provides automated data management and quality control for genotyping experiments employing the ABI 7900 HT-platform (e.g. TaqMan, KASPar Assays) or the Sequenom iPLEX platform. It automatically merges single raw output files of different DNA plates, converts them to ready-to-use genotype lists and stores the quality-controlled genotypes in a dedicated MySQL database. For each SNP assay QC values such as call rates, discordance rates and Hardy Weinberg Equilibrium (HWE) are calculated and a comparison of the observed genotype frequencies with the HapMap data is generated. It even provides a fast overview on these QC values for dozens of SNPs in one list. All data can be finally exported in well-arranged files for further analysis. Our software is, to the best of our knowledge, the first completely freely available, web-based application for an automated quality control of Sequenom iPLEX genotypes and can be accessed at genepi.i-med.ac.at/snpflow. It significantly improved the handling of and the overview on our genotyping projects in various cohorts.

P15.15

Experience and outcome of the EMQN External Quality Assessment Scheme for molecular analysis of Spinal Muscular Atrophy (SMA)

H. H. Lemmink[1], *V. Karcagi*[2], *O. Kamarainen*[3], *S. Patton*[3], *S. Eraslan*[4];

[1]*Department of Genetics, University Medical Centre Groningen, Groningen, Netherlands,* [2]*Department of Molecular Genetics and Diagnostics, National Institute of Environmental Health, Budapest, Hungary,* [3]*National Genetics Reference Laboratory, St. Mary's Hospital, Manchester, United Kingdom,* [4]*Bogazici University CHE Biosystems Eng. Research Group, Istanbul, Turkey.*

Spinal muscular atrophy is a hereditary motor neuron disease characterized by proximal muscle weakness due to degeneration of the anterior horn cells of the spinal cord. Approximately 94% of patients with SMA reveal homozygous absence of the *SMN1*gene. However, small intragenic mutations are not detected by *SMN1* gene dosage analysis and the presence of two normal *SMN1* copies on one chromosome 5 can mask a deletion of *SMN1* on the other chromosome 5 (carrier). Subsequently, *de novo* mutation rate is relatively high. Accurate risk assessment and clinical genetic counseling are particularly important due to the genetic complexity and high SMA carrier frequency. This external quality assessment scheme was designed to assess laboratories' abilities to correctly genotype cases suspected of having SMA and to identify carriers of SMA. Each year three DNA samples (accompanied by mock clinical information) were distributed to approximately 70 laboratories from more than 30 countries after validation of the *SMN1* and *SMN2* gene copy numbers. Each laboratory sent in their written reports, usually accompanied by raw lab data. Each of the written reports is marked for genotyping and subsequent interpretation according to predetermined evaluation criteria. Most laboratories used MLPA to quantify *SMN1* gene copy number for diagnostic and carrier analysis. The genotyping error rate has increased concomitant to a decreased number of labs with full interpretation score. A full report of the results of the SMA schemes and recommendations for best practice guidelines for molecular analysis of SMA are presented.

Genetic counseling: association of microdeletion 22q11.2 and Fragile X syndromes in one family

***N. Rumiantsava**, N. Venchikova, I. Novikova, O. Khurs, A. Polityko, L. Isakovich, K. Mosse;*
Republican Medical Centre "Mother and Child", Minsk, Belarus.

Association of few genetic disorders in one family is not rare. Quality of genetic counseling for the outcome prognoses (model of inheritance, risk) depends on the accuracy of nosologic diagnose.
We present results of clinical, genetic, laboratory, prenatal and morphological investigations of the family, affected by del22q11.2 and Fragile X syndromes (FraX), detected by FISH and DNA studies. Parents were young, healthy, nonconsanguineous. G1: population risks, standard combined prenatal screening (SCPS) results were unremarkable, healthy girl was born. G2: SCPS data were normal at 1-st trimester, but heart defect, suspected via sonography at 16 weeks, was confirmed at 20 weeks of gestation. Fetus karyotype: 46,XX. Pregnancy was terminated due to fetus malformations. Morphological examination showed heart defects (membranous VSD, bicuspid aortic valve, aortic stenosis, hypoplastic aorta ascendens, interrupted arch), thymus aplasia, cleft palate. Presumably DiGeorge syndrome (del22q11.2) was confirmed by FISH (autopsy, lymphocytes of umbilical cord blood). Karyotype: ishdel(22)(q11.2q11.2)(N25-)dn. Parents had normal karyotypes (GTG, FISH), low risk of del22q11.2 for offspring. G3: normal SCPS, but pregnant had mentally retarded non-examined brothers (halfsibs) and needed an outcome prognoses. FraX was detected by PCR in both (mother was obligate carrier of CGGn expansion). The daughter was not examined because fetus (female) had low risk. G4. Pregnant underwent DNA examination of FRM1 gene because of possible risk of FraX for fetus (male). Expansion of CGGn was excluded (low risk), healthy boy born. Next pregnancy prognosis: population risks, SCPS. Scheme of genetic counseling and prenatal diagnostics protocols, made for each pregnancy will be presented.

Are DentalFaculty Knowledgeable About Genetics and Understand its Implication forClinical Dental Practice and Education?

*R. J. Crout[1], **G. T. Casto**[2];*
[1]West Virginia University, Morgantown, WV, United States, [2]Indian River State College, Fort Pierce, FL, United States.

Objective: In a companion study, dental students at the West Virginia University School of Dentistry (WVU SOD) were lacking "Knowledge, Skills, and Attitudes Required for Oral Health Professionals to Care for Patients with Genetic Conditions" utilizing the Report of Panel 3 of the Macy Study. The aim is to investigate the genetic knowledge, skills and attitudes of West Virginia (WVU SOD) faculty utilizing the same report for specific questions.
Methods: All full time dental faculty (32) were invited to answer 16, primarily Likert style questions (1= Strongly Agree to 5 =Strongly Disagree). Questions included Knowledge: of genetic transmission; molecular biology of the human genome; principals of population genetics; Skills: to perform a head/neck exam with special attention to signs of major genetic disorders; recognize when to refer a patient for genetic screening, testing, and counseling; Attitude: to understand the potential for genetics to contribute to the development of new approaches to prevention, diagnosis and treatment.
Results: 15 (46.9 %) participated. When it came to their Knowledge of transmission, biology of the human genome, principals of population genetics and Skills to perform a head/neck exam and when to refer, 62.2%, 51.2%, 95.5% and 69.1% disagreed respectively. Attitude, however, revealed that 66.7% agreed they understood the potential for genetics to contribute to new approaches of disease with 86.7 % interested in a CE update.
Conclusion: Although baseline knowledge and skills of the WVU SOD faculty were lacking, they recognized the importance of this new technology and were interested in a CE update.

J01.03

Importance of prenatal diagnosis of chromosomal abnormalities in genetic counseling

***M. L. Sprincean**[1,2], E. Halabudenco[1], N. Barbova[1,2], M. Stratilă[1], V. Nour[1], V. Secrieru[1];*
[1]National Centre of Reproductive Health and Medical Genetics, Chisinau, Republic of Moldova, [2]State University of Medicine and Pharmacy "N. Testemitanu", Chisinau, Republic of Moldova.

Background: The role of genetic counseling in prevention of chromosomal abnormalities as genetic diseases is emphasized in the study.
Methods: Retro-prospective investigation included medico-genetic counseling of 572 pregnant women in 2006-2010. Were analyzed data regarding ultrasound examination, nuchal translucency, outflow tracts, biochemical screening, double test, fetal karyotype in the second trimester of pregnancy.
Results: Prenatal diagnosis identified severe fetal pathologies to pregnant women. Chromosomal abnormalities spontaneously occur, regardless of degree of genetic risk, as an outcome of „de novo" mutations. Diagnosis of chromosomal abnormalities to fetuses by cytogenetic methods (amniocentesis) contributed to the detection of deviations in fetal karyotype before their birth.
The age of pregnant women of low, medium and high genetic risk groups was from 17 to 44 years (average age 26,7 ± 5,1 years).
The study of fetal karyotype in amniocentesis (at 16-18 weeks of gestation) allowed to identify numerical and structural chromosomal abnormalities in 70 patients (12,2 %). From it: Down syndrome (n=28), Patau syndrome (n=4), Edwards syndrome (n=13), Turner syndrome (n=6), Klinefelter syndrome (n=5), other chromosomal abnormalities (n=14). Data analysis of fetal ultrasound indicated that the most frequent in the structure of the serious fetal pathologies are the abnormalities of cardio-vascular system (7.0%), followed by the abnormalities of central nervous system (3.2%), osteomuscular system anomalies (2.63%), renal system (2.7%) and digestive system (1.06%).
Conclusion: Using of prenatal diagnosis methods (fetal ultrasound, biochemical screening, karyotyping) in genetic counseling helps to reduce the frequency of chromosomal abnormalities and congenital malformations.

J01.04

The Role of Genetic Counselling in the Prevention of Hereditary Haemochromatosis: the perception of health professionals requesting HFE genotyping in Portugal

***B. Leandro**[1], M. Paneque[1], J. Sequeiros[1], G. Porto[2];*
[1]Institute for Molecular and Cell Biology, Porto, Portugal, [2]Centro Hospitalar do Porto - Hospital Geral de Santo António, Porto, Portugal.

AIM - To understand physician's main motivations behind requests for molecular tests of hereditary haemochromatosis and for consultation of genetic counselling, accessing to current medical practices of screening and early diagnosis of hereditary haemochromatosis and considering whether these can be improved to increase the effectiveness of prevention.
RESULTS - There is still a lack of awareness by physicians (especially by general practitioners) about the patient cases that should be sent for genetic counselling or for molecular test in hereditary haemochromatosis. This can compromise the prevention of the disease (early diagnosis and treatment) and a primordial family-based screening.
CONCLUSION - It's necessary to disclose more information about hereditary haemochromatosis among health professionals in order to improve strategies for screening and diagnosis.

J01.05

Pregnant women disorders and indications of legal abortion in Iran

***M. Amirian**[1], A. Solimanpour[2], Z. Nafei[3];*
[1]Yazd Legal Medicine Organization -Legal Medicine Research Center, yazd, Islamic Republic of Iran, [2]Yazd Legal Medicine Organization, yazd, Islamic Republic of Iran, [3]Shahid Sadoughi Medical University, yazd, Islamic Republic of Iran.

Maternal mortality in the world has decreased because high level of health and medical science. But some medical conditions such as cogenital heart disease in pregnancy can cause maternal mortality.
During pregnancy, pregnant women suffer from some diseases it can lead to infirmity, before sixteen weeks from last menstrual period, therefore the legal abortion is recommended . This subject in Iran would be done by requesting from judicial authorities. It would be accepted by three experts who are related to pregnant women disorders, then the legal abortion is issued by the legal medicine organization and eventually the legal abortion will be done by Obstetrics and gynecologist in public hospital.
This case is about a twenty four years old woman who three years ago due to aortic valve stenosis after the first pregnancy, before sixteen weeks of pregnancy, abortion was permitted and performed but she desire to have children regardless of comment her doctor was pregnant and died during

delivery. A recent research has shown that there are important conflicts in main branches of Islam that is related to the legal abortion but any disorders which can lead to infirmity or critical condition for pregnant woman is an issue related to the legal medicine organization in Iran and the legal abortion is issued.

J01.06
Assessing teaching and learning Medical Genetics

R. Dragotoiu;
Medical and Pharmacy University „Carol Davila", Bucuresti, Romania.

In the last years I have tried to improve the outcome of teaching genetics to medical first year students. This time I have questioned whether useful or not to send the lessons by e-mail.

Students from the Medical and Phramacy University „Carol Davila" in Bucharest, were given twice the same two open questions during the first term. 132 students participated in the practicals I taught in the academic year 2010/2011. 6 of them did not come to any of the two tests and 5 did not come to the second testing. In this academic year from 106 students 6 were absent at both tests. This year's students received the lessons by e-mail.

In this study I compared only the marks obtained by my students during the second testing in the two different academic years.

In case of this year's students the higher marks were more frequent (table). In both years the students received twice the questions, so that the repetition could not bias the result. The comparison was made only for the second testing, when most of this year's students became aware of having received by e-mail everything I had previously taught.

This study assessed the use of written material received from the teacher and it showed that the purpose was achieved, students having better results after learning individually, what was taught during oral presentations.

Comparison between students achievements in the academic years 2010/ 2011 and 2011/ 2012

Marks obtained by students	0	1	2	3	4	5	6	7	8	9	10
Students marks in 2010/ 2011 (%)	0.83	0	7.44	6.61	9.09	10.74	13.22	13.22	9.92	11.57	17.36
Students marks in 2011/ 2012 (%)	3	1	6	1	5	9	7	10	18	18	22

J01.07
Twinning antecedents in families of patients with Down Syndrome

S. Turyk, *M. Sakurai;*
Hospital Britanico de Buenos Aires, Buenos Aires, Argentina.

Twinning has been reported in association with many chromosome abnormalities . It has been suggested that the incidence of Down Syndrome (D.S.)is significantly higher in multiple pregnancies than among singletons. The aim of this study is to describe the association of twin pregnancies in families of patients with D.S.. Contained within this report is a detailed clinical and genealogical history of 72 patients with Down Syndrome. Statistics show that 41 (56,9%) with 47,XY,+21 karyotype and 31 (43,1%) with 47,XX,+21 karyotype. The mean maternal age was 35,7 (age range 22-43 years) and the mean paternal age was 39,1 (age range 19-58 years). The antecedent of multiple pregnancies was found in 11 (15,2%) families. The rate of twinning antecedents in D.S. families is significantly higher, compared with 2131 families in the control group. It is very important for families with twinning antecedents to have genetic counselling in order to make prenatal diagnosis.

J01.08
Promoting genetic counselling in South Africa by creating a comprehensive web-based genetics resource

S. Erasmus, *N. Kinsley;*
GC Network, Johannesburg, South Africa.

Genetic counselling in South Africa is a developing field with 16 practising genetic counsellors. Annually, approximately 57,000 individuals with genetic defects are born in South Africa, while genetic counsellors see around 2,000 clients. To date, no genetic counselling information and/or genetics resource website exists in South Africa even though internet usage is rapidly increasing with 14% of the population accessing the internet in 2011 compared to the 5.5% in 2000. More than 80% of the population have mobile phones that can potentially access the internet.

The growth of, and access to genetic counselling in South Africa is hindered by the lack of awareness and knowledge by the public and healthcare providers. To address this need, a new website http://www.geneticcounselling.co.za was created. The ultimate goals of this website are; to build an online genetic counselling community thereby connecting professionals, patients and the generally inquisitive, to be the first comprehensive web-based genetics resource and to promote and increase awareness of genetic counselling in South Africa.

The website is intended to be accessible and informative to both the lay public and medical professional. The focus is on genetic counselling and its available services but the site also includes pages on knowledge share (customised talks, corporate consults and continual professional development), resources (our pamphlets, and links to external information sites), local and international news and events, and local support groups. In due course we intend to use this as the foundation to build the ultimate genetics resource in South Africa.

J01.09
Using internet social media to enhance public understanding of genetics and provide support for the psychosocial concerns of genetic carriers.

J. Karwoski;
University of Nevada, Las Vegas, Las Vegas, NV, United States.

Communication is crucial to disseminating information and facilitating understanding. The Internet age provides unprecedented opportunity for communication of 'virtually' anything at all. This presentation will introduce a selection of current social media tools that are, or can be, used to facilitate supportive communication among previously isolated individuals and families from around the world who are dealing with relatively rare genetic health concerns. Several examples from the well over 500 online social networks will be considered in depth. The use of multilingual tools such as Facebook and Twitter will be summarized.

Although many individual genetic disorders have a presence on the Internet, their focus is understandably on what can be done for those with the disorder. But reproductive decision making is fraught for parents of affected children, as well as for persons aware of their genetic risk prior to starting a family. One site, MyBlueGenome^{SM} (.org), aims to address issues of interest to genetic carriers regardless of the particular disorder of concern. Instead of dealing deeply with one disorder, it deals broadly with one aspect common to many disorders: coping with carrier status. The emphasis is on those psychosocial dimensions that require long-term engagement and the support of peers who have been through similar experiences. Resources such as understandable summaries of research articles for the lay public and links to related sites can do much to expand the genetic knowledge available to the public.

J01.10
Pharmacogenomics and public health: Implementing populationalized medicine

L. A. Mette;
Charite Universitatmedizin, Berlin School of Public Health, Berlin, Germany.

Pharmacogenomics is most commonly used in personalized medicine to individualize therapy for a patient where it holds the potential to increase therapy benefits and minimize adverse drug reactions. Applying this technology to a population would produce the same benefits, in addition to saving already scarce health resources. The objective of this study is to review what has been researched and published in the fields of pharmacogenomics and public health, regarding how the two sciences can constructively intersect. Literature addressing pharmacogenomics in terms of global burden infectious diseases, public health initiatives, and public policy were researched in the PubMed database. Six major themes were identified and further discussed: interactions between public health and pharmacogenomics, pharmacogenomics and drugs, pharmacogenomics and diseases, benefits of including pharmacogenomics in public health policy, keys for implementing pharmacogenomics into public health policy, and points for consideration. Pharmacogenomics can prove to be a beneficial addition to a public health policy by maximizing therapeutic benefits, decreasing adverse drug reactions, and allowing for a better allocation of resources. Indirect health benefits can also be realized through economic advantages and international collaboration. The pharmacogenomics research surrounding major infectious diseases (malaria, tuberculosis, and HIV/AIDS) is limited, although important discoveries have been made. The implementation of this information and its implications are far reaching, and deserve extensive consideration. In order to realize the full benefits of this technology, support is needed from the private, public and governmental sectors in order to ensure the appropriateness, acceptability and affordability of this technology within a society.

Addiction is a social problem in Iran and other countries. Studies have shown that addiction may be related to some factors including environment, genes and fetal developmental events. This study has evaluated the effect of gene and gene mutations in the mu opioid receptor (MOR). One of the most important genes involved in addiction is the mu opioid receptor (MOR) gene located on the human chromosome number 6. This gene has multiple exons including exon number 3. Various mutations have been detected in this exon which are involved in the effects of MOR gene. This study has investigated the presence of single nucleotide polymorphisms in the exon 3 of MOR gene in Iranian people. 213 male and female individuals divided into two groups of addicted and non-addicted subjects participated in the study. After preparing blood samples from subjects, DNA was extracted with G-DEX kit. MOR gene exon 3 was amplified with thermocycler equipment. PCR products were sequenced. And analysis by DNA MAN software, a 877 G>A mutation and 759 C>T mutation was detected. Both of these samples were belonged to non-addicted male subjects. Furthermore, in addicted, a 1043 G>C mutation was found. After analysis by x2 analysis. no significant relationship between addiction and genotype and significant relationship between addiction and sex was obtained($P<0.05$). This is the time which 1043 G>C mutation has been reported in Iran.

J02.02
Phenotypic variant of Alpers syndrome in a Hungarian family

K. Hadzsiev[1], *K. Komlósi*[1], *G. Kosztolányi*[1], *A. Gál*[2], *M. Molnár*[2], *G. Csábi*[3], *K. Hollódy*[3], *B. Melegh*[1];
[1]Department of Medical Genetics, Pécs, Hungary, [2]Clinical and Research Center for Molecular Neurology, Semmelweis University, Budapest, Hungary, [3]Department of Pediatrics, Pécs, Hungary.

Alpers-Huttenlocher syndrome is an autosomal recessive mitochondrial DNA depletion syndrome that has been associated with pathogenic mutations in the mitochondrial polymerase γ (*POLG1*) gene. Comprised oxidative phosphorylation leads to progressive hepatoencephalopathy manifesting in severe, often intractable seizures, myocloni and stroke-like episodes, psychomotor regression and variable hepatic dysfunction. Symptoms usually appear following normal early development, initial symptoms are often infection-induced. The phenotypic spectrum associated with *POLG1* mutations is very heterogeneous, even intrafamilial phenotypic variablity is observed.

We present a case of a 19 months-old boy in whom myocloni, lethargy and elevated liver enzymes following a viral infection and a positive family history raised the possibility of Alpers syndrome. His sister died at 18 months after an adenoviral infection provoked fulminant hepatoencephalopathy, however, no diagnosis was achived at that time. *POLG1* mutation analyis in our patient revealed compound heterozygosity for the common c.1399 G>A (p.Ala467Thr) mutation and a novel, so far unpublished missense mutation, c.3589 T>C (p.Cys1127Arg) in the polymerase domain. During the 11 months of follow-up no progression or neurologic deterioration and no hepatopathy has been observed in our patient, despite abnormal EEG findings. The fulminant course in his sister might have been precipitated by several environmental factors, including valproate therapy and adenovirus infection.

Our case points to the difficulty of phenotype-genotype correlation in *POLG1* mutation associated disorders. We recommend investigation of mtDNA depletion and multiple deletions from muscle tissue and analysis of the *POLG1* gene in all children with progressive neurodegeneration accompanied by episodic, therapy resistent epilepsy and hepatic involvement.

J02.03
Deletion of SHANK3 gene detected by MLPA in a patient with autistic features and hyperactivity

F. Gonzalo, *A. Zuniga, L. Pedrola, Y. Bello;*
Hospital de la Ribera, Alzira (Valencia), Spain.

Autism is a severe neurodevelopmental disorder and one of the most heritable neuropsychiatric syndromes, with a male to female ratio of 4:1. The diagnosis of autism is based on impairments in reciprocal social interaction and communication, and restricted and stereotyped patterns of interests and activities, with abnormal development apparent within the first 3 years of life. Autistic spectrum disorders (ASDs) include: autistic disorder, childhood disintegrative disorder, pervasive developmental disorder-not otherwise specified, Asperger syndrome and Rett syndrome. There is substantial evidence from twin and family studies to support the involvement of genetic factors in ASDs.

We report a case of 3 years old boy with echolalia, irrelevant talk, not comprehensible. Muttered to himself occasionally, poor social interaction and avoided eye contact. He was unable to follow commands and responded to his name very rarely. The child was born after 8 yrs of a non consanguineous marriage, gestation was controlled and it was a full term caesarean delivery. The provisional clinical diagnosis was autistic features with hyperactivity. Karyotype was normal, X-fragile syndrome analysis was normal too and was performed a genetic analysis using MLPA (SALSA®MLPA® Subtelomeric Screening P070, X-linked mental retardation P106 and Microdeletion Syndromes P245). Analysis results showed a deletion in SHANK3 gene in 22q13.3. Parents were not carrier of this deletion.

Several studies have described similar results and these findings have led to the hypothesis that haploinsufficiency of SHANK3 may cause the behavioural phenotypic consequences of severe expressive language delay, severe/profound mental retardation and at times autism.

J02.04
Beckwith-Wiedemann Syndrome in a newborn caused by aberrant methylation in KvDMR domain in 11p15

G. Pi, *A. Zuñiga, L. Pedrola, Y. Bello;*
Hospital de la Ribera, Alzira (Valencia), Spain.

Beckwith-Wiedemann syndrome (BWS) is an overgrowth disorder usually (but not always) present at birth characterized by an increased risk of childhood cancer and certain congenital features. Five common features are used to define BWS are: macroglossia, macrosomia, midline abdominal wall defects (omphalocele, umbilical hernia, diastasis recti), ear creases or ear pits, and neonatal hypoglycemia. This condition is caused ba a genetic or epigenetic alteration within two domains of imprinted growth regulatory genes in chromosome 11p15, leading to deregulated expression of the imprinted genes within this region. Approximately 60-70% of the patients have imprinting abnormalities, other causes are uniparental disomy, mutations in the CDKN1C gene as well as small deletions and translocations.

We report a case of a premature newborn of 7 months old referred to Neuropaediatric Service. Parents were moroccan origin and without consanguinity, with two previous normal children. Pregnancy was controlled and it was diagnosed an omphalocele at 20 week. Birth was premature at 34 week with a weight 3,100 g, length 43,5 cm, cranial perimeter 34 cm and Apgar 8-9. There was a defective closure in abdominal wall of 3 cm with intestinal loops recovered with the umbilical cord. Karyotype was normal and he was diagnosed as a phenotype of BWS. Genetic analysis was performed using DNA from PBL and MLPA (SALSA® MS-MLPA® BWS/RSS ME030-C1). Methylation analysis showed an aberration methylation of KvDMR domain in the 11p15 region, confirming diagnosis of BWS. MS-MLPA results a low cost technique that is suitable for detecting imprinting alterations.

J02.05
Late diagnosis of non-syndromatic intrahepatic biliary atresia. Case presentation

O. N. Belei[1], *M. Pop*[2], *T. Marcovici*[1], *A. Militaru*[1], *C. Daescu*[1], *M. Puiu*[3];
[1]First Pediatric Clinic, University of Medicine and Pharmacy “Victor Babes” Timisoara, Romania, Timisoara, Romania, [2]Third Pediatric Clinic, University of Medicine and Pharmacy “Victor Babes” Timisoara, Romania, Timisoara, Romania, [3]Genetics Department, University of Medicine and Pharmacy “Victor Babes” Timisoara, Romania, Timisoara, Romania.

Biliary atresia (BA) is a progressive obliteration of intra or extrahepatic biliary system occurring in neonatal period. During the perinatal period an exogen factor influences the innate immune system of a genetically predisposed individual inducing an uncontrollable immune response with consecutive atresia of the intra/extrahepatic bile ducts.Genetic factors that could account for the disease are assessed by recent studies.GWAS identified a susceptibility locus for BA on 10q24.2, while other authors suggested region of potential disease susceptibility on 2q37.3.

The authors present a case of a 3 months female uninvestigated by the time of admission.The infant was admitted for sclero-tegumentary jaundice present since the first day of life and grow retardation.The family medical history was insignificant.Clinical examination showed cutaneous trophic disturbances and hepatosplenomegaly.The infant didn't associated phenothypic particularities or others malformations.Biological assessment showed increased conjugated bilirubin, increased colestasis enzymes, hipertransaminasemia, hipercholesterolemia and negative serology for maternofetal infections.The abdominal ultrasound combined with billiary scintigraphy and liver biopsy confirmed the diagnosis of intrahepatic BA.The differential diagnosis was made with Alagille syndrome-an autosomal dominant disorder that associates intrahepatic BA with heart, skeleton, eyes malformations and characteristic facial appearance.

Besides medical treatment ursodeoxycholic acid, bile acid sequestrants and parenteral liposoluble vitamins, the patient was proposed for liver transplantation.

The particularity of this case was the late stage of BA diagnosis associating chronic cholestatic hepatitis (Knodell 14/Fibrosis 3).The diagnosis should be established in the first weeks of life at every infant with prolonged colestatic jaundice by increasing the awareness about this condition to primary care physicians.

J02.06

Clinical features of a child with chromosomal abberation 46,XY,der(9),t(9;12)(p24;p11.2)

J. Jovanovic-Privrodski, I. Kavecan, M. Obrenovic, J. Rudež, L. Gacina, T. Tarasenko, D. Radovanov;
Institute for Children and Youth Health Care Vojvodina, Novi Sad, Serbia.

In this paper we report on a case of 17-months-old male child with chromosomal abberation 46,XY,der(9),t(9;12)(p24;p11.2). This is first child from first pregnancy. Ultrasound examination during pregnancy showed normal status. Invasive prenatal diagnosis wasn't done. Diagnosis of chromosomal abberation was made after child was born. Karyotype of mother was normal: 46,XX. Karyotype of father was presented balanced translocation: 46,XY,(9;12)(p24;p11.2). This child had: hypertelorism, epicanthic fold, high forehead, thick eyebrow, anteverted nostrils, delayed skeletal maturation, small hand, mental retardation. Parents are counseled that they have risk in every next pregnancy of having fetal chromosomal aberations and they are counseled for importance of having invasive prenatal procedure (amniocentesis or chorionic villi sampling) for diagnosis of unbalanced chromosomal abberations because husband has balanced translocation. In this situation it is importante for paretns to understand the risk for future pregnancy.

J02.07

Phenotypic description of interstitial deletion of 6q in a 13-year old girl

V. Okur, O. Cetin, A. Ayaz, F. Duzcan;
Pamukkale University, Denizli, Turkey.

Approximately half of the dysmorphic patients have remained undiagnosed. However, with implication of CGH and aCGH into clinical studies, most of these cases are being diagnosed as chromosomal abnormality. Here, we report, to best of our knowledge, the largest interstitial deletion of 6q with translocations of short arms of chromosomes 2 and 10.

13-year-old girl, born to nonconsanguineous couple, had referred to us with developmental delay/mental retardation, deafness, insomnia, dysphagia, characteristic expressionless glance and dysmorphic findings of skeletal system. We, first, cytogenetically detected distal deletion of 6q with translocation of chromosomes 2 and 10.Then we performed subtelomeric FISH analysis which revealed intact subtelomeric signals of both 6pter and 6qter. Hence, we determined that the chromosomal abnormality of our patient is interstitial deletion of long arm of chromosome 6 between bands of 6q16 to 6q25 with t(2;10)(p14;p13). The next step is to perform aCGH to identify deletion size and exact breakpoints in order to correlate dysmorphic findings with genotype of patient.

J02.08

First Alive Case of Yunis-Varón syndrome in Iran,

Z. Hadipour, Y. Shafeghati, F. Hadipour;
Genetic Department ,Sarem Cell Research center & Hospital, Tehran, Islamic Republic of Iran.

The Yunis-Varón syndrome (YVS) represents a rare autosomal recessive syndrome of easy recognition characterized by cleidocraneal dysplasia, ossification defects, absence of thumbs and halluces, distal aphalangia, ectodermal anomalies, generalized Hypotrichosis, and poor outcome. It is a multisystem disorder which, affect the skeletal, ectodermal, and cardio respiratory system. The molecular basis is unknown. Here, we report a 3.5 month old female neonate with Yunis-Varón syndrome, born to a consanguineously married, with normal parent. The mother was 39 year old gravid 6, and father was 46 year old. They have recurrent abortion in pervious pregnancies, and 2 daughters. In examination the baby has dysmorphic features, who had microgonathia, wide fontanel, Prominent eyes, Poor sucking, Congenital heart disease, Asymmetric face, Ambigus genitalia, Reduction anomaly in right hand, hypoplastic distal phalanges of 3th fingers, and thumbs, hip dislocation, and partial absence of clavicles(cleidocranial dysplasia).Her karyotype analysis is normal.

J02.09

A girl with possible Harboyan syndrome-a connection between corneal clouding and endolymph based hearing loss ?

T. B. Vamre;
Dept. of medical genetics, Oslo, Norway.

She was born two weeks after term after an uneventful pregnancy. At the age of six months it was noticed that she had corneal clouding. Cornea was oedematously thickened centrally. She made good eye contact. Visual acuity was reduced; she could not see her parents five meters away, but play with toys that she kept close to her eyes. She developed normally.

At the age of two she was diagnosed with Corneal endothelial dystrophy (CHED2). She was homozygous for the c.2240+1G>A in the SLC4A11 gene on chromosome 20p13p12. It is a congenital dystrophy of cornea probably due to failure in the function of sodium borate transporter. Swelling of the endothelial cells leads to destruction of cornea.

Ion transporter SLC4A11 has been associated with sodium-dependent transport of borate and flux of sodium and hydroxyl across cell membranes. The maintenance of ion concentration influences several organs, including the cornea, the
ear and the kidney.

At the age of four it was found that she had impaired hearing at the routine screening. Her hearing loss was mild, bilateral and basin shaped. Perceptive deafness is thought to be associated with ion concentration in the endolymph of the inner ear.

The hearing loss in Harboyan syndrome is progressive. One person in Great Britain is reported to have this mutation, but in a heterozygous state. We are presenting this girl hoping to learn about the hearing loss.

J02.10

New diagnostic problems in clinical genetics

Y. Lacassie;
Department of Pediatrics, Louisiana State University Health Sciences Center and Children's Hospital, New Orleans, LA, United States.

The major goal of clinical evaluation in genetics is to establish the etiological diagnosis, the cornerstone for providing genetic counseling. Historically, the percentage of diagnoses established by geneticists has been low compared to other medical specialties in which a phenotypic diagnosis may be enough. With the recent advent of microarray-based comparative genomic hybridization (aCGH) which allows the rapid detection of submicroscopic genomic deletions and duplications, the number of etiological diagnoses established has progressively increased. However, there are many old and new diagnostic problems, frequently neglected, that contribute to make it difficult to establish the diagnosis.

At the Latin-American Association of Genetics (ALAG)'s meeting in Mexico in 1994, we first presented a classification delineating four groups of problems. For teaching and educational purposes, we recognized problems due to the patient, the disease, the observer, and the environment. This systematic review and illustration of different diagnostic problems creates awareness and improves the effectiveness of medical practice. With the new technologies, big advances have been made but also new problems have been recognized. In 2008 this classification was expanded to include a fifth group: problems of informatic due to the interpretation of microarray (aCGH) results mainly secondary to the incomplete knowledge about CNV and phenotype-genotype correlation. The application of aCGH to diagnosis is evolving and requires intense communication among clinical geneticists and the laboratory specialists about their specific clinical queries or troublesome cases. In this presentation we will review the diagnostic process and will illustrate and discuss different diagnostic problems.

J02.11

Variable expression of Ehlers-Danlos syndrome in sibs

E. Sukarova-Angelovska, M. Kocova, N. Angelkova, S. Palcevska;
Pediatric Clinic, Skopje, The Former Yugoslav Republic of Macedonia.

Ehlers-Danlos syndrome (EDS) is a diverse group of syndromes caused by defect synthesis of collagen. It affects mostly skin, joints and blood vessels.

There are six major subtypes described so far, with variable mode of inheritance. Additional subtypes are described linked with other comorbidities.
We describe two sibs with major features of EDS. Two sibs - older sister and younger brother share the same facial features - broad face with coarse facial features, sagging cheeks, long, smooth filtrum, sparse hair, joint laxity, thin lax skin with skin wrinkling, hyperextensibility, poor skin healing with forming an atrophic scars. Both children had mitral valve prolaps. The girl , now aged 25 years started to lose her hair progressively, have mild form of kyphoscoloisis and experiencing menstrual irregularities. The boy develops seizures at the age of 14 years. EEG revealed spike-wave complexes. CT scan and magnetic imaging showed demyelinisation that progressed in years. During the last several years his mental and motor abilities deteriorated. Also the kyphoscoliosis that has been noticed at puberty became significant. The diagnosis in both children was established by skin biopsy and histology evaluation so far, showing destruction of collagen fibers.
Last classification of EDS is made upon major signs and symptoms that are present in the patient. Intrafamilial variability is described. In this case kyphoscoliotic type with variable expression can be suspected . Since both children had aged appearance that progresses with age, also progeriod form is assumed as well. Further evaluation is needed in this family.

J02.12

Examination of SCN1B in Iranian epileptic patient

B. Sedaghatikhayat[1], N. Hatamnejadian[1], M. Moghaddasi[2], S. Zeinali[3], M. Fallah[4], A. Ebrahimi[1];
[1]Parseh medical Genetics Center, Tehran, Islamic Republic of Iran, [2]Rasool Akram Hospital, Tehran University, Tehran, Islamic Republic of Iran, [3]Kawsar Human Genetics Research Center, Tehran, Islamic Republic of Iran, [4]Kawsar human genetics research center, Tehran, Islamic Republic of Iran.

Epilepsy is a common chronic neurological disorder that is characterized by recurrent unprovoked seizures. Molecular studies of candidate genes can help us to define a correct differential diagnosis. So we studied SCN1B gene in Iranian patient with Idiopathic Epilepsy includes Febrile Seizure, Generalized Epilepsy with Febrile Seizure (GEFS+) or Dravet syndrome, diagnosed clinically, to explain genotype-phenotype correlation. Materials and Method: We screened 34 selected epileptic unrelated Iranian propends for all coding regions of SCN1B by PCR amplification and direct Sequencing. All families and propends were previously screened for SCN1A and mtDNA mutations. Results: PCR amplification of whole coding regions and splicing site of SCN1B followed by direct sequencing revealed tow novel sequence variation in patients (p.248 R>S, p.210 L>P) which did not detected in the healthy normal family members. Conclusions: According to final results it seems that these two novels SCN1B variations are not causative mutation in epileptic patients but they can act as genetic predisposition factors in epileptic phenotypes which introduce susceptibility especially in response to antiepileptic drugs.

J02.13

Clinical and genetic studies in in Ewing sarcoma

R. Stefanescu, S. Dumitriu, C. A. Popa, M. Puiu;
University of Medicine &Pharmacy, Timisoara, Romania.

Throughout the latest years the results in treatment for familial Ewing's sarcoma, in the metastasis-free stages, have considerably improved. The prognosis remains somber for the metastatic disease patients at the first diagnosis time point or in case of relapse after therapy. Inefficient chemotherapy and the relapse are the major mortality causes in Ewing's sarcoma patients. For improving the therapy outcome in patients with potential relapse, the discovery of reliable markers that predict the tumor "behavior", help making the diagnosis or identifying the therapeutic molecular targets when relapse, is mandatory.
The study group includes 5 cases with Ewing syndrome, diagnosed and treated in the Pediatric Oncology & Hematology Clinic in Timisoara. The diagnostic protocol has included genetic testing (cytogenetic and molecular) and morphopatology testing (histomorphology, immunohistochemistry).
This article's scope is to highlight this way, the present concepts of the sarcoma genesis in Ewing's sarcoma and the comparison of different molecular markers which could affect its prognosis or contribute to the development of future therapies. A better understanding of the cells of origin and the molecular pathways that regulates carcinogenicity in Ewing's sarcoma could help in finding new therapies in Ewing's sarcoma.

J02.14

Facio-audio-symphalangism Syndrome in a patient with partial 17q22monosomy involving NOG gene

V. Ginocchio[1], G. Cappuccio[1], P. Boemio[1], R. Genesio[2], G. Minopoli[1], A. Casertano[1], A. Mormile[2], P. Tedeschi[2], L. Nitsch[2], G. Andria[1], D. Melis[1];
[1]Department of Pediatrics Federico II University, Naples, Italy, [2]Department of Cellular and Molecular Biology and Pathology Federico II University, Naples, Italy.

Multiple Synostosis Syndrome (SYNS - also called Facio-audio-symphalangism) is an AD disorder characterized by fusion of the proximal interphalangeal joints of the hands, multiple and progressive joint fusions in the hands, feet, cervical vertebrae, hips, brachydactyly, subluxation of the radial heads, associated with facial anomalies, strabismus and conductive hearing impairment. It is commonly caused by NOG (17q22) mutations, as a part of the so-called "NOG-related Symphalangism Spectrum Disorders". We report a 11-years old boy presenting with synostosis of the proximal interphalangeal joints of the fifth finger of the hands, tall stature, facial anomalies (broad nasal bridge, hypoplastic alae nasi, thin upper lip, prognatism), webbed second and third toes, pes valgus, synostosis of cervical vertebrae C3-C4, subluxation of the radial heads, conductive hearing loss; he had normal mental development. CT-scan of temporal bones and brain MRI showed normal data. A clinical diagnosis of SYNS was proposed. It is noteworthy that tall stature has been described in 2 other cases of SYNS. Search for mutations in the NOG gene resulted negative. Array-CGH analysis with a resolution of 100 Kb revealed a partial monosomy of 17q22, extending for about 320 kb, including the NOG gene. Deletions of the 17q22 have been associated to a more complex phenotype, including microcephaly, developmental delay, heart malformations, limbs anomalies (including symphalangism), tracheoesophageal fistula and hearing loss (either sensorineural or conductive). To our knowledge, this is the first case of SYNS due to a specific NOG gene deletion.

J02.15

Fibrochondrogenesis in a 26-week fetus: Hepatic fibrosis

U. Çetincelik, A. Atıs, D. Sakız;
Sisli Etfal Training & Research Hospital, İstanbul, Turkey.

Fibrochondrogenesis is a rare condition, neonatally and perinatally lethal osteocondrodysplasia with an autosomal recessive mode of inheritance. The disease is clinically characterized by a flat midface with a small nose and anteverted nares, significant shortening of all limb segments and a small bell-shaped thorax with a tuberant abdomen. We report a 26-week male fetus in which the diagnosis of lethal osteochondrodysplasia was suspected on prenatal ultrasound. After termination of pregnancy, fibrochondrogenesis was confirmed in the postpartum physical and radiological examination, the histopathological study showed us the presence of hepatic fibrosis in addition to fibrochondrogenesis. Here we present a new case of fibrochondrogenesis with hepatic fibrosis which is not previously described. We discussed the molecular pathogenesis of the case.

J02.16

Fibrodysplasia Ossificans Progressiva (FOP) in Cyprus: First case report and management issues

G. A. Tanteles, T. Delikurt, E. Spanou, A. Kotti, V. Anastasiadou-Christophidou;
Cyprus Institute of Neurology & Genetics, Nicosia, Cyprus.

Fibrodysplasia Ossificans Progressiva (FOP; MIM#135100), is a very rare and severely disabling autosomal dominant genetic disorder characterised by congenital malformation of the great toes and progressive heterotopic endochondral ossification in specific anatomic patterns. Bone forms at extraskeletal sites within tissues such as skeletal muscles, tendons, ligaments, fasciae and aponeuroses. Attempts to surgically remove heterotopic bone risk provoking explosive and painful new bone growth. Although most cases occur in individuals with no prior family history of FOP, autosomal dominant inheritance has been observed in a small number of families.
We report a 27-year-old lady with FOP, the first case ever reported in Cyprus. She presented with a long standing history of joint stiffness, episodic painful inflammatory soft tissue swellings over the arms and back and increasing mobility difficulties starting from her early teens. Analysis revealed that she was heterozygous for the c.617G>A (p.Arg206His) *ACVR1* mutation, reported in all classically affected FOP patients. She has recently started having reduced

temporomandibular joint mobility and chewing difficulties. The case illustrates management complexities for rare disorders particularly in relatively small centres.

J02.17

Identification of a novel de novo mutation in *FLNA* in a patient with late onset temporal lobe epilepsy

A. Beleza-Meireles[1], *L. Ramos*[1], *U. Hehr*[2], *F. Sales*[3], *J. M. Saraiva*[1];
[1]*Department of Medical Genetics, Paediatric Hospital, CHUC EPE, Coimbra, Portugal,* [2]*Center for and Department of Human Genetics, University of Regensburg, Regensburg, Germany,* [3]*Department of Neurology, Coimbra University Hospital, CHUC EPE, Coimbra, Portugal.*

Cortical malformations associated with defects in neuronal migration result in severe developmental consequences including intractable epilepsy and intellectual disability. However, female carriers of X-linked disorders may present very subtle clinical manifestations.

We present the case of previously healthy 34 year old woman, daughter of consanguineous parents, referred to our clinic due to late onset partial focal epilepsy. The initial presentation consisted of lightheadedness, dysphoric episodes and other unspecific symptoms, sometimes followed by loss-of-consciousness. The diagnosis of temporal lobe epilepsy was suggested. An MRI scan of the brain identified bilateral symmetric periventricular nodular heterotopias.

There was no relevant family history. Since the patient was planning a pregnancy, she was referred for genetic counseling at the Medical Genetics Department. Due to her parents' consanguinity, we performed linkage analysis for the ARFGEF2 locus, which revealed that the patient was homozygous for all informative markers. We proceeded to sequence analysis of this gene, which identified no mutation.

We then performed sequencing of FLNA, associated with X-linked periventricular nodular heterotopia. A *de novo* missense mutation p.Pro97Ser was identified in exon 2. This mutation has not been described previously, and is predicted to be disease causing.

The knowledge of this mutation will allow specific genetic counseling to this patient, who is at risk of having severely affected sons. This report also highlights the importance of considering de novo mutation in consanguineous families.

J02.18

Clinical and genetical study of patients from Republic Bashkortostan with novel mutation in GJB1 gene.

D. Galieva[1], *E. Saifullina*[1], *I. Skachkova*[2], *I. Khidiyatova*[2], *R. Magzhanov*[1], *E. Khusnutdinova*[2];
[1]*Bashkir State Medical University, Ufa, Russian Federation,* [2]*Institute of Biochemistry and Genetics, Russian Academy of Sciences, Ufa, Russian Federation.*

Hereditary motor-sensory neuropathy IX occurs in 13,7 % of all HMSN cases in the Republic of Bashkortostan. Two out of three GJBI missense mutations were previously described: p.Pro87Ala (259C>G) and p.Arg22Gln (c.65G>A). The p.Thr86Ile (c.257C>T) mutation is novel. In the family with novel mutation the disease began in two males in their second decade of life and was characterized by severe impairment of the peripheral nerves with CNS involvement. Their clinical picture was presented by progressive weakness and wasting of distal extremities, reduced sensation of proprioception, sensitive ataxia, bilateral pes equinovarus deformity. Generalized postural tremor, muscle fasciculations in the hands were seen in one of the patients. Median motor conduction velocity (MCV) was 33 m/s, the M-amplitude was 3 mV. In one of female patients, first signs of the disease also appeared in her second decade of life. Her clinical picture was presented by bilateral pes equinovarus deformity, distal hypoestesia, mild weakness of distal parts of the hands, moderate weakness of the legs. Four female patients had no health complaints. Meanwhile, physical examination showed the absence of the Achilles reflexes in two of them. In the remaining two patients - neuropathy signs were identified by electroneuromyography alone.

J02.19

Is 8860 variation a rare polymorphism or associated as a secondary effect in HCM disease?

M. Montazeri, *P. Bahgdadi, M. Houshmand, M. Ataei, M. Salek;*
National Institute for Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran.

Introduction: mtDNA defects, both deletions and point mutations, have been associated with hypertrophic cardiomyopathies. The aim of this study was to establish a spectrum for mtDNA mutations in Iranian hypertrophic cardio - myopathy (HCM) patients. Material and methods: The control group was chosen among the special medical centre visitors who did not have hypertrophic cardiomyopathy or any related heart disease. Hypertrophic cardiomyopathy (HCM) is widely accepted as a pluricausal or multifactorial disease. Because of the linkage between energy metabolism in the mitochondria and cardiac muscle contraction, it is reasonable to assume that mitochondrial abnormalities may be responsible for some forms of HCM. Point mutations and deletions in the two hot spot regions of mtDNA were investigated by PCR and sequencing methods. Results: Some unreported point mutations have been found in this study but no deletion was detected. Meanwhile some of these point mutations have been investigated among HCM patients for the first time. Conclusions: A8860G transition was detected in a high proportion, raising the question whether this rare polymorphism is associated as a secondary effect in HCM disease.

J02.20

Hemifacial microsomia: case report - from diagnosis to management

C. D. Bratu, *D. Belengeanu, M. Stoian, A. Belengeanu;*
University of Medicine and Pharmacy, Timisoara, Romania.

Hemifacial microsomia (HFM) is the most frequently encountered form of isolated facial asymmetry and is the second most common facial anomaly. The prevalence is 1 in 3000 up to 1 in 5600 births. HFM is an early vascular disruption, possible associated with chromosomal anomalies. Males appear to be more affected than females and the right side of the face is affected more frequent. We report a 13 year old male patient with right hemifacial microsomia and discuss the management steps from diagnosis to treatment aiming to improve the facial and occlusal aspects. The orthodontic diagnostic was class II division 1 malocclusion with frontal open bite. The maxilla was narrowed on the involved side with decreased palatal width and unilateral crossbite. Three-dimensional CT reconstruction showed hypoplastic, malformed right mandibular body, minimal underdevelopment of the condyle and unilateral aplasia of the mandibular ramus, with absence of the glenoid fossa. On the involved side: zygomatic arch was incomplete, maxilla, squamous temporal and malar bone were small; ear presented malformed lobule with rest of pinna absent and bony atresia of external auditory canal; hypoplasia of facial muscles has also been observed. Orthodontic treatment and partial aesthetic solving of the disability with silicone implant on the affected part improved the patient's facial appearance. The treatment of patients with HFM requires an interdisciplinary approach including at least maxillofacial surgery, plastic surgery and orthodontics. Co-operation not only within the team, but also with the patients and their families is essential in order to achieve the best results.

J02.21

Hereditary multiple exostoses - clinical study of nine illustrative cases

M. GROZAVU[1], *M. Volosciuc*[2], *E. Braha*[1], *L. Butnariu*[3], *M. Panzaru*[3], *S. Popa*[3], *R. Ababei*[3], *C. Iacob*[3], *E. Gorduza*[3], *C. Rusu*[3];
[1]*University of Medicine and Pharmacy, Iasi, Romania,* [2]*Pediatric Hospital „Sfanta Maria", Iasi, Romania,* [3]*University of Medicine and Pharmacy „Grigore T.Popa", Iasi, Romania.*

Hereditary multiple exostoses (HME) is a rare medical condition in which multiple bony spurs/lumps (exostoses/osteochondromas) develop on the bones of a child. The prevalence is estimated at 1:50,000 and seems to be higher in males (male/female ratio 1.5:1).

We present a clinical study of 9 cases of HME (6 male and 3 female) diagnosed in our Medical Genetics Center, to discuss suggestive features, particularities, long term follow-up, management and genetic counseling. This exploratory descriptive aims also to study the impact on daily living activities and quality of life.

According to literature, most commonly involved bones are the femur(30%), radius/ulna(26%), tibia(20%) and fibula (13%). Hand deformity, resulting from shortened metacarpals, is common. Axial sites, such as the pelvis, scapula, ribs and spine are more commonly the location of degeneration of osteochondromas to chondrosarcoma.

In our study exostoses are present in all patients. The most frequently involved bones were tibia and fibula - 6 cases (66.7%), ribs and scapula 4 cases (44.4%), humerus, radius/ulna and fist 3 cases (33.3%), the femur and knee are affected in 2 cases (22.2%), the spine and elbow in 1 case (11.1%). 3 cases were familial. No tumoral degeneration was identified.

Other associated anomalies are: scoliosis, lower-back pain, moderate pectus excavatum, tumefaction of the elbow joint, brachydactyly, clinodactyly of fifth finger, long fourth finger, genu valgum.

In conclusion, we present the clinical study of 9 illustrative HME cases, discussing particularities and consequences on daily living and quality of life, as well as management and genetic counseling issues.

Clinical and imagistic correlations among pathological forms of holoprosencephaly

***M. Boia**, D. Iacob, A. Manea;*
University of Medicine and Pharmacology ,V.Babes', Neonatology, Timisoara, Romania, Timisoara, Romania.

Introduction:
The absence or the incomplete cleavage of prosencephalon into diencephalon and telencephalon in the 4-8 th weeks of fetal life, leads to holoprosencephaly. This is often associated with severe facial anomalies, microcephaly, hipertelorism and labio-palatine clefting.
There are multiple and various genetic implications (chromosomal deletions 2p21; 7q36; trisomy 13) which are associated with multiple environmental factors.
In this paper the authors aim to process the clinical and imagistic data resulted from the study of 4 clinical cases.
Material and method:
The study lot consisted of 4 newborn: 3 on term newborn with GA (gestational age)= 39-40 weeks and BW (birth weight)= 3500-4000 g and 1 new born with IUGR (intrauterine growth restriction).
On term newborn presented labio-palatine clefting; two of them presented cardiac malformations (Atrial septal defect and Ventricular septal defect); they were classified as having Semilobar Holoprosencephaly.
Newborn diagnosed with Semilobar Holoprosencephaly had altered phenotype: hipertelorism (2 clinical cases); labio-palatine clefting (3 clinical cases); micrognathia; flattened nose and upper implanted ear.
Cranial ultrasound and MRI showed anomalies of the interhemisferic split, agenesis of the posterior region of corpus callosum, various degrees of fusion of the lateral ventricles, the absence of cavum septum pellucida.
Conclusions:
Semilobar Holoprosencephaly is a severe form of illness due to the brain malformation which determines growth anomalies and severe neurological retardation.

MLPA analysis in 25 Brazilians individuals with Holoprosencephaly

***B. F. Gamba**[1], C. C. Legnaro[2], M. C. S. Sandri[2], A. Richieri-Costa[2], L. A. Ribeiro-Bicudo[2];*
[1]Universidade Estadual Paulista - Unesp/Brazil, Botucatu, Brazil, [2]Hospital de Reabilitação de Anomalias Craniofaciais - HRAC-USP, Bauru, Brazil.

Holoprosecephaly is a common disorder of the developing forebrain in humans, occurring with a frequency of 1:250 conceptuses. The etiology is heterogeneous and complex, as this developmental disorder can be due to environmental factors, chromosomal aberrations, or genetic anomalies. SHH, ZIC2, SIX3 and TGIF genes are the four major genes implicated in the susceptibility to HPE, but have only been found to explain 25% of the genetic cases, including mutations and microdeletion. We analyzed a cohort 26 individuals within the holoprosencephaly spectrum thought Multiplex Ligation Dependent Probe Amplification (MLPA) technique using P187 Holoprosencephaly Kit (MRHC-Holland®). All individuals have been previously analyzed for mutation in SHH, ZIC2, SIX3 and TGIF genes. We found one case with deletion in SHH gene. Numerous isolated HPE case reported have shown that most of the chromosomes have been implicated, emphasizing the genetic heterogeneity of HPE. Considering this multigenic aspect of the disease, investigation of HPE loci and identification of new HPE genes must be continued. Mutations and deletions in HPE genes do not always lead to physical signs of HPE, however this information may be helpful for genetic counseling purposes.

Findings in a routine setup of molecular diagnostics in Hypertrophic and Dilated Cardiomyopathy

***C. Meyer-Kleine**[1], P. Binner[1], W. Maerz[2], T. Scheffold[3];*
[1]synlab MVZ Bad Nauheim, Bad Nauheim, Germany, [2]Institute of Public Health, University Heidelberg, Mannheim, Germany, [3]Celenus Fachklinik, Freiburg, Germany.

Background: Many findings has been published regarding the genetic background of hypertrophic (HCM) and dilated (DCM) cardiomyopathies. Hundred of mutations in a vast number of disease genes could be identified. However, most data were established using well defined study populations. In contrast, only few data are available about routine patients without study based preselection bias.
Materials and methods: We studied n=104 consecutive patients with HCM and n=22 cases with DCM. In HCM a panel of the most frequent disease genes MYH7, MYBPC3, TNNT2, and TNNI3 encoding for ß-myosin heavy chain, myosin binding protein C, cardiac troponin T and cardiac troponin I respectively, were analyzed using direct terminatorsequencing technology (ABI-BigDye-*Terminator*v1; 3130*XL*). In DCM a panel of the most frequent disease genes LMNA (encoding for Lamin A/C), MYBPC3, MYH7 and TNNT2 respectively, underwent analyses.
Results: In HCM of 104 pts in n=54 pts (52%) using the HCM diagnostic panel a mutation in one of the disease genes could be found, whereas in DCM of 22 pts in n=3 pts (14%) using the DCM diagnostic panel could be detected.
Conclusions: In molecular diagnostics of serial HCM and DCM patients using specific panels of the most frequent disease genes in HCM more than a half of all patients and in DCM more than 10% of all cases could be genotyped positively. This is comparable to study based data. These findings indicate the positive transfer of scientific data into clinical routine use in favour of a better patients care in the field of genetic counseling.

J02.25
KID syndrome: multiple joint contractures in Lithuanian patient with *GJB2* gene mutation

***B. Burnyte**[1,2], A. Utkus[1,2], H. Gabriel[3], V. Kučinskas[1,2];*
[1]Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Vilnius, Lithuania, [2]Centre for Medical Genetics, Vilnius University Hospital Santariskiu Klinikos, Vilnius, Lithuania, [3]Diagenos, Osnabrueck, Niedersachsen, Germany.

Keratitis-ichthyosis-deafness (KID) syndrome is a rare congenital ectodermal disorder, characterized by the presence of localized erythematous scaly skin lesions, sensorineural deafness and severe bilateral keratitis. We present the first Lithuanian patient with a heterozygous missense mutation c.148G>T (p.Asp50Tyr) in *GJB2*. The boy has typical clinical features for KID syndrome consisting of diffuse hyperkeratotic erythroderma, bilateral keratoconjunctivitis, moderate bilateral sensorineural hearing loss, paronychia with nail dystrophy, alopecia totalis. Besides, he developed multiple joint contractures at the age of 3. To our knowledge, these findings have not been reported previously. We propose that the multiple joint contractures observed in our patient with p.Asp50Tyr are a severe subtype of Keratitis-ichthyosis-deafness syndrome, thus expanding the spectrum of connexin-associated keratodermias.

J02.26
Possible mosaicism in a case of lingual plexiform neurofibroma

***F. F. Cionca**[1], L. Cionca[2], C. Nastasia[2], C. Ardeleanu[1];*
[1]"Victor Babes" National Institute for Research and Development in Pathology and Biomedical Sciences, Bucharest, Romania, [2]"Prof. Dr. Dan Teodorescu" Clinical Hospital of Oro-Maxilo-Facial Surgery, Bucharest, Romania.

Introduction
Neurofibromatosis type I is typically an autosomal dominant inherited disorder with complete penetrance and variable expressivity, generated by the neurofibromin mutation, a tumor suppressor gene located on chromosome 17q11.2.
50% of the cases are mutations de novo, with no other affected family members. Somatic mosaicism accounts for many sporadic cases.
The classic NF1 is characterized by multiple neuro-fibromatous tumors, including the plexiform neurofibroma, cafe-au-lait spots, freckling of the groin or the axilla, Lisch nodules in the eye and skeletal abnormalities.
The patients have increased susceptibility to develop other benign or malignant tumors, so they need regular follow-up to detect malignant degeneration, an early recurrence or appearance of other manifestations.
A particular aspect is described in some patients, presenting only one clinical criterion of diagnostic, possibly generated by a mosaic form and having, in this situation, serious implications for the patient's evolution and its family.
Case presentation
A 29 years old male was hospitalized for a large tumor located on the right hemi tongue. There were no other clinical findings in physical examination. The pathological personal antecedents and the family history were negative.
Histological examination demonstrated the presence of a lingual plexiform neurofibroma.
Conclusion
Despite their occurrence in the head and neck region, neural sheath tumors are rare in the oral cavity; oral manifestations are reported much often in patients affected by neurofibromatosis.
Because of this, we think our patient may present a form of mosaicism and needs genetic testing for NF1 mutations, considering the possible implications.

Investigation of Familial Mediterranean fever (FMF) in 25 Iranian patients

v. ghodsinejadkalahroudi[1], *a. arastehkani*[1], *m. balali*[1], *o. aryani*[1], *m. houshmand*[2];
[1]special medical center, tehran, Islamic Republic of Iran, [2]National Institute for Genetic Engineering and Biotechnology, tehran, Islamic Republic of Iran.

Familial Mediterranean fever (FMF) is an Autosomal recessive disorder characterized by recurrent Attacks of fever and inflammation in the peritoneum, synovium, or pleura, accompanied by pain. FMF is caused by mutations in MEFV gene that is located at 16p13.3 and encodes a protein, pyrin or marenostrin.

In this study , PCR and sequencing method was performed for four high rate mutation exons of MEFV gene (2,3,5,10) in 25 unrelated Iranian patients. The most frequent homozygote mutation was R202Q (in %24), followed by M694V (in 16%), and M680I (in 8%). Eight percent were compound heterozygotes for three mutations (V726A, E167D, F479L).

Proband with Hunter syndrome: ten years later

M. O. Mkheidze, *E. S. Shabanova;*
The North-West State Medical University named after I. I. Mechnikov, St.Petersburg, Russian Federation.

Mucopolysaccharidosis II, Hunter syndrome (MPS II, OMIM 309900, Xq28, IDS, OMIM 300823), is a rare disorder caused by deficiency of the lysosomal enzyme iduronate sulfatase ((EC 3.1.6.13), leading to progressive accumulation of glycosaminoglucans in nearly all cell types, tissues, and organs. We reported on this case of HS in EJHG, v.11, Suppl 1, P. 166, 2003. Now proband is 18 yr aged. His intelligence is normal and the youth is the tenth grader of a comprehensive school. Proband has progressive coarsening of facial features, short stature (124cm) and underweight (32kg), skeletal deformities of thorax and feet, protuberant abdomen, hypermetropic astigmatism (S=D), chronic purulent ethmoiditis, cerebral ventricular dilation, cardiac valvular disease (myxomatosis of mitral valve and mitral regurgitation, cardiomyopathy), hepatosplenomegaly. Joint mobility is decreased, and the fingers have clawlike deformities. Laboratory findings and imaging studies were found to show moderate abnormalities. Unilateral auditory prosthetics was made. Care for our patient with HS involves a multidisciplinary approach and includes pediatrician, neurologist, orthopedist, otolaryngologist, ophthalmologist, geneticist etc. To our regret ERT was not available.

J02.29

Novel mutations detected in the NF1-gene

F. Joncourt, *S. Gallati;*
Division of Human Genetics, University Hospital, Bern, Switzerland.

Mutations in the NF1 gene are the cause of Neurofibromatosis type1, the most common tumor-predisposing disorder in humans. As the mutation rate in the NF1-gene is among the highest known, analysis of the NF1 gene continues to reveal novel mutations in many patients. Because of the large size of the gene, the lack of a mutation hot spot and the diversity of pathogenic mutations found NF1 analyses have long been laborious and sometimes yielded unsatisfactory results. Newer techniques are more efficient and allow detection of a causative mutation in the great majority of NF1-patients. We report on 7 novel NF1 mutations not yet described in the HGMD mutation database (version 9.12.2011). Among them a spectrum of different mutation types was found: 3 splice site mutations, caused by a small deletion (c.654+2delT), a duplication (c.2325+1dupG) and a base change (c.7126+1G>A) respectively, all concerning splice site consensus sequence positions. Furthermore we detected 2 missense mutations (c.3503G>A, c.6718C>T), 1 nonsense mutation (c.4720C>T) and 1 duplication leading to a frameshift (c.6676dupA). Two of the patients were adults, for whom genetic analysis served the confirmation of the clinical diagnosis. The patients who benefit most from the ameliorated mutation detection, however, are young patients with only little clinical manifestations and hence uncertain diagnosis. This was the case for five of the patients, who at the time of diagnosis were 11 years old (1 patient) or younger than two years (4 patients).

Genetic testing for Neurofibromatosis (NF1). When and why?

H. Fryssira[1], *A. Syrmou*[1], *S. Psoni*[1], *S. Kitsiou-Tzeli*[1], *A. Mavrou*[1], *K. Claes*[2], *E. Kanavakis*[1];
[1]Department of Medical Genetics, University of Athens, «Aghia Sophia» Childrens Hospital,Greece, Athens, Greece, Greece, [2]Center for Medical Genetics-OMRB, Ghent University Hospital, Gent, Belgium, Belgium.

The diagnosis of Neurofibromatosis (NF1), a common autosomal dominant disorder affecting 1/3500 individuals, is based on well-defined clinical criteria in adults which are unsatisfactory in children. The responsible gene is the *NF1* tumor-suppressor coding for the neurofibromin. Approximately 50% of cases represent new mutations.

We describe the phenotypic and genetic variations in 39 Greek NF1 patients and point out the significance of early genetic testing, aged 7-months to 34-years (21 males/18 females).13 patients underwent molecular analysis of the *NF1* by cDNA sequencing of all exons and were found positive, 6 of them were younger than four years. If no mutation was detected the presence/absence of deletions was verified by MLPA. Our patients presented the following NF1 clinical features: café-au-lait spots in 34/39, two or more neurofibromas in 15/39, axillary or inguinal freckling in 9/39, optic glioma in 2/39, two or more Lisch nodules in 5/39, bony lesions in 13/39 and a first-degree relative affected with NF1 in 15/39. 5/39 patients had tumors (except neurofibromas) and mental retardation presented in 7/39 individuals older than 3 years. 15/39 patients had abnormalities in the brain MRI. 4/13 patients analyzed, carried novel mutations, 4/13 had missense, 2/13 frameshift, 6/13 nonsense and 1/13 a large deletion.

From our small group of NF1-patients we must strongly recommend the implementation of molecular testing at an early age as clinical diagnosis is difficult in young children. The sooner the molecular analysis is performed the more beneficial it is for the family counselling and the follow-up of the patients.

J02.31

A particular presentation in a possible case of segmental neurofibromatosis Type I

F. M. NEDELEA[1], *L. Turculet*[1], *V. Plaiasu*[2], *C. Ailenei*[1], *G. Peltecu*[1,3];
[1]Clinical Hospital Filantropia, Bucharest, Romania, [2]Institute for Mother and Child ”Alfred Rusescu”, Bucharest, Romania, [3]University of Medicine ”Carol Davila”, Bucharest, Romania.

Neurofibromatosis type I is an autosomal dominant condition, with birth incidence 1/3500 and a high degree of variability of clinical expression.

Segmental or regional neurofibromatosis type I (NF1) is diagnosed in individuals who have features of NF 1, restricted to a part of the body and has an incidence approximately 1/40.000. Some of those patients displaying only pigmentary changes or dermal neurofibromas, and others having both features .

In some cases the unusual distribution of features is probably just a chance occurrence in a individual with NF1. In other individuals segmental neurofibromatosis type I represents mosaicism for a somatic NF 1 mutation.

We report a case of a 30 years old woman who associates plexiform neurofibroma in lumbar region,and has also a pigmented area with asymmetrical distribution in lumbar region, flanks, and downwards on superior parts of the legs. She is the first affected person in her family. Because the tumor growth is progressive and patient associates also pain the surgical removal is the first priority.Patient wants to have children after this intervention, but counselling is very difficult, knowing that have been reported cases with segmental NF1 whose children have typical NF1. Prenatal diagnosis is controversial and limited , because even in presence of molecular diagnosis severity of the disease cannot be predicted in affected fetus

J02.32

Congenital heart defects in oculo-auriculo-vertebral spectrum

M. C. Panzaru[1], *C. Rusu*[1], *M. Volosciuc*[2], *E. Braha*[1], *L. Butnariu*[1], *L. Caba*[1], *M. Macovei*[1], *R. Popescu*[1], *E. V. Gorduza*[1];
[1]“Grigore T. Popa“ University of Medicine and Pharmacy, Iasi, Romania, [2]“Sf. Maria“ Children Hospital, Iasi, Romania.

The oculo-auriculo-vertebral spectrum (OAVS) is a non-random association of hemifacial microsomia with mandibular hypoplasia, ear malformations, preauricular tags and ocular dermoid cysts. Most cases are sporadic. The underlying genetic mechanism remains unknown. Congenital heart defects (CHD) have been reported in 5-60% of the patients.

We have analysed the types of CHD in 18 children with OAVS recorded in the files of Iasi Medical Genetics Center between January 2006 and December 2011. There were 7 girls and 11 boys. The diagnosis was based on the presence of the characteristic features of the disorder. CHD were present in 8 children - atrial septal defect (5/18), Fallot tetralogy (2/18) and ventricular septal defects (1/18). The prevalence of heart defects was higher in boys (54,54%) than in girls (28,5%). We found no correlation between the severity of the clinical manifestations and the association with CHD. In the literature ventricular septal defect and Fallot tetralogy are the most frequent CHD associated with OAVS. The comparison of our data and the literature data will be presented in detail.

In conclusion we present a study of 18 cases with oculo-auriculo-vertebral spectrum, 44,44% of them having heart defects. Cardiac defects are commonly associated to OAVS and males are more frequently affected than females. Echocardiography should be a routine investigation in patients with OAVS.

J02.33

Oral-Facial-Digital Syndrome (type I): A case report.

R. A. Cedeno;
Medical Genetic Unity, Maracaibo, Venezuela, Bolivarian Republic of.

Oral-facial-digital syndrome type 1 (OFDI; OFD1; OMIM 311200) is a rare developmental disorder transmitted as an X-linked dominant condition with embryonic male lethality. OFD1 is characterized by malformation of the oral cavity, face, and digits. Central nervous system (CNS) abnormalities and cystic kidney disease can also be part of this condition. Lesions in the mouth include median pseudoclefting of the upper lip, clefts of the palate and tonge, lingual tumors and dental anomalies (missing or supernumerary teeth, enamel hypoplasia, and teeth malpositions). Dysmorphic features affecting the face include hypertelorism, frontal bossing, micrognathia, facial asymmetry, alar hypoplasia and broadened nasal ridge. The digital abnormalities are syndactyly, clinodactyly, brachydactyly and, rarely, pre or postaxial polydactytly. Less frequently expressed phenotypic anomalies include skin milia, alopecia, deafness and trembling.It is considered to be a ciliopathy caused by mutations in the OFD1 gene. A variety of mutations have been described, and a genotype-phenotype correlation has been suggested.This disorder is due to mutations in the OFD1 gene that encodes a centrosomal protein localized at the basal bodies at the origin of primary cilia.

The proband was a female newborn, sporadic case with suspected OFD1. This newborn had many of the typical manifestations, including frontal bossing, micrognathia,lingual tumors, cleft tonge, clynodactily and others less frequently signs findings : alopecia and skin milia. We extended the pedigree to three proband's generations, performing a thorough physical examination .In the light of this case, the author discuss the variability phenotypic expression of OFD1 gene and the genetic counseling in this family

J02.34

Pathological findings of a male fetus with familial Pelizaeus-Merzbacher disease caused by a 320.6Kb Xq22.2 duplication

*S. Kitsiou-Tzeli[1], A. Konstantinidou[2], C. Sofocleous[1], **K. Kosma**[1], A. Syrmou[1], K. Giannikou[1], S. Sifakis[3], P. Makrythanasis[4], M. Tzetis[1];*
[1]Department of Medical Genetics, Medical School, University of Athens, Athens, Greece, [2]1st Department of Pathology, Medical School, University of Athens, Greece, Athens, Greece, [3]1st Department of Obstetrics and Gynaecology, University of Crete,, Heraklion, Greece, [4]Service of Genetic Medicine, University Hospital of Geneva, Geneva, Switzerland.

Pelizaeus-Merzbacher disease (PMD) is a disorder with clinical variability, ranging from the severe connatal form to the classical form. We present the clinical and molecular findings of two affected males, three carrier females and an aborted male fetus with familial PMD. The two male probands exhibited severe PMD phenotype and intellectual disability (ID). High resolution oligonucleotide based array comparative genomic hybridization (aCGH) identified Xq22.2 duplication of 320.6Kb [102641391-102961998, hg18], including the proteolipid protein 1 gene(*PLP1*) and surrounding chromosomal region. Postmortem examination was completed in the aborted male fetus. To our knowledge this is the first report of specific neuropathological lesions in a fetus with familial *PLP1* duplication. The observed early degenerative brain lesions occurring before the onset of myelination suggest that the *PLP1* gene has a more complex role in human brain development exceeding its structural function in myelin formation.

J02.35

A case with Rhizomelic chondrodysplasia punctata

***E. KOPARIR**[1], A. Gezdirici[1], A. Koparır[1], H. Ulucan[1], G. Güven[1], E. Yosunkaya[1], M. Seven[1], A. Yüksel[2], M. Ozen[1];*
[1]Istanbul university cerrahpasa medical school, Istanbul, Turkey, [2]Bezmialem Vakif University, Istanbul, Turkey.

Rhizomelic chondrodysplasia punctata (RCDP) is an autosomal recessive peroxisomal disorder with a phenotype of proximal shortening of humerus and femur, punctate calcifications around the large cartilage, possible calcification of the intervertebral discs, cataract, severe mental deficiency,and postnatal growth retardation. It usually results in death in the first decade of life. Characteristic biochemical criteria were present: decreased plasmalogens, elevated levels of plasma phytanic acid, and normal levels of very long chain fatty acids. Three variants: RCDP1, RCDP2 and RCDP3 are caused by mutations in the *PEX7*, *GNPAT* and *AGPS,* respectively. The clinical picture in RCDP2 and RCDP3 is similar with RCDP1, which is the most frequent type. To distinguish the subtypes, enzyme analysis is necessary from the skin fibroblasts.

Here, we report a 7-month-old female with bilateral cataract, punctate calcifications around the large cartilage, and postnatal growth retardation. Plasma phytanic acid level was elevated and long chain fatty acids levels were normal. The clinical phenotype and biochemical tests were consistent with RCDP and we analyzed our patient for *PEX7* mutations. Sequence analysis of all exons and intron-exon boundaries of *PEX7* showed no mutation. Enzyme analysis for subtyping and mutation analysis of the corresponding genes, *GNPAT* and *AGPS* are in progress.

J02.36

A Case of Sirenomelia Sequence with Aprosencephaly

*M. Ikbal[1], H. Kahveci[2], **M. Y. Alp**[1], B. A. Aksoy[2], F. Laloglu[2], E. Kacmaz[2];*
[1]Karadeniz Technical University, Medical Faculty, Department of Medical Genetics, Trabzon, Turkey, [2]Nenehatun Obstetrics Hospital, Neonatal Intensive Care Unit, Erzurum, Turkey.

Sirenomelia sequence is a rare congenital anomaly. This is also known as "mermaid syndrome" because of typical feature of lower limb. Sirenomelia sequence is characterized with a single midline lower limb. Our case is an infant delivered at 34 gestational weeks by spontaneous vaginal delivery from a 34 years old gravida 2, para 0. Parents are not relative. Infant has one femur, one tibia and one phalanx at lower extremity. Calcaneus, metatarsals and other bones of the footh are absent. Patient has anal atresia and renal agenesy. Determinig of sex was impossible since external genitalia was absent. Ultrasonographic examination revealed aprosencphaly. Altough some risk factors (e.g maternal diabetes) have been suggested, etiolgy of sirenomelia sequence is debated. In this report, we describe a premature infant with sirenomelia sequence because of very rare presentation.

J02.37

Gross deletion in the SLC22A5 gene

***A. Stepanova**[1], S. Lisicina[2], A. Polyakov[1];*
[1]Russian Academy of Medical Sciences, Research Center for Medical Genetic, Moscow, Russian Federation, [2]Research Center of Pediatrics and Child Surgery, Russian Health Ministry, Moscow, Russia, Moscow, Russian Federation.

Systemic primary carnitine deficiency is an autosomal recessive disorder of fatty acid oxidation. Disorder is affected by mutation in SLC22A5 gene, which consists of 10 exons, maps to chromosome 5q31 and encodes the novel organic cation transporter (OCTN2). Affected patients can have a predominant metabolic or cardiac presentation.

We have studied the patient with systemic primary carnitine deficiency. Primers for sequence analysis of coding regions and flanking intronic SLC22A5 gene were chosen. PCR products of exons 8, 9, 10 were not received. Exons 8, 9, 10 were amplified in diplex PCR with the control marker - exon 13 PAH gene, mapping outside the SLC22A5 gene. PCR product was found only from the control marker.

Therefore, a homozygous novel mutation - the deletion of exons 8, 9, 10 of the SLC22A5 gene was found.

As a result diagnosis of systemic primary carnitine deficiency was confirmed for the first time in Russia by molecular genetic methods.

J02.38

Coexistence of Townes-Brocks syndrome and Albinism in a case

***K. Nadir**, D. Gün, T. Çora, H. Acar;*
Selçuk University, Selçuklu Medical Faculty,The Department of Medical Genetics, Konya, Turkey.

Townes-Brocks syndrome (TBS) is a genetic disorder. The most common features of this syndrome are anal atresia, abnormally shaped ears, and hand malformations that most often affect the thumb. Most people with this condition have at least two of these three major features. Albinism is one of the archetypal inborn errors of metabolism. It is usually defined as a congenital hypopigmentation of the skin, hair, or eyes. In this report, we present 9 months male case having dismorphic features. The patient's mother and father were not consanguineous. Cytogenetic analysis was normal. The patient had an anal atresia, low and simple ears, ear tag, simian line and short palpebral fissure. In addition to these findings, he has also a congenital hypopigmentation of the skin, hair and eye, indicating albinism. This finding was seen in his mother diagnosed as albinism. This is the first case having coexistence of TBS and albinism in the literature. It is not clear whether this syndrome is associated with the other or independent event.

J02.39

The wide phenotypic variability of Tricho-rino-phalangeal syndrome type I - a five cases study

R. Ababei[1], *M. Volosciuc*[1], *M. Panzaru*[2], *L. Butnariu*[2], *E. Braha*[2], *S. Popa*[1], *A. Grozavu*[1], *C. Iacob*[1], *E. Gorduza*[2], *C. Rusu*[2];
[1]*Medical Genetics Center, „Sfanta Maria" Children's Hospital, Iasi, Romania,* [2]*"Grigore T. Popa " University of Medicine and Pharmacy, Medical Genetics Department, Iasi, Romania.*

Tricho-rino-phalangeal syndrome (TRFS) is a rare autosomal dominant syndrome, characterized by short stature, typical facial dysmorphism and skeletal abnormalities.
We present 5 cases of TRFS in order to illustrate this rare disorder, to present particularities and long term follow-up and to discuss management and genetic counseling.
Case 1: growth retardation, dysmorphic face (sparse/fine/depigmented hair, medial flare of eyebrows, bulbous nasal tip, hypoplastic nostrils, thin lips, microretrognathia), brachydactyly. Associated anomalies: scaphocephaly, hemangioma, cryptorchidism and right inguinal hernia.
Case 2: growth retardation, dysmorphic face (sparse/fine hair, lateral thinning of eyebrows, bulbous nose, hypoplastic nostrils, long/deeply grooved philtrum, thin lips), broad thumb, preaxial polydactyly (foot). Associated anomalies: umbilical hernia.
Case 3: short stature, dysmorphic face (sparse/fine/depigmented hair, lateral thinning of eyebrows, bulbous nose, long philtrum, thin lips, microdontia, micrognathia), thick nails. Hand X-ray: metacarpal shortening, cone-shaped epiphyses (middle/distal phalanges), delayed bone age. Associated anomalies: empty sella, posterior fossa arachnoid cyst (head CT), hypothyroidism.
Case 4: growth retardation, dysmorphic face (sparse/fine/depigmented hair, hypoplastic nostrils, long philtrum, high palate, abnormal tooth position, retrognathia), brachydactyly, kyphosis, scapulae alatae, mild mental retardation. Hand and forearm X-ray: slightly curved radius, clinodactyly.
Case 5: low weight, dysmorphic face (sparse scalp hair, abnormal columella, long/deeply grooved philtrum, thin lips, micrognathia, large ears), mild hypotonia. Associated anomalies: trigonocephaly, left inguinal hernia.
In conclusion, we present five cases of TRFS, in order to illustrate this rare genetic disorder, to discuss phenotypic variability and particularities found in our patients, as well as long term follow-up, management and genetic counseling.

Karyotype and treatment response correlations in Turner Syndrome

A. Chirita Emandi[1], *I. Micle*[1], *M. Marazan*[1], *C. Pienar*[1], *M. Puiu*[2];
[1]*„Louis Turcanu" Emergency Hospital for Children Timisoara, Timisoara, Romania,* [2]*University of Medicine and Pharmacy „Victor Babes", Timisoara, Romania.*

Aim: To assess treatment response to growth hormone (GH) and estrogenic therapy in girls with Turner syndrome (TS) and find possible correlations with karyotype. **Methods:** Nine girls diagnosed with TS that received treatment with GH for at least 2 years. We evaluated differences in height standard deviation score (HSDS), at baseline, at one and two years from baseline; and pubertal stage development in patients with or without estrogen therapy. **Results:** Median age was 12.1+/-3.7 years. Chromosomal analysis revealed six girls (66%) with pure 45X monosomy, while 3 (33%) had mosaic form. The patients had a baseline mean HSDS=-3.29±0.65. After 2 years of GH treatment only one patient achieved HSDS>-2 value for normal girls. Mean difference in HSDS after 1 year was 0.27+/-0.31; after 2 years it was -0.17+/-0.22 ($p=0.047$). Regarding estrogen replacement therapy: two patients from study did not reach puberty onset age; four of them had spontaneous puberty without treatment; two girls responded well to estrogen therapy, while one did not. We found weak correlations between pure monosomy and the necessity for estrogen therapy ($r=0.5$;$p=0.17$) and between pure monosomy and mean HSDS difference after 2 years with GH ($r=-0.35$; $p=0.34$). **Conclusions:** Results showed great variability in treatment response in girls with TS, in both GH and estrogen treatment, which could not be strongly correlated with karyotype. Larger studies are needed to assess these important correlations that could guide therapy for these patients in the future.

J02.41

Primary polytopic developmental anomalies - a particular form of VACTERL association?

T. Marcovici[1,2], *O. Marginean*[1,2], *O. Belei*[1,2], *C. Daescu*[1,2], *A. Militaru*[1,2], *L. Olariu*[1,2], *D. Chiru*[1,2], *O. Sarbu*[2], *M. Puiu*[1,2];
[1]*University of Medicine and Pharmacy „Victor Babes", Timisoara, Romania,* [2]*"Louis Turcanu" Children's Emergency Hospital, Timisoara, Romania.*

Background: VACTERL association occurs sporadic (16 cases/100,000 live births), more common in males. Low recurrence risk and heterogeneous causality are characteristic. The presence of at least three congenital malformations (Vertebral defects, Anal atresia, Cardiac anomalies, Tracheoesophageal fistula, Esophageal atresia, Renal anomalies, Limb defects) would specify diagnosis. Limb anomalies restricted to upper ones and cardiac septal defects are common. Intrauterine growth retardation and difficult weight gaining are noticed. Neurocognitive impairment is uncharacteristic. The management includes surgical correction of life-threatening abnormalities and long-term follow-up of their sequelae. Material and methods: We present a 5 months old male infant with multiple congenital anomalies (absence of right forearm, atrial septal defect, esophageal atresia, proximal tracheoesophageal fistula) admitted for pneumonia. He is the product of a full-term pregnancy complicated with hydramnios and threatened miscarriage. Birth weight was 2,600 g. Primary defects in family members and exposure to environmental factors were denied. Full assessment (history, clinical examination, biological and imagistic tests, neurological, cardiovascular and genetic evaluation) was done. Results: Productive cough, stridor, intermittent expiratory wheezing and mild weight deficit were noticed. Psychomotor acquisitions were age-appropriate. Barium swallow radiograph diagnosed gastroesphageal reflux and ruled out esophageal stricture. Child's complex pathology and mother's depressive disorder altered quality of family life. Conclusions: VACTERL association is probable in this case. Amniotic band syndrome with congenital amputation of the right forearm has been considered. Efficient orthopedic backing, genetic and family counseling, physical and occupational therapy are needed long term. Multiple and prolonged hospitalizations for recurrent pneumonia may worsen the prognosis.

J02.42

The evaluation of stress in 40 molecularly-confirmed patients with Williams-Beuren syndrome

V. A. A. S. Amaral[1], *C. R. D. C. Quaio*[1], *R. L. Dutra*[1], *R. S. Honjo*[1], *L. D. Kulikowski*[1,2], *M. N. Moreira*[1], *I. Gomy*[1], *M. C. T. V. Teixeira*[3], *D. R. Bertola*[1], *C. A. Kim*[1];
[1]*Unidade de Genética, ICr/FMUSP, São Paulo, Brazil,* [2]*LIM 3 - Hospital das Clínicas - FMUSP, São Paulo, Brazil,* [3]*Universidade Presbiteriana Mackenzie, São Paulo, Brazil.*

Psychological studies in Williams-Beuren syndrome (WBS) describe varying degrees of mental retardation, weakness in visuospatial/executive function, overfriendliness, empathy, a fluent speech and hyperacusis. They also show stereotyped behaviors, aggressiveness and some psychiatric disorders. These characteristics may increase the vulnerability of these patients to stress. The objective of this study is to determine the real extent of the stress in individuals with WBS and to identify the major events in their lives that might modulate a stress reaction.
A standard questionnaire based on DSM-IV-TR, the Brazilian version of intelligence measurement scales (WISCIII/WAIS-III) and objective stress scales (Lipp's Children Stress Scale or Lipp's Adult Stress Scale) were applied to 40 individuals with WBS. The stress scales were also applied to 40 normal individuals.
The major events related to stress reactions in the patients with WBS were excessive noise (60%), discrimination (58%) and excessive homework (35%). The average IQ in WBS was 68.5(SD: 8.89). Patients with WBS presented statistically significant ($p<0.001$) higher levels of stress (mean: 39.5) when compared to controls (mean: 24). No difference in subgroups of WBS patients stratified by gender (p: 0.74), level of IQ (p: 0.935) or whether they attended special education (p: 0.14) was observed.
Patients with WBS are at risk for stress. Hyperacusis was the most common stressor and, then, should be properly addressed in an attempt to improve the quality of life of patients with WBS.

J02.43

Meningomyelocele in the offspring of a patient with Waardenburg type 1 syndrome: a genetic counselling dilemna

M. Irabe[1], *J. Orbegozo*[1,2], *V. Mandengue*[3], *V. Pingault*[4], *L. Van Maldergem*[1];
[1]*Centre de génétique humaine, Besançon, France,* [2]*Dept of Pediatrics, University Hospital, Besançon, France,* [3]*Dept of Gynecology & Obstetrics, Regional Hospital, Vesoul, France,* [4]*Dept of Biochemistry & Genetics, CHU Henri-Mondor, Université de Paris-Est-Creteil, Créteil, France.*

We describe two cases of Waardenburg syndrome type 1, one being diagnosed in a 5 y-old male with moderate mixed deafness, *dystopia canthorum*, causing subtle skin pigmentary changes of upper limbs and the other one in the unrelated 31 y-old husband of a 29 y-old female after termination of a 22 weeks pregnancy for lumb sacral meningomyelocoele and Arnold-Chiari malformation diagnosed by serial ultrasound screening. Family history of the genitor was unremarkable, except for a recent diagnosis of moderate deafness, in the context of familial premature graying of hair before 25 years of age (mother, sister, brother). On clinical examination, he has *dys-*

topia canthorum, suggesting a diagnosis of autosomal dominant Waardenburg syndrome type1.Neural tube defects are thought to occur sporadically as the consequence of multifactorial inheritance. Based on this assumption, a low recurrence risk is usually given (<3%), and folic acid supplementation (4mg/d) in the periconceptional period recommended in the future pregnant woman. Rare occurrences of NTD due to mendelian disorders have been described. They include, among others, *MTHFR* homozygous mutations, and Meckel syndrome with respect to autosomal recessive inheritance, *Van Gogh* and *PAX3* mutations when considering autosomal dominant inheritance. If the diagnosis of Waardenburg type 1 syndrome is eventually established in the genitor of the malformed fetus, a recurrence risk of 10% (empirical value) has to be taken into consideration, three fold-higher than the *a priori* 3% risk in the present case. We recommend to be aware of premature graying, dystopia canthorum and/or deafness when counseling for NTD.

J02.44

Novel synonymic transthyretin gene mutation N98N in cardiomyopathy patient from St. Petersburg, Russia

K. V. Solovyov[1]*, N. A. Grudinina*[1]*, E. N. Semernin*[2]*, E. V. Shliakhto*[2]*, A. Y. Gudkova*[3]*, M. M. Shavlovsky*[1]*;*

[1]*Department of Molecular Genetics, Research Institute of Experimental Medicine, Northwestern Division, St. Petersburg, Russian Federation,* [2]*Almazov Federal Center of Heart and Blood, Federal Agency of High Technology Medical Assistance, St. Petersburg, Russian Federation,* [3]*Pavlov State Medical University, Institute of Cardiovascular Diseases, St. Petersburg, Russian Federation.*

Over the past several years we have been searching transthyretin (TTR) gene mutations in patients with cardiomyopathies from St. Petersburg (Russia). In our previous work TTR gene mutations H90N, V30M and deletion (del9) were found in patients with restrictive amyloid cardiomyopathy. In the present investigation new TTR gene mutation was identified in patient with hypertrophic cardiomyopathy without amyloidosis. Screening TTR gene for mutations was provided with SSCP-analysis followed by sequencing. Nucleotide substitution in position 6819 C>T according to NCBI reference sequence NC_000018.9 (c.354C>T according to NCBI reference sequence NM_00371.3) was found. This mutation leads to TTR codon substitution in the 98 position (from AAC to AAT, p.N98N (p.N118N according to the mRNA sequence)) in the 4-th exon of TTR gene which doesn‘t lead to the aminoacid substitution in the TTR polypeptide sequence. The N98N mutation was detected in heterozygous state. The mutation revealed in this study was not previously identified in other populations and was not previously described in literature and databases. The causal relationship of this mutation with the disease is an object for further discussion.

J02.45

Is there Influence of the Genetic Variations Associated with Thrombophilia on Sports Success?

V. P. Pushkarev[1]*, D. A. Dyatlov*[1]*, E. V. Lekontsev*[1]*, J. E. Pushkareva*[2]*, V. J. Vishnev*[1]*, L. M. Kulikov*[1]*;*

[1]*Ural State University of Physical Culture, Chelyabinsk, Russian Federation,* [2]*State Medical Academy, Chelyabinsk, Russian Federation.*

Regular physical activity reduces risk of thrombosis development. However cases of thrombosis in different sports are described. There is unresolved question, what influence of the genetic variations associated with thrombophilia on sports success.

The study was approved by Ethics Committee of the Ural State University of Physical Culture (USUPC). All participants gave written informed consent to genotyping. Junior group was consisted of 245 persons, who participated in sport competition and training on regular basis. Sportsmen group was consisted of 300 athletes from different sports (sub-elite level - 47%, elite level - 53%). Healthy sedentary control group was consisted of 255 students, employees of the USUPC. All participants were unrelated Caucasians living in Ural region of Russia. DNA was isolated from buccal epithelium. Genotyping was done using a TaqMan® SNP Genotyping Assays by use StepOne™ Real-Time PCR System (AppliedBiosystems, USA). The genotyping results were analyzed by using TaqMan® Genotyper Software (AppliedBiosystems).

Frequencies of heterozygote carriers of Leiden and prothrombine mutations in control group were identical - 2,4 %. Frequency of T/T genotype of C677T variation of *MTHFR* gene in control group was 9,8 %. Frequencies of studied sequence variations at juniors and athletes either didn‘t differ, or were a little above, than in control. Apparently, variations rs1799963 in *F2* gene, rs6025 in *F5* gene, rs1801133 in *MTHFR* gene, associated with thrombophilia, don‘t render strong negative influence on sports success. Possibly, prothrombotic action of the investigated variations is compensated by adaptive changes of a hemostasis as response on aerobic trainings.

INTRODUCTION

Some mutations in the desmoplakin gene generate an autosomal dominant inheritance pattern related to the involvement of the left ventricle (LV) in ARVC.

METHODS

It has made the study of 28 patients (14 women and 14 males), belonging to 3 families affected by ARVC. This cohort was obtained from a screening of 64 ARVC patients. The analysis of the 28 individuals was performed by sequencing of exons and flanking intronic regions for the DSP gene.

RESULTS AND CONCLUSIONS

We found a gene variant (Q447X) that is a heterozygous nonsense type not previously described. Is a C to T transition that generates a stop codon resulting in a peptide 85% smaller than the wild type and an autosomal dominant inheritance pattern with high penetrance (91%). In most cases, stop codon mutations are disease cause.

Eleven of the 28 studied patients were mutation carriers and ten of them were affected by ARVC. The rest were healthy patients. The eleven carrier patients consisted of eight women and three men.

The amino acid 447 is located in one of the globular head domains of desmoplakin to participate in the binding of this protein with plakoglobin and plakophilin. It is noteworthy that several mutations in this gene have been associated with the development of arrhythmogenic left ventricular dominance and even isolated involvement of the ventricle and simulating idiopathic dilated cardiomyopathy. We conclude this gene variant Q447X could be possibly the cause of ARVC with predominant LV.

INTRODUCTION

Through genetic screening of dilated cardiomyopathy patients, we identified a previously described deletion of arginine 14 (PLN-R14Del).

METHODS

Nine individuals were evaluated using dHPLC and bidirectional sequencing of the exon and intron regions flanking the PLN gene.

RESULTS

Seven of the nine patients studied were mutation carriers although only two of them met diagnostic criteria of dilated cardiomyopathy: the proband and her asymptomatic maternal grandmother. Five carriers´s ECG showed strikingly low voltage QRS complex, despite no echocardiographic abnormalities in 3 (mother and 2 maternal aunts). Apart from proband all carriers were asymptomatic with no history of arrhythmia evidenced. Proband´s father belongs to another family affected by Hypertrophic cardiomyopathy, although the father himself only express mild left ventricular hypertrophy with normal ECG.

R14Del mutation was described in 40 families to date. There is information available from 68 carriers. This mutation was identified as a mutation with founder effect in up to 14% of cases in a cohort of Dutch patients with dilated and arrhythmogenic cardiomyopathy. Carriers from this cohort characterized by low voltage QRS and negative T waves in lateral leads similar to that evidenced in carriers of some desmosomal mutations.

CONCLUSION

Low voltage ECG has a high sensitivity to identify PLN mutation carriers. Echocardiographic phenotype can be mild or normal in most carriers of R14Del mutation who can remain asymptomatic throughout life. Severe phenotype can be consequence of double mutations. Interpretation of genotype-phenotype correlations should be done in the context of large family trees and complete cardiac evaluation.

J02.48

Age-related penetrance in genetic carriers of hypertrophic cardiomyopathy

*A. Romero-Puche[1], **I. Perez**[2], M. Sabater-Molina[3], E. Garcia-Molina[2], I. Gomez Milanes[2], D. Lopez-Cuenca[2], M. Oliva[4], F. Ruiz-Espejo[5], J. Gimeno[4], P. Martinez[5];*
[1]Hospital Reina Sofia, Murcia, Spain, [2]genetic diagnisis laboratoy, Murcia, Spain, [3]genetic diagnosys laboratoy, Murcia, Spain, [4]Cardiology departament, University Hospital Virgen Arrixaca, Murcia, Spain, [5]Genetic diagnosys laboratoy, Murcia, Spain.

Introduction and Purpose: The aim is study the age-related penetrance of HCM in patients with different MYBPC3, MYH7 and TNNT2 mutations to determinate whether the age at diagnostic depends on genetic background.
Methods: We included 195 HCM causal mutation carriers (55% males, age 40±16 years); 64.8% had clinical manifestations of the disease. All patients were diagnosed in inheritance cardiomyopathy consultation, in a reference hospital. 146 patients were carriers of at least one mutation in MYBPC3 (IVS23+1G>A (72), Arg891fs (37), A107fsX116 (26), A216T (11), V896M (4)), 21 were carriers of a mutation in MYH7 (T1377M (21), D928N (4), E1348Q (8), E1356Q (4), R1382Q (4)) and 8 patients were carriers of R278C in TNNT2. IVS23+1G>A, the most prevalent mutation, was present in 18 unrelated families. We performed time-to-diagnosis analysis according to the affected gene and the most prevalent mutations.
Results: No differences in time to diagnosis were detected between the most prevalent mutations. Median age at diagnosis was 46±2 years old for IVS23+1G>A, 44±3 years old (Arg891fs), 43±2 years old (A107fsX116), 44±7 years old (T1377M) and 51±9 years old (A216T); log rank $p=0.963$. Similarly, there were no differences according to the 3 analyzed genes (log rank $p=0.935$). Median age at diagnosis for the whole was 47±2 yrs. Conclusions: Mutations in MYBPC3 encoding myosin binding protein C could be considered more benign form of HCM than initially was considered. Now, genetic diagnosis reveals that HCM-phenotype can appear later in life, reaching near full penetrance in the elderly.

J02.49

Imprinting defect in patients with Albright's Hereditary Osteodystrophy and platelet Gs hypofunction

__B. Izzi__[1], I. Francois[2], V. Labarque[2], C. Thys[1], C. Wittevrongel[1], K. Devriendt[3], E. Legius[3], A. Van den Bruel[4], M. D'Hooghe[4], D. Lambrechts[5], F. de Zegher[2], C. Van Geet[6], K. Freson[1];
[1]Center for Molecular and Vascular Biology- KULeuven, Leuven, Belgium, [2]Department of Paediatrics- KULeuven, Leuven, Belgium, [3]Center for Human Genetics- KULeuven, Leuven, Belgium, [4]General Hospital Sint Jan Brugge, Brugge, Belgium, [5]Vesalius Research Center- KULeuven and VIB, Leuven, Belgium, [6]Center for Molecular and Vascular Biology and Department of Paediatrics- KULeuven, Leuven, Belgium.

Pseudohypoparathyroidism (PHP) indicates a group of heterogeneous disorders whose common feature is represented by impaired signaling of hormones that activate Gsalpha, encoded by the imprinted GNAS gene. PHP-Ib patients have isolated PTH resistance and GNAS epigenetic defects while PHP-Ia cases present with hormone resistance and characteristic features jointly termed as Albright's Hereditary Osteodystrophy (AHO) due to maternally inherited GNAS mutations or similar epigenetic defects as found for PHP-Ib. Pseudopseudohypoparathyroidism (PPHP) patients with an AHO phenotype and no hormone resistance and progressive osseous heteroplasia (POH) cases have inactivating paternally inherited GNAS mutations.
We here describe 16 PPHP subjects and 1 POH patient with platelet Gs hypofunction but lacking Gsalpha mutations. The methylation for the three differentially methylated GNAS regions was quantified via Sequenom EpiTYPER. Patients showed significant hypermethylation of the XL amplicon compared to controls (36±3 vs. 29±3%; $p<0.001$); a pattern that is reversed to XL hypomethylation found in PHPIb. Methylation for NESP and ExonA/B was significantly different for some but not all patients, though most patients have site-specific CpG methylation abnormalities in these amplicons. Since some AHO features are present in other imprinting disorders, the methylation of IGF2, H19, SNURF and GRB10 was quantified. Surprisingly, significant IGF2 hypermethylation (20±10 vs. 14±7%; $p<0.05$) and SNURF hypomethylation (23±6 vs. 32±6%; $p<0.001$) was found in patients vs. controls, while H19 and GRB10 methylation was normal.
In conclusion, this is the first report of epigenetic defects in PPHP and POH though additional studies are needed to correlate epigenotype with the clinical phenotype.

J02.50

Contiguous Gene Deletion of ERCC8 and NDUFAF2; Case Report

A. H. Al-Awami[1], __N. A. Al-Sanna'a__[1], H. Y. Al-Abdulwahed[1], M. Kruer[2];
[1]Dhahran Health Center, Dhahran, Saudi Arabia, [2]Oregon Health & Science University, Portland, OR, United States.

Here we describe a patient with clinical manifestation of Leigh's disease including persistent lactic acidosis and chronic encephalopathy. In addition, there was associated dysmorphic facial features and abnormal brain structure. Molecular karyotyping detected a homozygous deletion of 11 oligonuleotide probes at 5q12.1, spanning approximately 248 kilobases. The deleted region contains two known genes, ERCC8 (OMIM # 609412) and NDUFA2 (OMIM # 609653). Mutations of ERCC8 are associated with Cockayne syndrome, and mutations in NDUFA2 are associated with mitochondrial complex I deficiency. Both of the parents were confirmed to be heterozygous for the same deletion. We believe that this chromosomal deletion contributed to the complex phenotype on this patient. Ultraviolet light toxicity assay and mitochondrial study are still in progress.

J02.51

An Egyptian patient with cholestasis lymphoedema syndrome (Aagenaes syndrome)

T. Abdel Ghaffar[1], __S. Elsayed__[2,1];
[1]Yassin Abdelghaffar Charity Center for Liver Disease and Research, Cairo, Egypt, [2]Medical Genetics Center, Cairo, Egypt.

Lymphoedema cholestasis syndrome (Aagenaes syndrome) is a rare autosomal recessive disease consisting of hereditary, recurrent cholestatic liver disease and generalized lymphoedema from birth or childhood. The disease was first described by Aagenaes et al. in 1968 in Norway. Since then, most patients reported are originally from the same part of Norway. Fewer than 40 cases have been described elsewhere. To the best of our knowledge, none was described in Arab countries. Here, we describe the clinical and laboratory characteristics of the first Egyptian patient with Aagenaes syndrome.
He is a 3.5 year old boy, the second in birth order of first cousin marriage after uncomplicated pregnancy. He had an older brother who developed jaundice soon after birth and died at the age of 35 days without any available investigation. Our patient has severe form of the disease with progressive cirrhosis and relatively low GGT and cholesterol levels. He also developed progressive arthritis, a feature which was not described before in this syndrome. Although molecular analysis was not done yet, we suggest that our patient could have a different severe form of the disease associated with arthritis that has a different locus than LCS1 similar to the Serbian Romani patient described by Frühwirth et al., 2003.

J02.52

An atypical case of Langer-Giedion-syndrome: the role of additional chromosomal abnormalities

__G. Cappuccio__[1], V. Ginocchio[1], P. Boemio[1], R. Genesio[2], G. Minopoli[1], A. Casertano[1], B. Granese[1], A. Mormile[2], L. Nitsch[2], G. Andria[1], D. Melis[1];
[1]Department of Pediatrcs Federico II University, Naples, Italy, [2]Department of Cellular and Molecular Biology and Pathology Department of Pediatrcs Federico II University, Naples, Italy.

Langer-Giedion syndrome (LGS), is defined as a contiguous gene disorder caused by the loss of functional copies of TRPS1 and EXT1 genes usually secondary to 8q microdeletion.
This condition combines features of trichorhinophalangeal syndrome type I (sparse scalp hair, bushy eyebrows, bulbous nose, long philtrum, cone shaped epiphyses, short stature), multiple exostosis, mild to moderate mental deficiency (MD).
We report a case of a 4-year-old girl presenting with facial dysmorphisms and skeletal abnormalities, short stature, congenital heart disease (CHD), central nervous system (SNC) anomalies, severe MD. A diagnosis of LGS was suspected.
The HR karyotype showed a reciprocal balanced translocation between: 2p24 and 11p15 chromosomes. The parental high resolution karyotype was normal. Array-CGH analysis revealed an interstitial deletion involving chromosome: 8q23.3-q24.11.
Our patient shares with LGS: microcephaly, sparse hair, dysmorphic facial features, growth retardation, multiple exostosis.
The presence of CHD, CNS anomalies (hypoplasia/agenesis of corpus callosum (CCA), pituitary gland dysmoprhism), severe MD has never been described in patients with LGS.
The Array-CGH confirmed clinical diagnosis. Up to date, this is the smallest deletion causing LGS.
The patient also showed a balanced chromosomal translocation involving 2p24 region where maps ASXL2 gene. Recently, a patient carrying a balanced translocation involving the same 2p24 region has been described showing CCA and MD.
We speculate that ASXL2 gene disruption might be responsible for the more severe neurological phenotype described in the current patient.

J02.53

An Italian case of X linked reticulate pigmentary disorder with systemic manifestations (XLPDR)

M. Gabaldo[1], *G. Tadini*[2], *M. Brena*[2], *L. Pezzani*[2], *P. Gentile*[3], *T. Balducci*[4], *M. Passarin*[5];
[1]Clinical Genetics, MD, Verona, Italy, [2]nstitute of dermatological science, Hosp. Maggiore, Milan, Italy, [3]XLPDR Italian association group, Como, Italy, [4]Pediatric Surgeon MD,, Verona, Italy, [5]Department of Neurology,ULSS 22 Orlandi Hospital, Bussolengo (Verona), Italy.

The X- linked reticulate pigmentary disorder with systemic manifestations (XLPDR) is a rare skin disorder affecting males and mildly females, and it's characterized by a hyperpigmentation disorder of the skin and several visceral problem. This disorder in females shows brown pigmentation of the skin which follows the lines of Blaschko, while it is appears as reticulate sheets in males. Males also suffers of systemic manifestations as severe gastrointestinal disorders in infancy with failure to thrive, corneal dystrophy with severe photophobia, chronic respiratory disease and, in the most sever cases, early death No causative mutation has been identify yet.

We report a case of a 3-year-old boy with clinical features that are consistent with the diagnosis of XLPDR match the one typically described, characterized by brown diffuse and reticulate hyperpigmentation of the skin reflux, hypohidrosis ,

growth retardation, electrolyte imbalance, dry skin, unruly hair, eyebrow flare, digital clubbing, photophobia due to corneal diskeratosis. Retinitis pigmentosa, lymphoedema and failure to thrive. The boy has been suffering also of recurrent

pneumonia and severe colitis and diarrhea The family history shows that the mother of the boy is affected by incontinentia pigmenti and the boy's sister is apparently unaffected, none of the other member of the family show symptoms of the disease. So far this case is the 6th case of XLPDR described in literature.

J02.54

Lymphoma in a patient with Noonan syndrome

F. Santos[1,2,3], *Y. Aoki*[4], *I. González-Casado*[5], *R. Gracia*[6], *P. Lapunzina*[1,2,3];
[1]INGEMM; Hospital Universitario La Paz, Madrid, Spain, [2]CIBERER, Madrid, Spain, [3]Idipaz, Madrid, Spain, [4]Department of Medical Genetics; Tohoku University School of Medicine, Tokio, Japan, [5]Pediatric Endocrinology, Hospital Universitario La Paz, Madrid, Spain, [6]Pediatric Endocrinology; Hospital Universitario La Paz, Madrid, Spain.

Noonan syndrome (NS) is a well recognizable syndrome characterized by short stature, facial dysmorphism, heart disease and cryptorchidism. Gain of function mutations in the PTPN11 oncogene are identified in half of the patients. Apart from the T73I mutation, there is no clear relationship between PTPN11 mutations and increased cancer risk. GH treatment has been proved to improve growth in these patients

We report on a 30 year old man who had been diagnosed in infancy with Dubowitz syndrome and due to short stature, had received treatment with growth hormone. On examination, he has typical facial features of NS, short stature, normal intelligence and has recently developed a lymphoma with good response to chemotherapy. His 2 year old son has clinical features consistent with NS (short stature, typical facial features, cryptorchidism and normal development). Both are heterozygotes for the E139D (c.417C>G) mutation in exon 4 of the PTPN11 gene.

The E139D mutation is not known to increase cancer risk in NS patients, but has been previously reported in two patients with NS who developed a cerebral glioma. Both our patients have had normal cerebral MRIs.

This is the first report of this mutation related to a lymphoma in a NS patient. It is difficult to assess what the relationship between the E139D mutation and the GH treatment have with the development of the lymphoma or if this is a casual finding. With current evidence, the risk of treating our proband with GH seems to outweigh its benefits.

We report eight unrelated individuals with intellectual disability and overlapping submicroscopic deletions of 8q21.11 (0.66-13.55 Mb in size). The deletion was familial in one and simplex in seven individuals. The phenotype was remarkably similar and consisted of a round face with full cheeks, high forehead, ptosis, cornea opacities, underdeveloped alae, short philtrum, cupid's bow of the upper lip, down-turned corners of the mouth, micrognathia, low-set and prominent ears, and mild finger and toe anomalies (camptodactyly; syndactyly; broadening of first rays). Intellectual disability, hypotonia, decreased balance, sensorineural hearing loss, and unusual behavior were frequently observed. High resolution oligonucleotide array showed different proximal and distal breakpoints in all of them. Sequencing studies in three of the individuals revealed that proximal and distal breakpoints were located in unique sequences with no apparent homology. The smallest region of overlap was a 539.7 kb interval encompassing three genes: a *Zinc Finger Homeobox 4* (*ZFHX4*), one micro RNA of unknown function and one non-functional pseudogen. *ZFHX4* encodes a transcription factor expressed in adult human brain, skeletal muscle and liver. It has been suggested to be a candidate gene for congenital bilateral isolated ptosis. Our results suggest that the 8q21.11 submicroscopic deletion represents a clinically recognizable entity and that a haploinsufficient gene or genes within the minimal deletion region could underlie this syndrome.

Characterization and isolation of a beta neurotoxin- Bt from scorpion venom

G. Eskandari;
Laboratory of Molecular Genetics, Institute of Molecular Biology, National Academy of Sciences of Ar, Yerevan, Armenia.

Scorpion venoms are a particularly rich source of neurotoxic proteins/peptides that interact in a highly specific fashion with discrete subtypes of ion channels in excitable and non-excitable cells. Scorpion venom has historically been one of the richest sources of polypeptide toxins with unusually high degrees of specific actions on and interactions with the ion-channel membrane proteins of both excitable and non-excitable cells. In this study, we report the characterization and isolation of a beta neurotoxin- Bt, from the venom glands of scorpion Androctonus crasicauda venom Kuzestan (Iran). Scorpions were collected from the Khuzestan province and transported to the reference laboratory of the Razi Institute . cDNA was synthesized with extracted total RNA as template and modified oligo(dT) as primer. Using RT-PCR techniques, a 281 bp cDNA fragment encoding a beta neurotoxin active on mammals or on insects have been isolated from the telsons of scorpion Androctonus australis. All cDNA sequences displayed one major open reading frame of about 310 nucleotides. The deduced precursor open-reading frame is composed of 59 amino acid residues that consist of a signal peptide of approximately 22 amino acid residues. This polypeptide has a molecular mass of 9324.86 kDa with an Isoelecric point of 4.96 which is closely packed by three disulfide bridges. Amino acid alignment and secondary structure prediction revealed that the peptide deduced from cloned cDNA is a functional homolog of potassium channel-blocking neurotoxins from the venoms of other scorpions.

Keywords: *Adnroctonus crasicauda*, beta toxin, scorpion

Chromosome abnormalities in children

A. Vibe, *E. Moldagulova*, *D. Samatkyzy*;
National Research Center for Maternal and Child Health, Astana, Kazakhstan.

For the purpose of studying of frequency of chromosomal abnormalities cytogenetic research of lymphocytes of peripheral blood was carried out of 1546 children.

The results of research study had found out in the 212 (13,7%) cases. Aneuploydia was found in the 186 cases (87,8 %) and structural abnormalities

were revealed in the 26 cases (12,2 %).
Among aneuploydia were detected Down‘s syndrome in the 117 (63 %), Turner‘s syndrome in the 25 (13,4 %), Klinefelter‘s syndrome in the 23 (12,4 %), Edwards‘s syndrome in the 9 (4,8 %), an androgen insensitivity syndrome (AIS) in the 5 (2,7 %), 47, in the 4 (2,2 %), the Patau‘s syndrome in the 1 (0,5 %), 47, in the 1 (0,5 %), the 69, in the 1 (0,5 %) cases.
Were carried out following abnormalities: del(5)(p15.1), 46,XY,del(2)(p15p21), 46„add(7)(q31), 47„add(X)(q27) 46„t(6;13)(q26;q13), 46„t(3;13)(q23;q32), 46,XX,t(14;18)(q13;q23), 46,XX,t(10;16)(q23;q11.2), inv(9)(p11q13), 46,XX,t(8;20)(q22;p18.1), 46,XX,t(9;12)(q34;q24.1), inv(3)(q23p26), 46„t(10;12)(q23;q15), 45„der(13;14)(q10;q10), 45„der(14;15)(q10;q10), 46,X,i(X)(q10), 46,XX,t(7;9)(q11;q31), 46,XX,t(7;13)(q11.2;p11.1), 46„t (X;5)(q23;p15.2), 46„t(X;1)(q27;p22) among 26 structural chromosomal abnormalities.

Human Infertility: the importance of cytogenetic analysis

F. Lopes[1], *P. Botelho*[2], *M. Souto*[2], *I. Gaivão*[1], *Z. Gomes*[3], *M. Martins*[2], *O. Moutinho*[3], *R. Pinto Leite*[2];
[1]*Department of Genetics and Biotechnology, CECAV, University of Trás-os-Montes and Alto Douro, Vila Real, Portugal,* [2]*Genetic Service, Cytogenetic Laboratory, Hospital Center of Trás-os-Montes and Alto Douro, Vila Real, Portugal,* [3]*Obstetrics and Gynecology Service, Hospital Center of Trás-os-Montes and Alto Douro, Vila Real, Portugal.*

Infertility is a failure to conceive after at least one year of unprotected intercourse. It has been estimated that approximately 15% of the population in industrially developed countries are affected. Reproductive difficulties are associated intimately with cytogenetic abnormalities that could be structural aberrations such as translocations, inversions and supernumerary chromosome (#); or, constitutional aneuploidies such Klinefelter syndrome, 47, XYY, Turner syndrome and 47, XXX.
The authors present two cases (two couples) that have been followed in infertility consultation. Cytogenetic study and semen analysis were required. The technical procedures (blood culture, GTL and CTL banding, FISH assay) and cytogenetic analysis was performed according standards protocols and guidelines. Semen analysis was done according to World Health Organization Laboratory Manual (5th Edition-2010). In the first case we found a normal female karyotype (46, XX) and a male karyotype with a reciprocal translocation involving the short arm of #4 and the long arm of #22 [46, XY, t(4;22)(p16.1;q11)]; in the semen analysis a low spermatozoa concentration was detected and concerning morphology a border line value was found (4%). In the second case the female karyotype presented a paracentric inversion of #14 [46, XX, inv(14) (q13q24.3)] and the male has a normal karyotype (46, XY) with a normal semen analysis.
This study strongly point out the importance of cytogenetic analysis of infertile couples to allow an appropriate genetic counseling.

J03.04

Clinical features and a de novo t(1;12)(p22;p12-13) in a 22-year-old man with myotonic distrophy

H. Acar, *N. Kocak, T. Cora, Z. B. Bulut;*
Selcuklu Medical School, Konya, Turkey.

We report on a 22-year-old patient presenting with attached ear lobule, thight skin, long height, short phalanges, gynecomasty, mucsle weakness, short philtrum, long neck, webbed neck. The clinic features are overlapped with myotonic distrophy. Standard cytogenetic analysis showed a de novo translocation, 46,XY,t(1;12)(p22;p12-13) karyotype. Three hypotheses have been postulated to explain such phenotype abnormalities, including a break in a gene, a positional effect and a cryptic deletion or duplication. According to the literatüre, coexistence of t(1;12)(p22;p12-13) karyotype with myotonic distrophy features has not been reported. This is the first case presenting both features and karyotype. As for myotonic distrophy, there are two types in adult onset. This identity may not be associated with the present karyotype. Therefore, it will be clarified of these two findings. This case places further emphasis on the importance of cytogenetics analysis in the study of de novo translocations with this abnormal phenotype. In conclusion, fine mapping and cloning of cytogenetically translocation chromosome breakpoints in patients with multiple malformations are a promising strategy for the isolation of new genes that may be related with myotonic distrophy. Now we have foced on the patient for the fonctional study.

J03.05

Partial trisomy 16q and pericentric inversion of chromosome 9 in a young patient with a complex phenotype

C. A. Popa[1,2], *M. Puiu*[1,2], *S. Arghirescu*[1,2], *M. Serban*[2];
[1]*University of Medicine and Pharmacy„Victor Babes”, Timisoara, Romania,* [2]*Emergency Children Hospital „Louis Turcanu“, Timisoara, Romania.*

Here we report a duplication of chromosome 16 at q11.2 to q21 and the pericentric inversion of chromosome 9 at p11 to q13 identified by routine karyotyping in a one month old male patient. Pure duplications of 16q have only been reported in a small number of individuals. Partial trisomy for the long arm of chromosome16 is a rare condition,uncommonly identified in children and adults. Cytogenetic aberrations on chromosome 9 have been reported to be one of the most frequent abnormalities. The pericentric inversion of chromosome 9 inv(9)(p11q13) is one of the most common balanced structural chromosomal aberrations found in 1 to 3% of the general population.
Physical examination of the ours patient revealed mild dysmorphic features including low set ears with slightly redundant/extracrease of the helix bilaterally, micrognathia, deep creases in the sole soft he feet and mild bilateral 5th finger clinodactyly. Conventional cytogenetics (G banding) revealed a male karyotype with an apparent duplication in the long arm of chromosome16 and the pericentric inversion of chromosome 9 [46,XY,dup(16)(q11.2q21), inv(9)(p11q13)] in all the 30 metaphase plates screened.

J03.06

A case of inverted duplication deletion of the short arm chromosome 5 in an infant girl without "cri du chat"

V. Antonenko, *N. Shilova, T. Zolotuhina, M. Minzhenkova, Y. Kozlova, N. Gerasimenko;*
Researsh Centre for Medical Genetics RAMS, Moscow, Russian Federation.

Proband is the first child of healthy unrelated parents. During pregnancy there were no complications, and the dates of prenatal screening were normal. Her birth weight was 3310g, length - 53 cm, occipitofrontal circumference - 34 cm. She did not have unusual cry. At the age of 1 year 3 months her motor development was slow: she could poise her head, but she couldn't sit or crawl. According to physical examination she had muscular hypotonia, dolyhocephaly, enlargement of fontanelle (3,5x4 cm), her weight was 8200g (<3cd), length - 74cm (<3cd). She showed minor dysmorphic features including: prominent forehead, preauricular pigs, epichantus folds, strabismus, coloboma of right iris, wide nasal bridge, long filtrum, carinate deformation of chest, thin skin, venous rete at the chest. Abdominal, transfontanellar and cardiac ultrasounds revealed right pyelectasis, enlargement of right corns of lateral ventriculuses of brain, patent ductus arteriosus, ventricular septum defect and ectopic of mitral valve cords.
The standard cytogenetic analyses revealed the additional chromosomal material on the short arm of chromosome 5. Parental karyotypes were normal. The FISH-analyses with the subtelomere probes for short and long arms of chromosome 5 (TelVision 5p, TelVision 5q, Vysis Abbott) revealed absence of signal on the p-arm with additional chromosomal material. M-FISH (24xCyte, MetaSystems) analyses revealed that additional material was due to chromosome 5. Consequently the karyotype of patient was interpretaited as inverted duplication with loss of subtelomeric region: 46,XX,der(5)del(5)(p15.3)dup(5)(p15.3p14)dn. This case confirms assumption that inverted duplications deletions are not very rare forms of chromosomal rearrangements.

J03.07

Fragile sites in recurrent pregnancy loss

D. Mierla[1], *V. Radoi*[1,2], *C. Bara*[2];
[1]*Life Memorial Hospital, Bucharest, Romania, Bucharest, Romania,* [2]*UMF Carol Davila, Bucharest, Romania.*

Introduction: Early pregnancy loss in the first trimester is the most common complication affecting at least 15 - 20% of the all clinically recognized pregnancy. Chromosomal structural abnormality in either parent is an important cause of recurrent pregnancy loss but increased spontaneous chromosome instability was reported in couples with recurrent spontaneous abortions but without constitutional chromosome aberrations
Objective: In this report we present the cytogenetic findings of the expression of fragile sites in couples with two or more spontaneous abortions.
Material and methods: We studied 636 couples with recurrent spontaneous abortions (>3) referred to Maternal - Fetal Medicine and Assisted Reproduction of Life memorial Hospital. No subject presented with obvious phenotype of chromosomal rearrangements.
Cytogenetic investigations were carried out from peripheral blood lymphocytes using standard techniques. The routine analyses was performed on G banded chromosomal preparations. Karyotypes of the fetuses were not studied.
Results: Autosomal fragile sites were found in 8 cases (0,62%). The fragile site was not typically folate-sensitive, being expressed in standard medium.
Conclusion

The role of fragile sites in causing abortion is still very difficult to asses. Fragile sites may possibly predispose to chromosome breakage and rearrangements in meiosis and consequent infertility

J03.08
Heterochromatin variants of human chromosome 9 and the reproduction failure

A. Sipek jr., *A. Panczak, R. Mihalova, L. Celbova, M. Janashia, M. Kohoutova;*
Institute of Biology and Medical Genetics, First Faculty of Medicine, Charles University, Prague, Czech Republic.

Pericentric inversion of chromosome 9 - inv(9) - is considered to be clinically insignificant heterochromatin variant of human karyotype. However, various author repeatedly mention possible association of inv(9) and selected pathologies, especially with reproduction failure. This can cause some consultation dilemma, especially when inv(9) is identified in potential gamete donor.

Some authors also suggest the same role for other variants of the heterochromatin region of the human chromosome 9 (like 9qh+ or 9qh) as well.

Using the data from our cytogenetic laboratory - we analyzed the clinical indications among 383 patients with heterochromatin variant of chromosome 9 and we have found the reproduction failure to be the most common diagnose (more then 43 %). That was far more, then was the incidence of reproduction failure in our control group of patients with normal karyotype. This difference was also statistically significant.

We have confirmed heterochromatin variants of chromosome 9 as relatively common finding, this time in population in the Czech Republic. The clinical significance, however, remains subject of discussion. Possible association of heterochromatin variants of human chromosome 9 with reproduction failure had quite low statistical significance and will require further investigation.

J03.09
Cytogenetic abnormalities detected in patients with non-obstructive azoospermia and severe oligozoospermia inNorth-West of Iran

A. Jalili[1], *S. Abdollahi Fard*[2], *K. Hasanzade*[2], *N. Karimiyan*[2], *Z. Seyedi*[1], *S. Rahmani*[1];
[1]*Islamic Azad University, Ahar, Islamic Republic of Iran,* [2]*Tabriz university of medical sciences, Tabirz, Islamic Republic of Iran.*

Introduction-Chromosomal anomalies have been postulated to be as one of the principal genetic factors in male infertility. find the frequency and types of major chromosomal abnormalities with nonobstructive azoospermia and severe oligozoospermia in men who were referred because of primary infertilityto give appropriate genetic counseling before assisted reproduction techniques in north-west of Iran, and investigate the general characteristics in this infertile male population,was objective of study.

Material & methods-A total of 50 infertile males (35 were azoospermic, 15severe oligospermic) were studied for the cytogenetic evaluation prior to use of assisted reproduction techniques. Also, 60 fertile males as a control group were studied. Karyotyping was performed on peripheral blood lymphocytes according to the standard methods.

Results -The total prevalence of chromosomal abnormalities was found to be 16% (8/50), includingfive patients (10%) were 47,XXY;one patient (2%)46 ,XY/47,XXY;one patient (2%) 46,XY/45,XO. All of them were azoospermic males , and one patient (2%) 46,XY,del(Y)(q11.2) that was Oligozoospermic, And in control males except one case that was 46,XYY and fertile man,all control males had no chromosomal abnormalities.

Conclusions-Comparison of our results with the review of the literature shows a relatively similar incidence of chromosomal anomalies in infertile men.The occurrence of chromosomal abnormalities among infertile males strongly suggests the need for routine genetic testing and counseling prior to the employment of assisted reproduction techniques.

J03.10
Cytogenetic biomonitoring of general population of FB&H using micronucleus assay test

S. Ibrulj[1], *M. Mackic*[1], *I. Aganovic*[1], *D. Celik*[2];
[1]*Center for genetics, Sarajevo, Bosnia and Herzegovina,* [2]*Cathedra for Epidemiology and Biostatistics, Sarajevo, Bosnia and Herzegovina.*

The aim of this study is to determine values of Micronucleus Assay from peripheral blood lymphocytes of 200 healthy examinees both gender from general population of Federation of Bosnia and Herzegovina. We have determine micronucleus frequency and number of cells with micronucleus for each examinee, average (median) frequency of MN for each group of examinees divided into groups by the age (20-30y; 30-40y; 40-50y; 50-60y; 60-70y), as well as the gender (20M: 20F) and their smoking habits. 200 was the total number of analyzed examinees.

For each sample were analyzed 1000 binuclear lymphocytes and determined total number of MN, cells with MN as well as their distribution (number in cells). MN was determined according to proposed HUMN criteria.

Statistical analyze revealed following conclusions:

1. There is significant difference among number of MN found among genders ($p<0,05$).
2. There is highly significant difference in frequency number of MN among different age groups ($p<0,001$).
3. There is significant difference in frequency of 2 micronucleus and smoking habits of examinees while that difference is not present for 1 micronucleus frequency.

The results of this study considering age, gender and smoking habits are in accordance with results determined for general population of healthy people in other cytogenetic laboratories else in the world.

J03.11
Multiples and different chromosome aberrations in a healthy female patient

L. Rodríguez, *M. García, M. Sánchez, E. Abarca;*
Laboratorio AbaCid-Genética. Hospital de Madrid., Madrid, Spain.

It is widely known that the presence of a chromosome alteration in a patient has usually associated different congenital abnormalities, nevertheless the vertical transmission of a chromosomopathy has also been described to be associated with no phenotypic effects, defined as "variants".

In fact, once a chromosome alteration is found in a patient, such a chromosomopathy is present in all cells, unless it is a mosaicism (with two or three different cell lines) or it is a chromosomal instability syndrome, such as Nijmegen syndrome.

Here we present a very atypical case where multiples and different chromosome alteration were diagnosed in a peripheral blood karyotype of a 32 years old healthy female patient, who wanted to have a baby. As an antecedent she refers to have had a Hodking lymphoma 8 years ago, which was treated with chemotherapy for 6 months and with radiotherapy for 21 sesions (30 greys). Once she was cured, she decided to have a baby although the chromosome findings in the lab where frightened scared, showing multiples and different chromosome aberrations in 20% of cells. The karyotype was repeated and the same findings were observed. The question is: Could it be any relation between the lymphoma treatment which happened 8 years ago and the multiple chromosome alterations? If so, is there any risk for a pregnancy in our patient? Should she avoid her ovocites and consider a donor? Is there any other patient describe with a similar karyotype? Shall we check her hematology looking for another lymphoma?

J03.12
Incidence And Clinical Significance Of Pericentric Inversion Of Chromosome 9.

S. Eren, *N. Çine, B. Doğruoğlu, Z. İlkay, R. U. Akkoyunlu, E. Gümüşlü, D. Sünnetçi, H. Savlı;*
Kocaeli University, Kocaeli, Turkey.

Aim: The aim of the study was to study the frequency of inv(9) and its clinical correlation with human genetic diseases

Background: Pericentric inversion of the chromosome 9 is such a common occurrence that some cytogeneticists would consider them as normal variants. The frequency estimated to be 1 to 3% in the general population. Despite being categorised as a minor chromosomal rearrangement which does not correlate with abnormal phenotypes, there have been many controversial reports indicating that it may lead to abnormal clinical conditions such as subfertility, recurrent abortions, leukemia, dysmorphic features and psychosis.

Materials and Methods: We studied retrospectively the incidence and clinical significance of pericentric inv(9) from the collected peripheral blood karyotypes of 1,800 cases being referred to our department with suspected genetic diseases over a 3-year period.

Results: Pericentric inv(9) was detected in 21 cases (1%). Ten cases were adult patients, four (40%) of them were with obstetric and fertility problems, five adult patients (50%) had a sibling or offspring with inv(9) and 1 adult patient (10%) had the diagnosis of acute myeloid leukemia. Eleven cases (52%) were paediatric patients with dysmorphic features and congenital anomalies.

Conclusion:

The significance of inv(9) is still mostly unknown and hence to understand the clinical significance of the pericentric inversion of Chromosome 9 it will be required reporting of new additional cases with detailed chromosomal studies.

J03.13

Cytogenetics abnormalities of spontaneous abortion

I. I. Kavecan, *J. Jovanovic Privrodski, M. Obrenovic, M. Kolarski, L. Gacina, J. Rudež, M. Fojkar;*
Institute for Children and Youth Health Care Vojvodina, Novi Sad, Serbia.

The loss of the desired pregnancy is always a stressful event for both partners/spouses, and therefore it is always important to establish the cause that led to the loss of pregnancy and how to achieve success in the next pregnancy and get a healthy child.

Research objectives: To determine the frequency, distribution and type of pathological karyotypes of spontaneous abortions.

Materials and methods: The study group consists of partners who underwent karyotyping of spontaneously aborted fetuses. The analysis of 549 samples of spontaneous abortions revealed 19.85% of chromosomal aberrations. **Conclusion**: Most frequent chromosomal aberration in spontaneous abortion group was the Turner syndrome, followed by triploidy, trisomy of chromosome 18, trisomy of chromosome 15 and Down's syndrome. Rare chromosomal aberrations were frequently present in earlier gestation ages. Women with spontaneous abortion, which is caused by a chromosomal aberration often have a history of adverse outcome of previous pregnancies.

J03.14

Probability rates of different pregnancy outcomes and meiotic segregation analysis of spermatozoa in carriers of t(1;11)(p36.22;q12.2)

A. T. Midro;
Department of Clinical Genetic Medical University Bialystok Poland, Bialystok, Poland.

The unique rearrangement i.e. t(1;11)(p36.22;q12.2). ish t(1;11)(RP11-1115A15-,RP11-476D13-,RP11-498B2-,RP11-807G9-,RP11-496H15-,RP11-575L21-,RP11-874A11+;RP11-855010-,RP11-881M11+,799F14+) was found in two relatively large pedigrees of carriers studied due to occurrence of three miscarriages (pedigree 1) and the birth of newborn with hydrocephalus and myelomeningocele (pedigree 2). The same hybridization pattern was found in both families indicating similar, if not the same, rearrangement. STS marker walking analyses using hybrid containing derivative chromosome 1 did not allow us to define the 1p36 and 11q12.2 breakpoints in this rearrangement at the sequence level. Segregation analysis of cumulative data of pedigrees was performed by indirect method of Stengel-Rutkowski and showed that probability rate for unbalanced child at birth was 0/40 i.e. <0.9.% after ascertainment correction, the risk for stillbirths/early newborn deaths was 1/40 i. e. 2.5%±2.5.% and for miscarriages was 15/40 (37.5%±7.6 %). We didn't found any differences between males and females carriers.

Meiotic segregation pattern after the sperm analysis by three-colour FISH method of one male carrier from pedigree showed all possible combinations after 2:2 and 3:1 segregations. The most common segregation types were alternate and adjacent I (similar frequency). Low frequency was observed in adjacent II type, in opposite to 3:1 segregation with the high proportion of unbalanced gametes. However we suggest, that only one form of chromosome imbalances i.e. monosomy 1p36.22→pter with trisomy 11q12.2→qter may be observed in progeny at birth but with limited survival after delivery.

Obtained results of risk estimation of different pregnancy outcomes for carriers of t(1;11)(p36.22;q12.2) may be used in genetic counseling of carriers of this rearrangement.

J03.15

Case of diagnostics of a rare syndrome 18p-.

A. R. Shorina[1], *T. A. Gayner*[2], *V. A. Makasheva*[1];
[1]*Novosibirsk Regional Children's Clinical Psychoneurological Dispansery, Novosibirsk, Russian Federation,* [2]*Center of New Medical Technologies of the Siberian branch of the Russian Academy of Science, Novosibirsk, Russian Federation.*

Partial monosomies of short and long shoulders of a chromosome 18 are clinically distinguished syndromes. Considering a rarity of these syndromes, data on new cases deserve special attention. We result a case of diagnostics of a partial monosomy of a short shoulder of 18 chromosomes at the woman of 24-th years who have addressed for medicogenetic consultation. The patient had an expressed psychoneurological semiology: an intellectual development delay (F70), organic disorder of the person. At survey became perceptible phenotypic signs: mycrocephalia; hypertelorism; ptosis; mandible hypoplasia; dysplasia of auricles; an asthenic constitution; the low growth and the lowered mass of a body; kyphoscoliosis of thoracal department of a backbone; short neck; cross-section-longitudinal platypodia; clinodactyly of little fingers; hypoplasia of trailer phalanxes of brushes; hypermobility of interphalanx and radiocarpal joints; recurvation of ulnar joints; hypomyotonia.

From integuments were taped: the expressed dryness, ecdysis, diffusive pigmentation, signs of a follicular hyperkeratosis. The accompanying somatic pathology is diagnosed for the patient: a peptic ulcer duodenum and an iron deficiency anemia. Developmental anomalies in the given observation it did not become perceptible.

The proband karyotype has been identified as 46,XX,del(18)(:p11.31→qter). From parents of the patient it was possible to survey only mother, it has a normal karyotype.The phenotype of our patient corresponds to clinical descriptions of patients with a partial monosomy of a short shoulder of 18 chromosomes which were published earlier. However, along with characteristic craniofacial dismorphias and a delay of mental development, expression of somatic and dermal implications pays attention to itself.

J03.16

A case of 16p subtelomeric duplication with vascular anomalies

A. Laku (Babameto);
University Hospital Center „Mother Teresa", Faculty of Medicine, Tirana, Albania.

We report a patient, a boy 12 months old, with karyotype 46,XY,der(4), recognized by standard cytogenetic techniques, presenting with facial features, neurological impairment and pulmonary hypertension. He was the first child of healthy nonconsanguineous parents. Family history was unremarkable. Distinct facial anomalies included microcephaly, high frontal hairline, blond thin hair, bilateral blepharophimosis and palpebral ptosis, short nose, everted upper lip, cleft palate, micrognathia, cupped anteverted ears. He had also hypoplastic distal phalanges and bilateral inguinal hernia. Pulmonary hypertension with tricuspidal regurgitation and cavernous liver hemangioma were found in our patient. Subtelomeric analysis by Multiplex Ligation-dependent Probe Amplification (MLPA) technique (a set of probes for testing subtelomeric imbalances in the SALSA P070 and P036B human telomere test kits, MRC-Holland, Amsterdam, Netherlands) demonstrated a duplication of the subtelomeric region of chromosome 16p and a deletion of the subtelomeric region of chromosome 4q, suggesting a translocation between 4q and 16p. A duplication of the subtelomeric region of 16p in the parents was excluded by MLPA technique. The imbalance of our patient resulted de novo. In comnclusion, we have confirmed the clinical features of patients with dup16p, involving the terminal 16p13.1-p13.3 region. Vascular anomalies have been previously described in association with dup16p. Thus, pulmonary vascular disease and other vascular anomalies can be a feature of dup16p, suggesting that this subtelomeric region in some patients could be related to vascular anomalies.

Cytogenetic effects in Chernobyl accident liquidators in delayed terms following radiation exposure

O. W. Shemetun, *M. A. Pilinskaya;*
National Research Centre of Radiation Medicine, Kijiv, Ukraine.

Genome response to radiation exposure caused by mutagenic effects both in the exposed targeted cells as well as in the unexposed bystander cells. In delayed terms following radiation exposure during cytogenetic examination of Chernobyl accident liquidators the frequency of all types of chromosome aberrations in their lymphocytes with the help of G-banding chromosomes staining had been established. The elevated chromosome aberrations frequency in Chernobyl accident liquidators lymphocytes exposed in doses 270-690 mGy formed due to translocations that are stored in the generations of irradiated target cells and chromatid breaks induced by bystander-type effect in the untreated cells had been established. The frequency of deletions, dicentrics and centric rings had no significant difference from control that was result of their elimination in time. In lymphocytes of Chernobyl liquidators exposed to radiation in doses 1010-2540 mGy the level of chromosome aberrations exceeded the population's one at the expense of high frequency of stable cytogenetic markers of radiation exposure, rings chromosomes and chromatid breaks. The results obtained confirmed the persistance of bystander-type cytogenetic effects in somatic cells of exposed persons for many years following radiation exposure. Our data confirm the need to asses the frequency of stable chromosome aberrations as basic cytogenetic markers of radiation exposure under the cytogenetic dosimetry in the late terms following human irradiation and incorrect using such indicators as the „frequency of aberrant cells" and „mean level of chromosome aberrations" that may be overestimated because of chromosome instability markers (chromatid type aberrations) due to the induction of bystander-type effect.

Clinical characterization of five patients with microdeletion at 15q13.2-q13.3

K. Õunap[1,2], E. Oiglane-Shlik[2,3], I. Talvik[2,3], R. Teek[1,2], O. Zilina[1,4], K. Kuuse[1], M. Yakoreva[1], T. Reimand[1,2];
[1]Tartu University Hospital, Department of Genetics, Tartu, Estonia, [2]Department of Pediatrics, University of Tartu, Tartu, Estonia, [3]Tartu University Hospital, Children's Clinic, Tartu, Estonia, [4]Department of Biotechnology, Institute of Cell and Molecular Biology, University of Tartu, Tartu, Estonia.

Individuals with 15q13.3 microdeletion may have wide range of clinical manifestations including intellectual disability (ID), cardiac malformations, seizures, autism and schizophrenia. Deletion of *CHRNA7* gene in this region is causative for the majority of neurodevelopmental phenotypes in the 15q13.3 microdeletion syndrome. Subsets of persons with the deletion have no obvious clinical findings. During 2009-2011 the chromosomal microarray analysis (CMA) was performed in 596 individuals due to their clinical indications. In four individuals 15q13.3 microdeletion was found. In one patient 15q13.2-q13.3 microdeletion was diagnosed previously during research study of the children with ID. Here we present the clinical features of five patients with 15q13.2-q13.3 microdeletion.

All our patients (aged 6-17 years, among them two sibs) had normal growth parameters, except one boy with larger deletion 15q13.2-q13.3 who had short stature and microcephaly. Mild or unspecified ID, speech delay and mild facial dysmorphism was noticed in all patients. Abnormal EEG was found in three of them (60%) and one boy has severe treatment resistant generalized epilepsy (20%). Positive family history for epilepsy was documented in two families. Therefore, it is highly possible that their epilepsy may be also caused by 15q13.3 microdeletion (not investigated yet) as in 1-2% of individuals with generalized epilepsy 15q13.3 microdeletion is found. Cardiac anomaly was occurred in three children (60%).

Microdeletion 15q13.3 is one of the most common microdeletions found by CMA in individuals with ID. In our cohorts of patients it was detected in 0.7% of investigated individuals.

J03.19
Gene polymorphisms and the frequency of chromosomal aberrations in persons exposed to long-term occupational irradiation (Microarray for using)

***L. G. M. K. Takhauov R.M.**;*
Seversk Biophysical Research Center, Seversk, Russian Federation.

There has been studied the correlation between SNP and the frequency and range of chromosomal aberrations in 96 employees (male) of Siberian Group of Chemical Enterprises, exposed to chronic γ-radiation: European, Age - 45-65 year, Cumulative Dose 100-300 mSv. At all employees, the analysis of frequency and range of chromosomal aberrations has been carried out (not less than 300 metaphases). Genotyping were performed by using the microarray „Cancer_SNP_Panel" (http://www.illumina.com/Documents/products/datasheets/datasheet_cancer_snp_panel.pdf). Panel contains 1 421 SNP of 406 genes.

SNP with Call Rate below 80% (25 SNP), SNP with the frequency of rare alleles below 10% (134 SNP), 80 SNP with genotype frequencies, that do not meet Hardy-Weinberg equilibrium, were excluded from the analysis. All in all p-value of 1 262 SNP were calculated with Bonferroni correction for recessive model („SNPassoc" program). There were analyzed the frequencies: aberrant cells; single chromatid breaks; paired fragments; point fragments; dicentric and ring chromosomes; translocations; chromatid exchanges.

Studies have shown that 23 SNP (mutant genotype) (rs2725349, rs2392221, rs1041163, rs2114443, rs6083, rs7462102, rs1760904, rs1051690, rs4986894, rs488133, rs5742694, rs2373721, rs5742667, rs1269486, rs1149901, rs2873950, rs1574154, rs10934500, rs4688046, rs889162, rs230532, rs312016 rs4807542), associated with the high frequency of different types of chromosomal aberrations, including 11 SNP associated with more than one type of chromosomal aberrations.

Whole Genome Array- CGH analysis in patients with Developmental Delay/ Mental Retardation /Congenital Malformations in Saudi Arabia

***I. M. R. Hussein**[1], A. G. Chaudhary[1], R. Bassyouni[2], A. PeerZada[1], H. Schulten[1], M. M. Al Quaiti[1], S. Sogati[3], M. H. Al-Qahtani[1];*
[1]King Abdulaziz University, Jeddah, Saudi Arabia, [2]Ministry of Health, Al-Taif, Saudi Arabia, [3]Maternity & Child Hospital, Jeddah, Saudi Arabia.

Microarray - based Comparative Genomic Hybridization (a-CGH) has enabled wide investigation of the genome at high resolution and has been implemented in different centers as a clinical diagnostic tool. Chromosomal imbalances are implicated in the etiology of Developmental Delay (DD)/Mental Retardation (MR). However, most of these cases could not be diagnosed by conventional cytogenetic techniques. We aimed to establish (a-CGH) technique and assess its potential as a diagnostic tool of chromosomal imbalances and to detect chromosomal aberrations in patients with DD/ MR. Subjects & Methods: A cohort of 47 patients diagnosed as having DD/ MR with or without congenital malformations were referred to the CEGMR for cytogenetic analyses. We used both conventional cytogenetic G-banding and Fluorescent in-situ hybridization techniques, besides we applied (a-CGH) high resolution Agilent scanner with 1X244 K array format, and Affymetrix 2.7 M cytogenetics array. Chromosomal aberrations could be detected in 6/47 (13%) patients by G-banding technique and 4/47 (8%) by FISH technique, however, 14/47 (30%) were diagnosed by a-CGH techniques. The following microdeletion syndromes were detected: (Del 15 (q11.2); Del 15 (q13-14); Del 22 (q11.2); Del 7 (q11.23); Del 18 (q21 q23); Del 1 (p36); and duplications: dup 18p (tetrasomy); dup 15 (q11 q23); dup 18 (q23).We noticed the increased number of CNVs detected by a-CGH which need further investigation for contribution to phenotypes. Our results indicate the strength of high resolution genomic arrays in diagnosing cases of unknown etiology and in detection of contiguous genomic alterations in the wide spectrum of cases with DD/mental retardation.

J03.21
Clinical correlation of mentally retarded individuals suffering from pervasive developmental disorders (PDDs) in South Indian population

***S. Rajiv**[1], V. G. Abilash[1], M. Papakumari[2], M. Murugan[2];*
[1]VIT UNIVERSITY, VELLORE, India, [2]Rama Rao Polyclinic, Chennai, India.

Aim and objective: To clinically correlate and analyse the relation between mentally retarded individuals suffering from PDDs.

Methodology: From 130 cases suffering with PDDs a sample of 30 individuals showing MR were chosen according to diagnostic and statistical manual of mental disorders (DSM-IV). We performed cytogenetic analysis by measuring the extent of chromosomal aberrations (CA) along with cytokinesis-block micronucleus (CBMN) assay in human leucocytes. This assay was performed to measure more specifically the DNA damage occurring in peripheral blood leucocytes. Buccal cells were collected and analysed for measuring DNA damage using micronucleus assay. We also checked three genes namely CNTNAP2, SHANK3 and MECP2 for mutations and its association with MR through molecular analysis by Polymerase Chain Reaction (PCR), Single Stranded Confirmation Polymorphism (SSCP) and sequencing.

Result: Cytogenetic analysis (i.e) chromosomal aberrations study ,CBMN assay in leucocytes and micronucleus assay using buccal cells showed significant variations in all MR cases, when compared with control samples. Molecular analysis revealed mutations in CNTNAP2, SHANK3 and MECP2 through PCR, SSCP and Sequencing.

Conclusion: The study showed a variety of cytogenetic abnormality along with significant changes in base pair content in the three genes considered for this study in the MR individuals. More number of these studies with a much larger sample size has to be conducted. So that it helps in biomonitoring and creating awareness in the population. Such studies will help in developing a simpler diagnostic method that can help identify the prevalence of MR in PDDs.

J03.22
Cytogenetics and molecular analysis of beedi workers among Vellore population

***V. G. Abilash**, P. Vasantha Srinivasan, S. Soumit, S. Nishu, S. Rajiv;*
VIT University, Vellore, India.

Beedi is a thin South Asian cigarette made of 0.2-0.3g of tobacco flake wrapped in Tendu (Diospyrox melanoxylon) leaf and secured with colored thread at both ends. This work is based on the study of the beedi workers who are extensively engaged in beedi making in Elagiri village, Vellore for generations. Workers roll an average of 500-1000 beedies per day, handling 225-450 grams of tobacco flake, and inhaling tobacco dust and other volatile components. Our aim is to study the induced chromosomal abnormalities by tobacco, a potent carcinogen from cytogenetic and molecular aspects.

Cytogenetic analysis was performed to check the chromosomal aberrations in the beedi workers. Totally 27 workers samples and 15 controls are collected; the result shows that there is a significant increase in the aberrant cells to the workers than the control. Also there is an increased evidence of chromosomal aberration to the workers having the habit of smoking than the non-smokers. The aberration differences observed is due to smoking while the other group got tobacco exposure indirectly through tobacco dust while manufacturing.

In molecular analysis, DNA was extracted from the blood samples followed by PCR amplification with primers specific for the cyp1a1 gene (Exon-1). The PCR amplification product was determined by 1% agarose gel electrophoresis, then SSCP (Single Strand Conformational Polymorphism) was carried out to detect mutation by deletion or addition in bands. In this study 3 deletions were observed out of 10 beedi workers when compared with control.

J03.23

Study of methylparathion on bone marrow cells from mice, in vivo: Micronucleus assay

I. P. Aranha;
Dept. Genética, IBRAG, Univ. do Estado do Rio de Janeiro, Rio de Janeiro, Brazil.

Methylparathion is a largely used pesticide. To exert its biological effect it must be biotransformed into methylparaoxon. Previous work in our laboratory, using the chromosome aberrations assay in human lymphocytes in vitro has shown that while methylparathion had no clatogenic or aneugenic effect on chromosomes, methylparaoxon was responsible for the alterations in structure observed. The objective of the present work was to study the effect of methylparathion on chromosomes of mice bone marrow in vivo, using the micronucleus assay. Animals were separated into four groups. In the first group, 6 animals received methylparathion intraperitoneally during five consecutive days in a concentration equivalent to 25% of the LD_{50}. In the 6th day, animals were sacrificed, their femurs removed, the bone marrows collected and smears were made for slides preparation. After 24h cells were stained with Giemsa Gurr (2%) and analyzed under optical microscope. As positive control, 6 animals received cyclophosphamide (50mg/mL) once. Six animals were injected intraperitoneally with the solvent (corn oil) and 6 animals not exposed to any drug served as negative control for the experiment. In the test group, 12000 cells were observed and 199 showed micronuclei. In the group exposed to the solvent, 12000 cells were analyzed and none had micronucleus. In the positive control group, 12000 cells were observed and 102 had micronuclei and in the negative control group, of 12000 cells observed, none had micronucleus. The chi-square test for independence showed that our results were extremely significant (P<0.0001). They suggest that methylparathion is responsible for the micronuclei observed.

Genetic and demographic aspects in Kaluga region and among the families with reproductive losses

B. Ginzburg;
Regional Hospital of Kaluga, Kaluga, Russian Federation.

The national composition of Kaluga region is chiefly represented by Russians (93.5%).

Beginning from 2000 the parity of childbirth in Kaluga region changed as follows: the number of primiparas decreased by 5 %, while the number of women giving second birth increased by 3%, and the number of women with three childbirths increased by 2%. The number of women with 4 and more childbirths remained unchanged (4%).

Within the last 11 years Kaluga region birth rate increased by 30%, this fact being accompanied by the increase of childbearing women's average age from 25,05 to 26,85 years.

In the group of 957 families with reproductive losses the average age of women ranges from 26,92 to 28,5 years, which is distinctly higher than general population rate. The expected Down syndrome frequency among the families with reproductive losses amounts to 14,46 per 10000 neonates, general population rate being 11,51. This fact may initiate age-related fetal pathology and cause present and future reproductive losses. The average age of the men from the families with reproductive losses amounts to 29,46, which turns out to be lower than general population rate (30 years). Based on this, the fact described above should not influence the frequency of age-related fetal pathology in the families with reproductive losses.

Thus, we obtained certain evidences of possible influence of the age of women from the group with reproductive losses on the increase of age-related neonates pathology frequency and possible increase of repeated reproductive losses among them due to fetus trisomies.

J04.02

Frequency of mutation FV Leiden among the women of reproductive age living in the Novosibirsk region, and communication of this mutation with reproductive losses

L. F. Mitrohina[1], *A. B. Maslennikov*[1,2], *A. R. Shorina*[1], *E. V. Maslova*[1];
[1]*State Novosibirsk Regional Clinical Diagnostic Center, Novosibirsk, Russian Federation,* [2]*Scientific research institute of molecular biology and biophysics of the Siberian branch of the Russian Academy of Medical Science, Novosibirsk, Russian Federation.*

Factor FV Leiden mutation (replacement G on A at nucleotide position 1691 gene *F5*) is the autosomal dominant disorder that predisposes affected persons to venous thromboses and may have an increase risk for pregnancy-related venous thromboembolism finally leads to pregnancy loss.

In control group of 238 women of genital age with the normal obstetric anamnesis, living in the Novosibirsk region and selected by epidemiological criteria, frequency of 1691A gene *F5* has made 0,0044 (in the absence of homozygous genotypes). Results of inspection of 303 women, which anamnesis has been burdened by spontaneous interruption of pregnancy on term till 24 weeks, testify about authentic to higher frequency of 1691A gene *F5*. In this group its frequency has made 0,0396, thus two women have homozygous genotypes. The received results confirm the importance replacement G on A at nucleotide position 1691 gene *F5* as one of genetic factors contributing to early reproductive losses and confirm the big prognostic value of molekuljarno-genetic testing of the FV Leiden mutation at mediko-genetic consultation of families in which there were early reproductive losses, and families which plan pregnancy.

J04.03

Study of Oct4 and Sox2 Genes expression in Haematopoietic Stem Cells

S. Sajadi[1], *M. Hashemi*[1], *M. Soleimani*[2];
[1]*Islamic Azad University,Tehran Medical Branch, Tehran, Islamic Republic of Iran,* [2]*Department of Hematology and Blood Banking , Faculty of Medical Sciences , Tarbiat Modares University, Tehran, Islamic Republic of Iran.*

Every tissue in body needs to regenerate itself after injury. Stem cells because of their abilities of differentiation and self-renewal can expand and give cells to the tissues. Stem cells have various types; one of them is hematopoietic stem cells; in addition to differentiation of hematopoietic cells hsc can also differentiate in to neural, mascular, and cartilage cells. This unique possibility can help us in investigation of new treatments for cancers. So recognition of mechanisms in this process has multipular importance. In the present study expression of sox2 and oct4 genes -known as main genes in self renewal - were considered with RT-PCR from cord blood CD133+ cells. Our results show that both genes expressed in the first and 8th day of expantion but at 12th day despite of sox2 expression; oct4 was not expressd. Because of necessity of oct4 for keeping multipotency; loss of expression will cause to differentiation which seems to appear after 12th day.Our study demonstrated that mechanism of self-renewal in CD133+ cells are similar to embryonic stem cells or embryonic carcinoma cells and different with mesenchyme CD105+34-.

The role of the genetic factors in the recurrent miscarriage

I. Sultanov[1], *N. S. Osinovskaya*[2];
[1]*St.Petersburg State University, St.Petersburg, Russian Federation,* [2]*Ott's Institute of Obstetrics and Gynecology, St.Petersburg, Russian Federation.*

Recurrent miscarriage (RM) is a serious problem of the modern obstetrics. Adrenal hyperandrogenism, which come from congenital adrenal hyperplasia (CAH), is one of the common reasons of RM. We analyzed 10 mutations of the CYP21A2 gene (P30L, I2splice, del8bp, I172N, V236E, V281L, Q318X, R356W, P453S, delA2) and the presence of two types of chimeric genes in two groups of women. The population group (first group), consisted of 82 women, and the second one included 102 women with RM.

Mutations in the 21-hydroxylase gene were detected in 15,5% (17/102) of women with RM and in 2,5% (2/80) of women from population group (p = 0.0013).

The chimeric genes were identified in 25% (25/102) of women in the second group and in 8,5% (7/80) of women in the first group (p = 0.0093).

We have studied 76 women of population group and 73 women with RM by means of the Real time-PCR method, in order to detect the CYP21A2 gene and CYP21A1P pseudogene copies. We found a statistically significant difference between both groups in gene duplications and deletions of pseudogene (p = 0.0235, p = 0.0345, respectively).

Thus the presence of mutations in CYP21A2 gene and chimeric genes has a substantial impact on development of recurrent miscarriage. It is notable that both studied groups differ from each other by the number of pseudogene copies, that might be due to the presence of unknown mutations. Further studies are needed to clarify the role of CYP21A2 gene in the development of RM.

J04.05

Interaction between maternal KIR and fetal HLA-C in success of pregnancy

M. Khosravifar[1], *M. Sanati*[1], *H. Gourabi*[1], *R. Habibi*[1], *N. Chaparzadeh*[2];
[1]*Department of Genetics, Reproductive Biomedicine Center, Royan Institute for Reproductive Biomedicin,ACECR, Tehran, Islamic Republic of Iran,* [2]*1- Department of Biology, Faculty of Science, Azarbaijan University of Tarbiat Moallem, Tabriz, Islamic Republic of Iran.*

Introduction: Killer-cell Immunoglobulin-like receptors (KIR) expressed by natural killer (NK) cells at the site of placentation, can bind to human leukocyte antigen (HLA-C) molecules on trophoblast cells. Both systems are genetically highly polymorphic, in which their interactions result in release of varieties of cytokines and chemokines. The factors modulate placental relationship between mother and her fetus. Thus, it has been hypothesized that each of the particular maternal KIR/fetal HLA-C genotype combinations have different effect in pregnancy success.

Materials & Methods: The patients were 92 couples and 8 women with three or more recurrent miscarriage (RM) with no physiologic or pathologic reason for their problem. Also, 100 healthy porous women were selected as control group. DNA were isolated from the whole blood specimens and genotyped for HLA-C groups and 5 KIR genes (*KIR2DS1, KIR2DS2, KIR2DL1, KIR2DL2, KIR2DL3*) using PCR-sequences-specific primer method (SSP).

Results: Statistical analysis shown, that frequency of the HLA-C2 group is raised in the affected female compared with porous women. The frequencies of activating KIRs in the male of partner of RM were similar to controls women while it had been decreased in the affected female compared with porous women although these don't reach significant.

Conclusion: Our findings support the idea that interaction between maternal KIR on NK cells and paternal HLA-C expressed trophoblast cells, affect the successful placentation.

J04.06

Investigation of association between FABP9 gene mutations and sperm morphological defects in a group of Iranian Men

F. Pouresmaeil, *J. Jamshidi*;
Department of medical genetics, faculty of medicine, Shahid Beheshti university of medical science, Tehran, Islamic Republic of Iran.

Introduction : The male germ cell-specific fatty acid-binding protein 9 (FABP9/PERF15) is the major constituent of the murine sperm perforatorium and perinuclear theca. Because of its cytoskeletal association and sequence homology to myelin P2 (FABP8), it has been suggested that FABP9 tethers sperm membranes to the underlying cytoskeleton. Furthermore, its upregulation in apoptotic testicular germ cells and its increased phosphorylation status during capacitation suggested multiple important functions for FABP9. Also recently it is shown that it can affect sperm morphology in mice . According to these data , we designed a study to evaluate if mutations of this gene can affect sperm morphology in human.

Material and methods : The DNA was extracted from peripheral blood from the infertile males that their sperm count was normal but the number of morphologically abnormal sperms on their semen was above normal. Then the exon sequences of the FABP9 gene was amplified by PCR. These exons were sequenced and then analyzed for detection of potentially mutations.

Results : We couldn't detect any mutation in the four exons, intron 3 and splice sites of the FABP9 gene in our 100 samples which we studied.

Conclusion : As there was no mutation in the exons of this gene in our samples, we can conclude that the mutations of this gene may have a neglectable effects on sperm morphological defects and the infertility caused by that. However, because we didn't analyze the promoter and introns 1 and 2 of this gene, we couldn't say this surely.

J04.07

Human karyotype changes associated with hereditary thrombophilia

R. Mihaescu[1,2], *A. Stoian*[2], *C. Gug*[1], *S. Negru*[1,2], *A. Dan*[2], *C. Serban*[1];
[1]*University of Medicine and Pharmacy, Timisoara, Romania, Timisoara, Romania,* [2]*Oncomed, Timisoara, Romania.*

Background: Thrombophilia is a inappropriate tendency to thrombus formation. In recent years numerous studies were conducted in the field of thrombophilia, in an attempt to prevent the consequences of thrombotic disease.

Methods: Between 02.2010-01.2012 in Oncomed Center we evaluated 104 patients with thrombophilia. 94 were women and 10 men. In 38 women were conducted karyotype.

Results: The study group showed a rate of 92.1% associated mutations. Only 7.9% of patients had a single form of thrombophilia. Thus, 89.5% showed PAI mutation, MTHFR C677T mutation - 52.6% , A1298C MTHFR mutation- 21.1% , double mutation MTHFR in heterozygous form - 4 patients , factor XIII mutation- 12 patients, fibrinogen mutation in 4 and factor V Leyden, factor II, protein S deficiency and GPIIb / IIIa each in 2 patients each.

Of the 38 patients, 28 had different chromosomal polymorphisms. The most common were the presence of satellites in 12 patients: chromosome 13 , 21, 14, 15 and 22. The remaining 16 patients had combined changes, both satellites and constituent heterocromatina. Constituent heterocromatina was present on chromosome 1, 9 and 16, all with PAI1 mutation. 26 patients achieved pregnancy. No differences were found between patients without changes in karyotype and those with this chromosomal satellites, but the patients with combined changes, only 6 (37.5%) have achieved pregnancy.

Conclusions: Both chromosomal changes and status of thrombophilia cause repeated reproductive failures. Further studies are needed to specify the combination of mutations at greatest risk and how therapeutic dose should be adjusted to be effective.

J04.08

Detection of AZF Factor of Y Chromosome

B. Kamaliyeva, *G. Abildinova*;
National Research Center for Maternal and Child Health, Astana, Kazakhstan.

Molecular genetic study of AZF region deletions of Y chromosome was carried out in order to investigate reproductive disorders in men. The material of the study were 177 men with a history of reproductive disorders (57% astenoteratozoospermia, oligoastenoteratozoospermia in 32% and azoospermia in 11%). Cytogenetic and molecular genetic studies were carried out.

Normal karyotype - 46, XY was diagnosed in 159 cases. The 18 cases (10%) showed chromosomal abnormalities: 16 patients -47, XXY - Klinefelter's syndrome, in one case- disomy of Y chromosome-47, X YY, and one structural abnormality - 45,XY,der(14,15)(q10;q10).

The 88 men with infertility and normal karyotype - 46, XY received molecular genetic study. Genomic DNA was extracted from peripheral blood by «Promega» set, USA. Multiplex polymerase chain reaction (multiplex PCR) was performed using Taq-polymerase. 9 STS-markers, specific to AZF-locus, were used, the results of amplification were evaluated by electrophoresis in 7% polyacrylamide gel. 7 patients had deletions of AZF locus, of which AZFa in the 15%, AZFb in the 15%, AZFa+b in the 15%, AZFc in the 55%. The obtained results allowed to establish the genetic cause of spermatogenic disorders, to avoid unnecessary treatment and the tactic of IVF / ICSI program.

J04.09

Use of Y chromosome specific repeat sequencing for sexing by PCR and Single cell PCR

A. Mahjoubi, *F. Mahjoubi*;
Department of Clinical Genetic, National Institute of Genetic Engineering and Biotechnology (NIGEB), Tehran, Islamic Republic of Iran.

Embryo sexing is one of the important ways for sex selection of offspring. This is a potential method to considerably improve animal breeding and the efficiency of dairy and meat production. A novel repeated sequence specific to male cattle has been identified and named S4. S4 is a 1.5 Kb repeating unit contains various internal repeated sequence. S4 is localized on long arm of the Y chromosome in the region near to ZFY genes. Aim: The objective of this study was to establish a simple, sensitive, reliable, reproducible and cost effective PCR based technique for sexing. Materials and Methods: Genomic DNA was extracted from the whole blood samples of male and female cattle. PCR and single cell PCR were performed using specific primers for this region. Result: By this PCR based methods we could differentiate between female and male genomic DNA. Discussion: With this technique we can distinct male from female using as much as 0.1pg DNA. Using this method we could determine the sex of embryo (4 blastomers). This method may optimize for the quantitative detection of Y chromosomes in semen.

Effect of Oxidative Stress on MicroRNAs Expression in Testis, Sperm Quality and Testis Histopathology in Mature Mouse

N. Fatemi[1,2], *H. Gourabi*[1], *M. Sanati*[1,3], *M. Jamali Zavarei*[4], *H. Ayat*[2];
[1]*Department of Genetics, Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Islamic Republic of Iran,* [2]*Department of Genetics, Faculty of Basic Science, Shahrekord University, Shahrekord, Islamic*

Republic of Iran, [3]Department of Medical Biotechnology, National Institute for Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran, [4]Department of Pathology, Tehran University of Medical Sciences, (TUMS), Tehran, Islamic Republic of Iran.

Male infertility is responsible for approximately 50% of infertility in the world. Reactive oxygen species (ROS) is one of the causative agents of infertility in males which effects on sperm quality and function. In this study, the effects of oxidative stress induced by tertiary-butyl hydroperoxide (TBHP) were investigated on sperm quality, testis tissue and miRNAs expression.

Adult male mice strain Balb/c was randomly selected from mouse colony. After a primary study to determine LD_{50}, TBHP was injected at the concentration of 1:10 LD_{50} for 2 weeks. The mice were sacrificed and their testis tissues were used for cell viability, macroscopic-histopathology analysis, ROS assay and miRNAs expression. Epididymis was also surveyed for sperm analysis by CASA system.

The sperm motility, count and viability were decreased in the TBHP treated mice in comparison of the control mice. The flowcytometry analysis showed a significant increase in H_2O_2 and $O_2^{\bullet -}$ levels in both testis and sperm 2 weeks after intra-peritoneal injection. Body weights revealed no treatment-related effects but atrophy of testis and decrease of testis cells viability, the expression of mmu-miR-34a and mmu-miR-181b was observed. Results showed that exposure to TBHP can lead to morphological changes in somniferous tubules.

TBHP-induced oxidative stress caused to decrease in sperm vitality and motility and testis cells viability. Results indicated that oxidative stress induction in testis reduced its normal function. That is due to an increased level of H_2O_2 and $O_2^{\bullet -}$ in testis and their deleterious effects on genomic levels.

Keywords: male infertility, oxidative stress, miRNA.

J04.11

No association between gr/gr deletions and non-obstructive azoospermiain Iranian males

***R. Mirfakhraie**[1], A. Movafagh[1], N. Salsabili[2], S. Rahmani[3];*

[1]Department of Medical Genetics, Shahid Beheshti University of Medical Sciences, Tehran, Islamic Republic of Iran, [2]IVF Dept, Mirza Kouchak Khan Hospital, Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran, [3]Islamic Azad University, Science and Research Branch, Tehran, Islamic Republic of Iran.

Objective: Genes located in the azoospermia factor (AZF) region including AZFa, AZFb, AZFc and AZFd on the long arm of Y chromosome play an important role in spermatogenesis. Microdeletions in these regions have been seen in 10% of infertile males with azoospermia or oligozoospermia. Partial deletions of the AZFc region were also reported to be a significant risk factor for oligo/azoospermia. In this study, we estimated the frequency of partial AZFc microdeletions in Iranian azoospermic men with spermatogenic failure and in fertile controls.

Methods: A total of 150 Iranian azoospermic infertile men were selected for the molecular study of Y chromosome microdeletions. Patients without classical AZFa, AZFb and AZFc deletions and with elevated serum FSH levels were analyzed for detection of partial deletions in the AZFc region. 100 fertile men were also studied as the control group.

The presence or absence of the AZFc gr/gr subdeletion in all subjects was tested by multiplex PCR using sY1191, sY1291, sY1206, sY1201, sY142, sY1258, sY1197, sY1054 and sY1161 STS markers. The unique absence of sY1291 product was considered as a gr/gr deletion.

Results: The prevalence of gr/gr deletions in patients and controls were 8.45% (12/142 cases) and 10 % (10/100 cases) respectively. Statistical analysis showed no significant differences in the frequency of gr/gr deletions between the patient and control groups (p>0.05).

Conclusion: The present study revealed no evidence of association between the occurrence of gr/gr deletion and male infertility in Iranian azoospermic infertile men.

J04.12

Genetic polymorphisms and predisposition to a polycystic ovary syndrome

***T. Hristova**;*

National Genetic Laboratory, Sofia, Bulgaria.

Background: Polycystic ovary syndrome (PCOS) is one of the most common reproductive health problems of women. It is characterized by hyperandrogenia, oligoovulation or anovulation and polycystic ovaries. Although a major genetic contribution is suspected, no particular genes or family of genes have been confirmed to be causal for PCOS.

Methods: 34 women with PCOS and 32 healthy female controls were genotyped by RFLP and SSCP techniques for polymorphisms PvuII T/C and XbaI A/G and (TA)n repeats in ER*α* gene; C polymorphism in STK11 gene; RsaIG/A - in ERβ gene, and Asn680Ser and Thr307Ala in FSHR genes - respectively. Both selected groups (clinical and control) meet all requirements for conducting associative studies.

Results: No differences were found between the alleles distribution in patients and controls for STK11 gene, PvuII T/C in ERα, RsaI G/A in ERβ, Asn680Ser and Thr307Ala polymorphisms in the FSHR. XbaI A/G polymorphism in ER*α* gene was related to a higher risk for PCOS since the prevalence of A alleles was 67.2% in PCOS group vs. 46.9% in the controls (p=0.032). Women with two shorter (TA)n alleles in the ER*α* gene were found more often among PCOS patients in comparison to healthy women (44.1% vs. 18.8%, p=0.036).

Conclusions: Our study suggested that the XbaI A/G and (TA)n polymorphisms of the ER*α* gene could be related to the development and clinical features of PCOS. Larger studies in different ethnic groups are needed to establish the precise role of the estrogen receptor polymorphisms for the ovarian function.

J04.13

Comparison between Molecular and Histopathological Methods for Assessment of Spermatogenesis in Non-Obstructive Azoospermic men

***M. Eghbali**[1], M. Akhondi[2], H. Soltanghoraee[3], H. Zeraati[4], H. Edalatkhah[1], N. Lakpour[2], M. Sadeghi[2], M. Modarressi[1];*

[1]Department of Medical Genetics, Faculty of Medicine, Tehran University of Medical Science, Tehran, Islamic Republic of Iran, [2]Reproductive Biotechnology Research Center, Avicenna Research Institute (ARI), ACECR, Tehran, Iran., Tehran, Islamic Republic of Iran, [3]Avicenna Infertility Clinic, Avicenna Research Institute (ARI), ACECR, Tehran, Iran., Tehran, Islamic Republic of Iran, [4]Epidemiology and Biostatistics Department, School of Public Health, Tehran University of Medical Sciences, Tehran, Iran., Tehran, Islamic Republic of Iran.

In Non-Obstructive Azoospermic (NOA) men, evaluation of spermatogenesis is performed with histopathological techniques as a gold standard. Pathological assessment of testes could be imprecise due to randomized biopsy and presence of focal spermatogenesis. NOA men showed a variety of defects in spermatogenesis stages, therefore molecular analysis of the stage-specific of gene expression in the testis could be confirmatory of histopathological techniques in evaluation of spermatogenesis in NOA men.

In this study, spermatogenesis status evaluated through expression of germ cell specific genes (DAZ, TSPY1, SPTRX3 and SPTRX1) in testicular tissue of azoospermic men. Histophatological evaluation was performed using H&E routine method. Semi-nested RT-PCR was performed on synthesized cDNA. The molecular results prepared from gene expression were compared with the histopathological findings using Kappa test.

RT-PCR results showed a significance difference (Kappa coefficient=0.009, P value = 0.894) with the histopathological results. TSPY1, DAZ, SPTRX3 and SPTRX1 were expressed in 94%, 94%, 17.6% and 52.9% respectively in azoospermic men diagnosed as Germ cell aplasia. Detection of DAZ, TSPY1 and SPTRX1 transcripts in testicular tissue can be used to predict the presence of mature spermatid / sperm in the testis especially in men diagnosed as spermatogenesis arrest using histopathological technique and may provide the better chance of finding the mature sperm to use through ART.

J04.14

Complex molecular study of Klinefelter syndrome

***V. B. Chernykh**, T. M. Sorokina, L. F. Kurilo, O. P. Ryzhkova, E. A. Bliznetz, A. L. Chukhrova, A. V. Polyakov;*

Research Centre for Medical Genetics, Russian Academy of Medical Sciences, Moscow, Russian Federation.

We examined 46 KS patients with following karyotypes: 47,XXY (n=37), 47,XXY,t(3;8)(q23;p21) (n=1), 47,XY,derX (n=1), mos 46,XY/47,XXY (n=4), mos 47,XXY/48,XXXY/46,XY (n=1), mos 46,XX/47,XXY (n=1) and 48,XXYY (n=1).

Molecular study included the analysis of Y chromosome microdeletion, CAG-repeat of exon 1 of the Androgen Receptor (AR/HUMARA), X chromosome inactivation (XCI) and PCR amplification of 12 STR loci of the X chromosome (Investigator Argus X-12 Kit, Qiagen).

No classic (complete) AZF deletion was found. Partial AZFc deletions (b2/b3, n=4; gr/gr, n=1; del sY1197 and sY1206, n=1) were detected in 6 of 46 (13%) patients. AR CAG-repeats number varied from 16 to 30, alleles with 26-30 repeats were found in 7 of 43 (16.3%) patients. Homozygosity and heterozygosity for CAG-allele was revealed in 17 and 26 of 43 examined individuals, respectively. Eleven homozygous for AR-allele patients were tested for 12 STR loci. We found that X chromosomes were different in 3 cases (two 47,XXY and one 48,XXYY), and X-haplotypes were the same in 8 cases. XCI was evaluated in 21 of 26 AR-allele heterozygous individuals. Skewed XCI with the rate 70-80% was found in 3 of 21 (14.3%) 47,XXY men, 4 patients presented XCI rate (67-69%) near to skewed.

In contrast to partial deletions classic AZF deletions no found in KS. No strong genetic and phenotypic correlation was revealed between KS patients with or without Y chromosome microdeletion, normal or high AR CAG-repeats, and random/skewed XCI. However severe oligozoospermia was detected only between KS patients with normal CAG-repeats, not-skewed XCI and without AZF deletion.

J04.15

Male infertility and polymorphisms in CREM, LRP8, ABCA1, SMPD1 genes.

H. Jaklič[1], N. Teran[2], B. Zorn[3], I. Novaković[4], M. Ristanović[4], C. Tulić[4], B. Peterlin[1];
[1]Institute of Medical Genetics,Dep.of Obsterrics and gynaecology,University Medical Centre Ljubljana, Ljubljana, Slovenia, [2]Institute of Medical Genetics,Dep.of Obsterrics and Gynaecology,University Medical Centre Ljubljana, Ljubljana, Slovenia, [3]Dep.of Obsterrics and gynaecology,University Medical Centre Ljubljana, Ljubljana, Slovenia, [4]Institute of Human Genetics, School of Medicine, University of Belgrade, Belgrade, Serbia.

The lipid metabolism genes play essential role in mouse spermatogenesis, but their role in human infertility has not been fully established. Products of CREM gene are essential for the initiation of spermatid maturation and development. Mice lacking CREM gene exhibit specific arrest of round spermatid development, fenotype similar to some human infertility conditions. Few studies have shown that CREM deficiency is associated with spermatogenic disorders in man. ATP-binding cassette transporter 1 (ABCA1) mediates lipid efflux from Serotoli cells and influences male fertility. Apolipoprotein E receptor-2 (LRP8) and acid sphingomyelinase (SMPD1) play important role in sperm development, maturation and function in mice. This case-control study investigated associations between polymorphisms in the CREM, LRP8, ABCA1 and SMPD1 genes of lipid metabolism and male infertility.
Screening of eight polymorphisms (CREM: rs1531550,rs17499247, LRP8: rs17108177,rs3737983, ABCA1: rs2230806,rs2066714, SMPD1: rs1542705,rs1050239) was performed in 522 Slovenian and Serbian men with azoospermia and/or oligoasthenospermia and in 445 Slovenian and Serbian controls.
Distribution of genotypes and alleles of investigated polymorphisms were in accordance with Hardy-Weinberg equilibrium in different groups or with the total population. We have found significant differences in genotype frequencies of ABCA1 gene rs2066714 polymorphism ($p<0,002$) between group of patients with azoospermia and control group. However, no significant differences in genotype frequencies of other tested polymorphisms (CREM,LRP8,SMPD1) and male infertility were observed (azoospermia and/or oligoasthenospermia).
The ABCA1 gene rs2066714 polymorphism might represent a possible risk factor for infertility susceptibility in Slovenian and Serbian men. Further studies with a larger sample size are needed to confirm these findings.

A novel nonsense mutation in HSD17B3 gene in a Tunisian patient with sexual ambiguity

B. Ben Rhouma[1], N. Belguith[1,2], M. Mnif[3], T. Kamoun[4], N. Charfi[3], M. Kamoun[3], F. Abdelhedi[1,2], M. Hachicha[4], H. Kamoun[1,2], M. Abid[3], F. Fakhfakh[1];
[1]Faculty of medicine, Sfax, Tunisia, [2]Department of Medical Genetics, Hedi Chaker Hospital, Sfax, Tunisia, [3]Department of endocrinology, Hedi Chaker Hospital, Sfax, Tunisia, [4]Department of Pediatrics, Hedi Chaker Hospital, Sfax, Tunisia.

17 β-hydroxysteroid dehydrogenase type 3 isoenzyme (HSD17B3) is present almost exclusively in the testes and converts delta 4 androstenedione (Δ4 androstenedione) to testosterone. Mutations in the *HSD17B3* gene cause HSD17B3 deficiency and result in 46 XY disorders of sex development (DSD).
The present paper is the first to report on 46,XY DSD case due to HSD17B3 deficiency in Tunisia. The two years old patient belongs to a consanguineous family, her clinical presentation and endocrinology evaluation showed a sexual ambiguity (Prader IV) and testosterone/Δ4 androstenedione ratio equal to 0.16, reflecting a defect in HSD17B3 enzyme activity (normal range is>0.8). The karyotype was realized by standard G banding technique and was 46,XY and the mutational analysis identified a novel homozygous nonsense mutation in *HSD17B3* gene in the exon 9 (c.618 C >A) leading to the substitution p.C206X. The protein lacked 105 amino acids in the C-terminal region. According to the multiple alignments, the missing 105 amino acids of the C-terminal region were almost conserved in different species. This conservation together with the absence of the mutation in 50 controls support the pathogencity and explain the 46,XY DSD observed in our patient.
In conclusion, we detected and reported, for the first time, a novel nonsense mutation leading to 17BHSD3 deficiency in a Tunisian patient. Based on the present data, the screening of this mutation could help contribute to the rapid diagnosis of HSD17B3 deficiency. The genetic confirmation of mutation in *HSD17B3* gene provides crucial information for genetic counseling and prenatal diagnosis.

J04.17

Genetic investigation of mov10L1 gene in azoospermic men with complete maturation arrest

H. Sarkardeh[1], H. Gourabi[1], M. Totonchi[1], M. Sadighi Gilani[2], N. Almadani[1], P. Borjian[1];
[1]Department of Genetics, Reproductive Biomedicine Research center,Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Islamic Republic of Iran, [2] Department of Andrology, Cell Science Research Center, Royan Institute, ACECR, Tehran, Islamic Republic of Iran.

Thousands of genes are involved in spermatogenesis. Alterations in any of these genes could be one cause of infertility in men. Mov10L1 gene is one of the genes that are expressed specifically in germ cells. Genetic disruption of this gene in mouse stops spermatogenesis during Meiosis I and causes Azoospermia.
In this study, the genetic changes of mov10L1 gene analyzed in a population of 30 infertile patients with a complete cessation of spermatogenesis as the patient group and 70 fertile men who had at least one child as the control group.
After DNA extraction from blood samples of selected individuals, PCR-SSCP method was done to classificate individuals and ultimately sequencing was used to confirm genetic changes of the mentioned area.
Analyzing the data shows, from 30 azoospermic patients, 6 patients had (C25A) and (A101G) changes in exon 18and also(G105A) change in exon 18 was seen in only three of patients . Change (A101G) causes the Arginine amino acid convert to Glutamine at its protein level, while the other two Changes are nonsense polymorphisms. The changes were not observed in the control group.
Based on the results, it is expected that mutations and polymorphisms in mov10L1 gene could be a genetic factor in the incidence of infertility in men which requires further studies.

An analysis of 2000 cases of amniocentesis in our hospital over 30 years

Y. Goto[1,2], A. Kondo[1,2], S. Sato[1,2], Y. Ohnuki[2], H. Moriya[2], K. Tsuji[2], H. Yokoyama[2], M. Mizoguchi[2], S. Izumi[1,2];
[1]Dept. of Obstetrics and Gynecology, Tokai University School of Medicine, Kanagawa, Japan, [2]Clinical Genetics, Tokai University Hospital, Kanagawa, Japan.

Amniocentesis is one of the prenatal diagnosis which is an invasive procedure. In 1966, Steele et al. performed amniocentesis first and they succeeded the fetal chromosome analysis. Our hospital performed the first amniocentesis in 1976. Since then, we have done more than 2000 cases over 30 years. When we started amniocentesis, we examined amnio fluid and fetus by feeling with the hands because ultrasonography had not developed enough. In addition, obstetrician had to cultivate cells because there was no processing section. Ultrasonography has become a common tool and it makes us to perform amniocentesis easier. We could perform amniocentesis with more information such as placentation, fetus and leiomyoma. We also could order chromosome analysis to a commercial company.
Amniocentesis is getting easier and more people would like having it, so we have to consider more carefully about the ethical and social aspects of the prenatal diagnostic examinations. Before performing prenatal diagnostic test, we have to give some information such as the maternal and fetal risk and complications and also have to discuss together what the clients would like to do after knowing the results.
In this report, we show patient's motives, age, gestational weeks and chromosome results of amniocentesis in our hospital and discuss about the ideal way of amniocentesis.

Laboratory investigation of affected fetuses in beta-thalassemia

F. Bayat, A. Valaei, M. Taghavi Basmanj, S. Ahmadi, Z. Kainimoghadam, M. Mortezazadeh, A. Amirian, F. Navab Moghadam, A. Sanjari, M. Choobini, N. Sabokbar, F. Maryami, A. Kordafshari, M. Karimipoor, S. Zeinali;
Pasteur Inisititute of Iran, Tehran, Islamic Republic of Iran.

introduction
The beta thalassemia is the group of blood disorder in which the function of one or both beta hemoglobin genes is affected. About 13 beta-globin mutations encompass 70 - 90% of mutation spectrum in Iran .The total annul Iran

with more than 1800 affected individuals, represents one of the areas in the word with an unusually high prevalence of beta thalassemia.
Material and Method
Couples of beta-thalassemia were referred to Pasteur Institute of Iran from Primary Health Care(PHC)center. Fetal samples of chronic villous were collected according to the gestational age .DNA extraction was performed according to standard methods by Roche kit. We used PCR -ARMS and RFLP and direct sequencing technologies, for detection mutations of fetuses.
Result
We detected mutations from 360 couples who were beta thalassemia carriers. 192 of these couples referred for prenatal diagnosis. 28 families had more than one pregnancy. The Result of our study shown that 25/2% of fetuses were affected. 24/8% were normal and remained were carrier. 60% of fetuses were compound heterozygous and 40% were compound homozygous. The expected compound homozygous were (IVS II-1/ IVS II-1) &(IVS I-5/ IVS I-5) and the expected compound heterozygous were (IVS II-1/IVSI-6),(IVS II-1/ IVS I-5),(IVS II-1/CD 8/9),(IVS II-1/CD30).
Discussion
Since the Iranian population is mixture of different ethnic group, it is necessary to determine the frequency and distribution of mutations. It helps us to diagnosis prenatal and preventing to birth of affected fetus in couples at -risk of having an affected child.

J05.03

Detection of Fragile x chromosome mutation in males with developmental delay / mental retardation

A. Erjavec Skerget[1], V. Kuncnik[2], Š. Stangler Herodež[1], B. Zagradišnik[1], A. Zagorac[1], N. Kokalj Vokač[1];
[1]University Medical Centre Maribor, Maribor, Slovenia, [2]University Medical Centre Maribor, Ljubljana, Slovenia.

The fragile X syndrome gene (FMR1) contains a highly variable repeat of the nucleotide triplet (CGG). A variety of clinical conditions is associated with the expanded allele sizes that predominantly affect males. Fragile X syndrome is caused by a large expansion of CGG repeat (full mutation) which silences the FMR1 gene and stops the protein (FMRP) production. An important feature of the syndrome is mental impairment which may include mental retardation, autism, etc. It is therefore important to exclude FXS whenever patients are in diagnostic procedure for developmental delay affecting mental capabilities.
For the detection of the FXS patients, a PCR-based technique, designed as an exclusion test, was used. This technique is useful for the detection of normal variants of the CGG repeat number in males and heterozygous females. The definitive diagnosis of FXS based on molecular genetic analysis, Southern blot technique, which is labour intensive and time consuming.
We analyzed DNA samples from 97 male subjects from North Eastern Slovenia referred for genetic testing because of developmental delay / mental retardation. The PCR amplification for FXS was successful in 92 patients out of 97 (94.8%). The presence of normal CGG sequence variations was detected in 91 subjects; in one patient (1.08%, 1/92) FXS was suspected and subsequently confirmed by Southern blot analysis.
Presented methodology, based only on PCR assay as screening test, is suitable as a preliminary test to exclude FXS in males or heterozygous females. With this approach we detected full mutation in 1.08% of males.

J05.04

Prenatal invasive diagnostics chromosomal pathology

M. Bayanova, G. Abildinova, A. Kostina, E. Moldagulova;
National Research Center for Maternal and Child Health, Astana, Kazakhstan.

The prime value among actions for the prevention of a birth of children with a hereditary pathology belongs to prenatal diagnostics the leading part in which is taken away to invasive methods.
In 3432 cases for the purpose of diagnostics of a chromosomal pathology at a fetus in the first and second trimesters of pregnancy for prenatal karyotyping Indications for prenatal research were: the age of the pregnant woman of 35 years also is more senior, a deviation of indicators of the biochemical serum markers, ultrasonic markers of a chromosomal pathology at a fetus.
In 95 % cases (3260) have defined the normal karyotype - 46, /46, has been diagnosed. Percent of detestability of chromosomal aberrations - 5,0%. At prenatal diagnostics of a fetus it has been taped - 172 cases of a pathology. From them 83,1% cases of aneuploidy (143), the 16,9% structural aberrations: translocations, duplications, inversions (29).
Structure of a chromosomal pathology: the Down's syndrome - 47,5 % (68), Edwards's syndrome - 20,3 % (29), the Patau's syndrome - 6,3 % (9), the Turner's syndrome - 8,4 % (12), the Klainfelter's syndrome - 3,5 % (5), triplo X - 4,9 % (7),the other aneuploidy - 9,1 % (13).
Above cited data most visually reflects necessity of carrying out of prenatal invasive diagnostics at pregnant women of group of high risk on chromosomal anomalies.

Quantitative Real-time PCR for non-invasive rapid and reliable diagnosis of Turner Syndrome

J. Ezzati[1], M. Hashemi[2], R. Mahdian[3];
[1]Islamic Azad University,Science and Research Branch, Tehran, Islamic Republic of Iran, [2]Islamic Azad University,Tehran medical Branch, Tehran, Islamic Republic of Iran, [3]-Department of Molecular Medicine, Biotechnology Research Center, Pasteur Institute of Iran, Tehran, Islamic Republic of Iran.

The aim of the study is a method of non-invasive for prenatal diagnosis, which is based on quantitative real-time PCR. Materials and Method: Genomic DNA were extracted from peripheral blood lymphocytes of Turner syndrome subjects (n=15), and normal controls (n=10) that were tested by quantitative real-time PCR. This technique was applied by a MGB TaqMan probe based real-time PCR assay for rapid diagnosis of monosomy X-linked status in Turner syndrome. In the present study, we have measured and determined the gene dosage of FVIII (target gene on X chromosome) relative to PMP22 (reference gene on 17p11.2). Results: The formula ratio = 2-ΔΔCt applied for the calculation of the FVIII/PMP22 ratio. The gene dosage ratio was quel 1.005±0.00342 and 0.4867±0.00797 for normal individuals and Turner syndrome, respectively. Conclusion: This technique, including quantitative real-time PCR can be used as a rapid and standard and reliable method for rapid detection of prenatal diagnosis of monosomy X-linked.

Investigation of Hb variants among patients referred to Pasteur institute of Iran

M. Taghavi, S. Ahmadi, F. Bayat, A. Valaei, A. Amirian, Z. Kainimoghadam, M. Mortezazadeh, A. Kordafshari, A. Sanjari, N. Sabokbar, M. Choobini, S. Sadegh, F. Navabmoghadam, F. Maryami, M. Karimipour, S. Zeinali;
Pasteur Inisitute of Iran, Tehran, Islamic Republic of Iran.

Background and Objective: More than 700 hemoglobin variants have been described, of which clinically most important ones requiring diagnosis are HbS ,HbC ,HbE ,HbD Panjab and Hb O Arab. Here We have investigated the frequencies and types of Hb variants in β-globin gene among patients referred from primary health care to Pasteur institute of Iran.
Materials and methods: After obtaining informed consent, the blood samples were collected in tubes containing EDTA. Genomic DNA was extracted using the salting out method. ARMS- PCR was used for molecular characterization of HbS. The region containing exon 3 was amplified for HbD and the PCR product of this amplicon was digested by EcoRI restriction enzyme. DNA sequencing techniques were used to analyze for samples without finding any mutations.
Results and discussion:
In this study we showed that Hb D was the most common Hb variant with(50%) and after that Hb S with(36%), in order of frequency by Hb C(5.5%),Hb E(2.7%),Hb monoro(2.7%),Hb G(2.7%).These Hb variants other than Hb S are probably rare(except Hb D) because they do not provide any selective advantage for any severe disease and usually do not any health problem even in homozygous states.

J05.07

The relationship between polymorphisms & sites of beta-globin gene

A. Valaei, F. Bayat, S. Ahmadi, M. Taghavi basmanj, Z. Kainimoghadam, A. Amirian, N. Sabokbar, M. Mortezazadeh, F. Navab moghadam, A. Sanjari, M. Choobini, F. maryami, A. Kordafshari, M. Karimipour, S. Zeinali;
Pasteur Institute of Iran, Tehran, Islamic Republic of Iran.

Introduction
The thalassemia syndrome the most common monogenic disorders in the world . Polymorphism in biology occurs when two or more clearly different phenotypes exist in the same population of a species . The term is also used somewhat differently by molecular biologists to describe certain point mutations in the genotype, such as SNPs(IVSII-666 , CD2,…). IVSII-666 and CD2 are located in the second intron and first exon of the β-globin gene respectively. In this research we investigated relationship between polymorphisms and haplotypes.
Materials& Method:
Informed consent was obtained in all cases before the collection of blood samples.DNA extraction was performed by salting out method.175 unrelated families of heterozygous thalassemia that referred to Pasteur Institute of Iran including carrier of α and β-thalassemia that didn't find any mutation was investigated. we were determined by direct sequencing using Big Dye

from ABI. With RFLP was studied at 3 sites within the beta-globin gene cluster, including 3`ψ βHincII, βAvaII, βHinfI.

Results:

total of them 20% had different polymorphisms there were relationship between IVSII-666 and CD2 polymorphisms with three sites within the β-globin gene cluster**.** This results were shown that about 90% pattern of AveII /β site in IVSII-666 , CD2 was -/+ . about 70% pattern
of 3`ψHincII /β site in IVSII-666 , CD2 was -/+ and in HinfI/β was +/+

Discussion:

With sequencing method we found pattern of 3 sites in the cluster of beta globin. So, These relations can help us in Prenatal Diagnostic.

J05.08

Two cases of 22q11 deletion syndrome prenatal detection

Y. Kozlova, *N. Shilova, M. Minzhenkova, E. Yudina;*
Federal State Budgetary Institution "Research Centre for Medical Genetics" of the Russian Academy of, Moscow, Russian Federation.

22q11 deletion syndrome (22q11DS) is a well known syndrome with the occurrence of 1 in 4000 life births. Up to 75% of 22q11DS detected due to presence of congenital heart defect (CHD), mostly conotruncal. It is widely described and detected in pre- and postnatal diagnosis. Despite ultrasound (US) techniques improvement and specialists' awareness of the possible fetal phenotype suggestive for this deletion, 22q11DS prenatal diagnosis remains complicated because of atypical phenotype that may present and difficulties of the syndrome's earliest detection. We evaluated two groups of pregnant women referred to invasive procedures in 1st (22 cases) and 2nd (27 cases) trimesters due to US findings. Two fetuses were found to carry 22q11 deletion. Indications of the 1st trimester were increased nuchal translucency (NT) -19 (none detected) and lymphatic formations in the neck area - 3 (1 detected). In the 2nd trimester one of 20 fetuses with CHD had 22q11 deletion and none of 7 with intrauterine growth retardation and/or palatal malformations was found to carry 22q11 deletion. 22q11DS prenatal diagnostics in 2nd trimester could be proposed when US reveals CHD, e.g. conotruncal, while in 1st trimester the main US-findings are increased NT, lymphatic malformations (edemas, cysts), which may later transform to CHD. For now isolated NT is admitted as unreliable US-key for 22q11DS, so we suppose that such a rare symptom as lymphatic formations could be another indication for 22q11DS investigation in early diagnostics. Further elaboration of diagnostic criteria's for early deletion detection can help genetic consultation of these families.

J05.09

Prenatal case of Pallister-Killian syndrome in conjunction with unbalanced t(15;18)

N. V. Shilova, *Y. O. Kozlova, M. E. Minzhenkova, E. V. Yudina, Z. G. Markova, T. V. Zolotukhina;*
Federal State Budgetary Institution „Research Centre for Medical Genetics" under the Russian Academy of Medical Sciences, Moscow, Russian Federation.

A 28-year-old primigravida was carried cordocentesis after an expert fetal ultrasound at 22 weeks of gestation which revealed increased nuchal translucency, hypoplasia of nasal bone, smoothed profile, intrauterine growth retardation (2-3 weeks), micromelia of predominantly rhizomelic type, a left severe congenital diaphragmatic hernia, right-sided displacement of the heart, hypoplasia of the left lung, small for the gestation age ears. GTG-banding karyotype in cultured fetal blood lymphocytes showed 46,XX,der(15). mFISH (24XCyte, MetaSystems) revealed an additional material of chromosome 18 on q-arm of chromosome 15. FISH with subtelomere 18p/q DNA-probes (TelVysion, Vysis, Abbott) showed presence of 18q-material. Paternal karyotype was normal and mother was found to have balanced translocation 46,XX,t(15;18)(q24;q21). Since ultrasound phenotype was also rather suggestive for Pallister-Killian syndrome (PKS), FISH-analysis was performed with CEP12 DNA-probe (Vysis, Abbott) on non-cultured fetal blood. Three copies of D12Z1 loci were revealed in 10% of cells. Two metaphase spreads with supernumerary i(12)(p10) also were found by FISH-analysis of cultured lymphocytes with XCAP 12 short DNA-probe (MetaSytems). Thus fetal karyotype was determined as 46,XX,der(15)t(15;18)(q24;q21)mat[58]/47,XX,der(15)t(15;18)(q24;q21)mat,+i(12)(p10)[2]. Considering severe life prognosis, the family opted for termination of pregnancy after genetic counseling. Postmortem examination corroborated ultrasound findings. Prenatal detection of PKS remains significant and also complicated because of well known tissue specific mosaicism and low presence of additional isochromosome 12p in cultured lymphocytes. Thus, if fetal phenotype is suspected of PKS, despite of normal karyotype in cultured lymphocytes, it is necessary to use FISH with chromosome-specific 12 DNA-probes on direct blood samples or another fetal tissues.

J05.10

Mutation spectrum of CD40LG gene in Russian families with X-linked HIGM

I. Sermyagina, *V. Zabnenkova, A. Poliakov;*
Research Center for Medical Genetics, Moscow, Russian Federation.

Defects in CD40L gene are the cause of X-linked immunodeficiency with hyper-IgM type 1 (HIGM1). HIGM1 characterized high or normal by levels IgM and low IgA, IgG and IgE concentrations. The clinical manifestations of HIGM1 include current infection of respiratory ways, an intermediate pneumonia, a chronic diarrhea, oral ulcers, sclerosing cholangitis and a hepatitis. Gene CD40L includes 5 exons, 4 introns, and mapped to Xq26. In the given work we describe nine patients of a various family tree which have various mutations in CD40L gene. A search of mutations was performed by direct DNA sequencing analysis of all exons and exon-intron junctions and PCR-RFLP. The mutations identified in this research include one combined mutation (c.[744C >A;745C >A]), two splice site mutations (c.156+2T>C, c.346+1G>A), and four deletions/insertions defects (c.13_14delTA, c.158_161delTAGA, c.207_208insA, c.532delT). Two additional patients with the large deletions included exons 1-2 and exons 4-5, but exact borders of defects are not defined. As a whole, this supervision confirm heterogeneity of mutations in HIGM1. The splice site mutation c.346+1G>A and deletion c.158_161delTAGA are in hotspot for these mutations in CD40LG. Mothers of all patients were heterozygous for a mutations. Also, seven prenatal diagnostics of HIGM1 have been made.

J05.11

Unbalanced translocation with two partial monosomies in fetus with 45 chromosomes

S. Mandal[1], *B. B. Ganguly*[1], *N. N. Kadam*[1], *N. M. Oza*[2];
[1]*MGM Centre for Genetic Research & Diagnosis, Navi Mumbai, India,* [2]*Oza's Maternity Hospital, Navi Mumbai, India.*

Constitutive unbalanced translocations are generally inherited from one parent carrying balanced translocation, and described as derivative or recombinant chromosome carrying partial monosomy of one and partial trisomy of the other chromosome. However, transmission of partial monosomy of both chromosomes of a parental balanced translocation is a very rare phenomenon. In the present case, increased fronto-nasal angle detected through routine ultrasound imaging as a measure of antenatal screening was the only deformity to consider fetal karyotyping. FISH test was also performed for quick testing of the numerical status of chromosomes 13, 18, 21, X and Y, which appeared normal. However, conventional G-banding karyotype appeared with 45 chromosomes and monosomy 21. Since interphase FISH presented two normal signals of 21, a critical analysis following high resolution banding was performed and could trace the second 21 rearranged on 9p. Therefore, the fetus was carrying 45,XX,der(9)t(9;21)(p22;q11.2) karyotype with a constitutive abnormality. Subsequently parental karyotyping confirmed mother being the carrier of t(9;21)(p22;q11.2) transmitted the unbalanced translocation. The present fetus had 45 chromosomes without the other derivative chromosome resulting in partial monosomy of both chromosomes. Therefore, it is apparent that meiotic nondisjuction, most likely maternal, resulted in aneuploid condition. Had the child inherited the normal 21 from the mother, the child would have had partial trisomy 21q which might have produced clinical expressions of Down syndrome. This is the first case to describe two partial monosomies in an aneuploid fetus with 45,XX,der9t(9p22;21q11.2). The study also describes the complementation of FISH and G-banding techniques in prenatal diagnosis.

J05.12

Gene expression profile as a prenatal test for Down syndrome

M. Volk, *A. Maver, L. Lovrečić, B. Peterlin;*
Clinical Institute of Medical Genetics, UMC Ljubljana, Ljubljana, Slovenia.

The effect of supernumerary chromosome 21 in Down syndrome (DS) on global profile of gene expression in various cell types has been demonstrated in several previously performed studies. However, diagnostic utility of these transcriptional alterations has been poorly studied. For this reason, we performed global expression profiling to find differentially expressed genes (DEG) and subsequently performed targeted validation and diagnostic performance evaluation on a larger group of case and control samples.

Initially, transcriptomic profiles of amniocytes from 10 fetuses with trisomy 21 and 9 euploid fetuses were determined using Agilent 4x44K expression microarrays. DEG were discovered using linear regression modelling implemented in limma package. Subsequently, top DEG were validated using RT-PCR quantitation on independent sample of 16 cases with DS and 32 controls. The classification was performed using support vector machine classification kernel and evaluated using leave-one-out cross validation ap-

proach.
Global profiling has revealed 1292 DEG in trisomy 21 samples at the adjusted p-value cut-off set at 0.05. Of these, 8 upregulated and 1 downregulated genes were incorporated in the validation core set, and the significant differences in expression were confirmed in all but one gene in core set. Classification performance of this core gene set attained discriminatory rate with AUC values reaching 0.985.
In conclusion, we demonstrate good classification performance of a small expression biomarker set. As expressional alterations reflect both, causal and reactive cellular mechanisms, such biomarker may thus have potential in diagnosis of a wide array of heterogeneous diseases that result from genetic, epigenetic or environmental disturbances.

J05.13
The impact of gene-gene interaction in the development of necrotising enterocolitis in the neonates

N. Gorovenko[1], *Z. Rossokha*[2], *S. Kyryachenko*[3];
[1]*National Medical Academy of Post-Graduate Education, Kyiv, Ukraine,* [2]*Reference-centre for molecular diagnostics of Ministry of Public Health, Kyiv, Ukraine,* [3]*State Institute of Genetic and Regenerative Medicine Academy of Medical Sciences, Kyiv, Ukraine.*

Background: Necrotising enterocolitis (NEC) is a widespread disability in the neonates but its developing mechanism is not completely investigated.
The **aim** of our study was to evaluate gene-gene interaction in the development of NEC in the neonates.
Methods: We conducted a case-control study of 69 neonates with NEC and 110 healthy neonates (control group). The *I/D, A1166C, G308A, C677T* polymorphism of *ACE, AT2R1, TNF-a, MTHFR* genes were detected using PCR and RFLP analysis. Statistical analysis was performed to assess the effects of all analyzed genes and their combinations (Statistica 6.0) and MDR model (MDR_2.0)).
Results: We observed significant differences of several investigated genotypes between neonates with NEC and neonates from control group [table1]. The statistical model including all investigated genes had the higher predictive value (Percentage Correct=69.3, p <0.0001), but we found no additive interaction between investigated genes.
Table 1. The results of statistic analyses

Gene (genotype)	x^2	p	OR	95% CI
ACE (ID)	2,54	>0.05	1,64	0,89-3,00
ACE (DD)	12,48	<0.001	3,6	1,73-7,49
TNFa (AG)	5,37	<0.05	2,12	1,12-4,04
TNFa (AA)	4,7	<0.05	5,14	1,01-26,3
MTHFR (CT)	10,2	<0.05	2,72	1,46-5,06
MTHFR (TT)	4,25	<0.05	3,15	1,01-9,83
AT2R1 (AC)	1,67	>0.05	1,57	0,79-3,11
AT2R1 (CC)	6,16	<0.05	6,1	3,23-30,26

Conclusion: *DD* genotype of *ACE* gene*, CC* genotype of *AT2R1* gene*, AG, AA* genotypes of *TNF-a* gene, *TT, CT* genotypes of *MTHFR* gene in the neonates is independent risk factors with high predictive value for the NEC development. The further research with including other prognostic factors may be useful for new approaches to early diagnostics.

J05.14
The association of genes polymorphism with necessity and duration of oxygen supplementation in respiratory distress syndrome cases

S. Kyryachenko[1], *Z. Rossokha*[2], *N. Gorovenko*[1];
[1]*National Medical Academy of Post-Graduate Education named after P.L. Shupic, Kyiv, Ukraine,* [2]*Reference-centre for molecular diagnostic of Ministry of Public Health, Kyiv, Ukraine.*

Background: The role of genes polymorphism in the development and course of perinatal lung disorder in the neonates is studied insufficiently.
The **aim** of this study was to evaluate the influence of genes polymorphism on neonatal course in neonates with respiratory distress syndrome (RDS).
Methods: We conducted a case-control study of 151 neonates with RDS (including preterm, full-term) and 110 healthy neonates (control group). The *I/D, A1166C, G308A, C677T* polymorphism of *ACE, AT2R1, TNF-a, MTHFR* genes were analyzed using PCR and RFLP analysis. Statistical analysis was performed to assess the analyzed influence (logistic regression, Statistica 8.0).
Results: The risk of RDS was significantly increased for neonates with mutant allele of all investigated genes, excluding *AC* genotype of *AT2R1* gene. We found the influence of certain genotypes on neonatal adaptation course among neonates with RDS [table1].
Table 1. The influence of gene polymorphism on neonatal adaptation among RDS cases

Medical interventions	Genes polymorphism associations			
	Medical interventions	ACE I/D	AT2R1 A1166C	MTHFR C677T
Necessity of emergency care		p<0,01	p>0,05	p<0,01
Duration of hospitalization	p<0,02	p>0,05	p<0,03	p<0,01
Necessity of oxygen therapy	p<0,001	p>0,05	p<0,03	p<0,001
Duration of oxygen therapy	p<0,04	p>0,05	p<0,01	p<0,03

Conclusion: The investigated polymorphism of *ACE, TNF-a, MTHFR* genes is involved in the RDS development and necessity of medical interventions. The further analyzes may be useful for new personalized approaches in the treatment.

Association of 3a4 *1g gene Polymorphism in the development of Acute Leukemia

S. Vuree, *A. C, N. Dunna, V. Satti;*
Department of Genetics, Hyderabad, India.

Acute leukemia is a progressive malignant disease of the blood-forming organs, marked by distorted proliferation and development of leukocytes and their precursors in the blood and bone marrow. Human cytochrome P450 3A enzyme catalyzes the metabolism of exogenous and endogenous compounds. SNPs in the gene encoding this enzyme are known to be associated with altered expression and function. Hence the genetic variation within the CYP3A4 gene may contribute to interindividual variability in drug metabolism.
The present study consists of 392 acute leukemia cases collected from MNJ Regional Cancer Institute and Nizam institute of Medical Sciences, Hyderabad as well as 264 age and sex matched healthy controls. The CYP 3A4 *1G polymorphism was analyzed by PCR-RFLP technique.
Heterozygous GA genotype frequency was slightly elevated in acute leukemia patients (54.0%) when compared with controls (49.0%) indicating the presence of G allele might predispose to acute leukemia. When the data was stratified with respect to type if leukemia, the elevation GA genotype frequency was observed only in AML group.
Attempt was also made to evaluate the interaction of genotype with confounding epidemiological variables like age at onset, occupation, habits and area of living as well with clinical variables like WBC count, Platelet count and complete remission rate.

Antimutation and anticancer effects of Morin in human cutaneous T cell lymphoma

M. Khademi[1], ***R. Karimi***[2], *M. Hashemi*[1], *K. Parivar*[2];
[1]*Islamic Azad University,Tehran medical Branch, Tehran, Islamic Republic of Iran,*
[2]*Islamic Azad University,Science and Research Branch, Tehran, Islamic Republic of Iran.*

At present cancer is one of the mortality factors in the world and treating it debilitates the patient.Therefore,prevention can be considered as important as treatment in cancer.Diet can play a vital role in cancer prevention. Nowadayes the scientists are looking for natural food which can prevent the cancer occurrence.The purpose of this research is to examine antimutagenicity and
anticancer effects of morin in Cutaneous Human T cell Lymphoma(Sezary syndrome).
In this Experimental study HUT-78 cell line were cultured in %90 RPMI1640 , supplemented with10%fetal calf serum,l-glutamine,peniciline,streptomycin and then incubated at 37°cfor2days.The cancer cell line was treated by different morin concentrations and cellular vital capacity was determined by MTT.The morin was subsequently evaluated in terms of antimutagenicity and anti cancer properties by a standard reverse mutation assay[Ames test This
was performed with histidine auxotroph strain of Salmonella typhimurium[TA100] .Thus, it requires histidine from a foreign supply to ensure its growth.The aforementioned strain gives rise
to reverted colonies when expose to carcinogen substance [Sodium Azide].
During MTT,Tcell lymphoma cancerous cells reveaed to have a meaningful cell death when compared with controls[p<0.001].In Ames test morin prevented the reverted mutations and the
hindrance percent of morin was 98.16 % this value in anticancer test was was 99.23 %. These results have revealed morin has anticancer and antimu-

tagenesis effects in the Sezary Syndrome in vitro.

Dose- and Time-Dependent Response of Human Leukemia Cell Line, NB4, to Arsenic Trioxide Treatment

M. Sharifizadeh[1], *M. Hashemi*[2];
[1]*Islamic Azad University,Science and Research Branch, Tehran, Islamic Republic of Iran,* [2]*Islamic Azad University,Tehran medical Branch, Tehran, Islamic Republic of Iran.*

Background: Although arsenic trioxide was shown to be a potential drug in treatment of APL, most notably in patients with relapsed APL, the nderlying mechanisms remains unclear. In this study, the cytotoxicity effect of ATO on APL cancer cells was evaluated.
Material and methods: In this basic-applied study, the human leukemia (NB4) cell line was used as a model to evaluate the cytoxicity effects of arsenic trioxide in APL cells. NB4 cells were exposed to different concentrations of ATO (0.5, 1, 2 µM) for 2, 4 and 6 days and dimethylthiazol diphenyl tetrazolium bromide (MTT) assay was applied on them.
Results: Data obtained from this assay indicated that arsenic trioxide significantly reduced the viability
of NB4 cells and inhibited cell growth in a time and dose dependent manner.
Conclusion: Findings from the present study indicate that arsenic trioxide is highly cytotoxic to human leukemia cells, supporting its use as an effective therapeutic agent in the management of acute promyelocytic leukemia.

Is The BCL-2 Prompter (-938C>A) Polymorphism Associate with IRANIAN Breast Cancer Patients Susceptibility?

B. Motahari[1], *M. Ghaffarpour*[2,3,4], *F. Fereidooni*[5], *G. Javadi*[1], *M. Houshmand*[2,4];
[1]*Dep of Biology,Science and Research Branch,Islamic Azad University, Tehran, Islamic Republic of Iran,* [2]*Medical Genetics Department, National Institute of Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran,* [3]*Iranian Research Organization for Science and Technology(IROST), Tehran, Islamic Republic of Iran,* [4]*Special Medical Center, Tehran, Islamic Republic of Iran,* [5]*The Cancer Institute of Iran ,Imam Khomeini Hospital Complex, Tehran University of Medical Science, Tehran, Islamic Republic of Iran.*

Background and aim: Breast cancer is the first most common
cancer among the females in Iranian cancer patients. Apoptosis and cellular proliferation play role an important role during normal mammary development &carcinogenesis of the mammary gland.Bcl-2 is the one of the most important anti apoptotic genes.Bcl2 gene has been demonstrated with breast cancer development and a single nucleotide polymorphism (SNP-938C >A) has been identified recently.The aim of this study was to identify whether Bcl-2(-938C>A) polymorphism which is located in the inhibitory P2 promoter of Bcl-2 is associate with breast cancer ,as well as clinicopathological characteristics. Materials and methods: patients and tissue specimens: tissue samples were obtained from 34 consecutive patients with BC from IRANIAN National Tumor Bank ,National Cancer Institute, Imam Khomaini Hospital Complex,
Medical Tehran University,Tehran,Iran. Histopathological examinations were performed, and all tumors were confirmed as adenocarcinoma. Mutational analysis of Bcl-2 (-938C> A) in tumour samples: fresh tumours and their adjacent were extracted for genomic DNA using the QIAamp Mini Kit . We searched for
-938C>A in this gene.The Bcl2 (-938C>A) analysis were made by means of PCR sequencing. Result and conclusion:
10 of 34 (29%) samples were analyzed. The frequency of polymorphism in Bcl2 (-938C>A) was not present in the samples (0%).It also was not a significant associated with histopathological grade, age or cancer stage in Iranian Breast Cancer Patients. Although some study have been shown in BC,Bcl-2(-938C>A) polymorphism, our study was not shown and more samples should
be investigated in Iranian Breast Cancer patients.

High prevalence of A15326G alteration in mitochondrial complex III in Iranian breast cancer patients.

M. Arabzadeh[1], *S. Eslamizadeh*[1], *M. Ghaffarpour*[2], *A. Arastehkani*[3], *V. Ghodsinejadkalahroudi*[3], *S. Rahmani*[1], *M. Houshmand*[2];
[1]*Islamic Azad University, Ahar, Tabriz, Islamic Republic of Iran,* [2]*National Institute of Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran,* [3]*Special Medical Center, Tehran, Islamic Republic of Iran.*

Mitochondria play a decisive role in the regulation of apoptosis and thereby exhibiting major changes in their structure and function. A decrease in mitochondrial membrane potential is an early universal event of apoptosis. Numerous somatic mitochondrial DNA (mtDNA) mutations have been found in various types of neoplasms, including breast cancer. Cytochrome b (CytB) of mitochondrial electron transport complex III is encoded in mtDNA 14747-15887 and has also been reported mutated in a large variety of human tumors as breast cancer. Establishing the mtDNA mutation pattern in breast cancer cells may enhance the specificity of cancer diagnostics, detection and prediction of cancer growth rate and/or patients' outcomes; and therefore be used as a new molecular cancer bio-marker. Mitochondrial DNA of 24 patients comprising the coding complex III was analyzed by PCR-sequencing methods. The aim of this study is to summarize data on mtDNA mutation involvement in breast cancer and estimate effects of resulting amino acid changes on mitochondrial protein function. Also T14783C, T14798C, A14820C, G14831A, C14872T, C14929T, C14953T, G15043A, G15110A, T15115C, G15148A, A15158G, A15203G, A15283G, G15301A, C15452A, A15488T, T15514C, G15617A, G15768A, T15793C polymorphisms were found in cyt b.
The polymorphism A15326G resulting in the change of T194A in the Cytb protein was found in the large majority (>95%) of patients. So we think this polymorphism may use as biomarker in breast cancer but more investigation needs to prove it.

J06.06

C14766T polymorphism in mitochondrial complex III as biomarker in Iranian breast cancer patients ?

V. Safarpour[1], *M. Arabzadeh*[2], *S. Eslamizadeh*[2], *M. Ghaffarpour*[3], *V. Ghodsinejadkalahroudi*[2], *A. Arastehkani*[2], *M. Houshmand*[3];
[1]*Islamic Azad University, Dezful, Islamic Republic of Iran,* [2]*Special Medical Center, Tehran, Islamic Republic of Iran,* [3]*National Institute of Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran.*

In most pathways of apoptosis, the release of mitochondrial cytochrome b and apoptosis-inducing factor are also key events in initiating the cascade of reactions leading to apoptotic cell death. Mitochondria play a decisive role in the regulation of apoptosis. Mitochondrial dysfunction is relevant to the genesis of many types of cancers , including breast cancer. Numerous somatic mitochondrial DNA (mtDNA) mutations have been found in various types of neoplasms, including breast cancer. Cytochrome b (CytB) of mitochondrial electron transport complex III has been reported mutated in a large variety of human tumors as breast cancer. Mitochondrial DNA of 24 patients comprising the C14766T was analyzed by PCR-sequencing methods. The aim of this study is to summarize data on mtDNA mutation involvement in breast cancer and estimate effects of resulting amino acid changes on mitochondrial protein function. Amongst patients with breast cancer, this alteration is present in 33.3% of affected females. The polymorphism C14766T resulting in the change of Threonine to Isoleucine missense mutation in the Cytb protein was found in the large majority (33.3%) of patients. It is therefore possible that the C14766T SNP constitutes an inherited predisposition factor for the development of breast cancer.So we think this polymorphism may use as biomarker in breast cancer but more investigation needs to prove it.

J06.07

A12308G alteration in tRNA Leu(CUN) as a biomarker or usual polymorphism in Iranian breast cancer patients?

S. Eslamizadeh[1], *M. Arabzadeh*[1], *M. Ghaffarpour*[2], *V. Ghodsinejadkalahroudi*[3], *A. Arastehkani*[3], *S. Rahmani*[1], *M. Houshmand*[2];
[1]*Islamic Azad University, Ahar, Tabriz, Islamic Republic of Iran,* [2]*National Institute of Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran,* [3]*Special Medical Center, Tehran, Islamic Republic of Iran.*

Mitochondrial dysfunction is relevant to the genesis of many types of cancers , including breast cancer. mitochondrial tRNA genes perform several functions including processing and translation and are essential components of mitochondrial protein synthesis. Until now only few somatic mitochondrial tRNA mutations have been reported in cancer cells. In this study all 22tRNA genes in 24 Iranian females with breast cancer were investigate by PCR-Sequencing methods. A novel homoplasmic C12187T mutation located at the Tloop site for the tRNAHis and A12308G, G12192A, T15968C polymorphisms in TrnaLeu, tRNAHis and tRNAPro were found respectively. The mtDNA A12308G polymorphism is highly conserved between species during evolution and also encodes for the most represented amino acid in the oxidative phosphorylation, suggesting a key role of this tRNA in mtDNA-coded OXPHOS subunits. Inaddition, recently have been shown that breast cancer cell lines with the higher mutation frequency of A12308G are highly metastatic. Amongst our Iranian patients with breast cancer, this alteration is present in 23% of affected females. This SNP has been also reported in many types of disease as Alzheimer, Ataxia, CPEO, LHON, MERF, MELS and...

in Iranian patients. So it needs more investigate to prove the role of this alteration as a common polymorphism or an inherited predisposition factor for the development of breast cancer.

J06.08

Cisplatin and MNPs(Fe3O4) Synergistically Alter Apoptotic Genes Expression

***Z. Hosseinian**[1], A. Akbarzadeh[2], M. Mokhtari[1], M. Taghavi[1], M. Hashemi[1];*
[1]Islamic Azad University, Tehran, Islamic Republic of Iran, [2]Pasteur Institute of Iran, Tehran, Islamic Republic of Iran.

Breast cancer is a common cancer in women. Cisplatin is an anticancer drug. There is high rate of cisplatin resistance in breast cancers, therefore cisplatin is not the first choice in treatment of breast cancer. The mechanism of cisplatin is interaction with DNA and induction of apoptosis. Apoptosis is a common pathway that finally mediates the killing functions of cisplatin anticancer drug. In order to induce apoptosis, many gene functions must be altered. In this study, MCF-7 breast cancer cell line was used. The aim of this study was investigate the potential benefit of combination therapy with magnetic nanoparticles of Fe_3O_4 (MNPs(Fe_3O_4)) and cisplatin. Viability of cell was studied by MTT assay and gene expression was studied by RT-PCR. Analysis of viability percentage and apoptotic genes expression alteration showed that combination of cisplatin and MNPs(Fe_3O_4) have a potent cytotoxic effect on MCF-7 breast cancer cell lines. Combination of cisplatin and MNPs(Fe_3O_4) reduced IC50 of drug in 24 h from 42 µM to 10.35 µM in MCF-7 cell lines. MNPs(Fe_3O_4) and cisplatin can synergistically enhance induction of apoptosis. Cisplatin by itself can not change *BCL2* expression in MCF-7 cell line, but combination of MNPs(Fe_3O_4) and cisplatin can reduce expression of an antiapoptotic gene ,*BCL2*, after 48 h and 72 h. Thus cisplatin therapeutic dose can be reduced and consequently cisplatin side effects can be decreased. Thus our *in vitro* data strongly suggest a potential application of a combination of MNPs(Fe_3O_4) and cisplatin for treatment of breast cancer cell lines.

J06.09

Up regulation of NM23H1 a metastasis suppressor gene in the MCF-7 breast cancer cell line treated by cisplatin

***M. Hashemi**[1], M. Mokhtari[2], A. Akbarzadeh[3], R. Mahdian[4];*
[1]Islamic Azad University,Tehran Medical Branch, Tehran, Islamic Republic of Iran, [2]Islamic Azad University,Science and Research Branch, Tehran, Islamic Republic of Iran, [3]Pilot Biotechnology department, Pasteur Institute of Iran, Tehran, Islamic Republic of Iran, [4]Department of Molecular Medicine, Biotechnology Research Center, Pasteur Institute of Iran, Tehran, Islamic Republic of Iran.

Breast cancer is one of the most common cancers in developed countries. Most of cancer deaths are due to the development of metastasis. Nm23-H1 gene is an anti metastatic factor whose expression is correlated inversely with tumour metastatic potential in breast. Nm 23-H1 encodes nucleoside diphosphate kinase A, which is responsible for the synthesis of most non-ATP nucleoside triphosphates, suggesting that this protein might be involved in a wide variety of biological phenomena in the cell. Cisplatin is the key anticancer drug in the therapy of a wide spectrum of cancers. In the present study, the expression of Nm23-H1 gene in MCF-7 cells treated with different concentrations of cisplatin at 24h was evaluated.

In this study, MCF-7 cells were treated with different concentrations of cisplatin at different times. The IC50 was determined. RNA was extracted by RNX Solution. Then cDNA was synthesized. Precise primers were designed for Nm23-H1 and TBP genes by specific software. Quantity of Nm23-H1 gene expression compare to TBP gene in different concentrations of cisplatin was analyzed using very sensitive quantitative Real-time PCR.

Nm23-H1 gene expression in MCF-7 cells treated by different concentrations of cisplatin at 24h was increased.

The results of quantitative Real-time PCR indicated that cisplatin can probably decrease metastasis, by up-expression of Nm23-H1 metastasis suppressor gene in MCF-7 cells.

J06.10

Quantitative detection of Major BCR-ABL gene transcripts by competitive RT-PCR in chronic myeloid leukemia(CML) patients

***A. Nazemi**[1], M. Hashemi[2];*
[1]Islamic Azad University,Tonekabon Branch, Tonekabon, Islamic Republic of Iran, [2]Islamic Azad University,Tehran medical Branch, Tehran, Islamic Republic of Iran.

Chronic Myeloid Leukemia (CML) is a form of leukemia with chromosomal translocation and fusion bcr/abl genes. The purpose of this study is development of a simple and low-cost technique for
quantitative detection bcr/abl transcripts in CML patients.
In this study, we used the competitive RT-PCR technique to determine the number of bcr/abl transcripts. The internal control designed from a non-human DNA source with the same flanking sequences but a smaller size than the target segment. After amplification and purification of internal control DNA, PCR products quantified based on copy numbers. In order to optimizing the reaction condition, competitive
RT-PCRs carried out separately on target and internal control DNAs each with specific copy numbers and final products of all concentrations runed on agarose gel electrophoresis.
The simultaneous reactions of target RNA with different copy numbers of internal control DNA that
showed the copy numbers of target RNA can be determined by comparison of dye density emission of DNA bands(target and control DNA) on the gel.
This study shows that competitive RT-PCR is a partially efficient and cheap method for quantitative
determination of bcr/abl transcripts, compared to other methods such as Real-time PCR.

Antimutagenicity and Anticancer Effects of mother's milk on Acute Promyelocytic Leukemia(APL) cell line

***M. Entezari**, M. Hashemi;*
Islamic Azad University,Tehran Medical Branch, Tehran, Islamic Republic of Iran.

Currently cancer is considered as one of the main factors of mortality globally. Diet can play a vital role in cancer prevention. The purpose of this research is to examine antimutagenicity and anticancer effect of mother's milk.In this basic-applied study, the human leukemia (NB4) cell line was used as a model to evaluate the cytoxicity effects of mother's milk.in APL cells.NB4 cells were exposed to different concentrations of mother's milk (2, 5, 10 µl) and dimethylthiazol diphenyl tetrazolium bromide (MTT) assay was applied on them. The mother's milk was subsequenthy evaluated in terms of antimutagenicity and anticancer properties by a standard reverse mutation assay
(Ames Test). For Ames Test the particularity of the strain of salmonella typhimurium chosen TA100 resides in the fact that undergone a specific mutation in the Histidine operon,and for this same reason it requires histidine from a foreign supply to ensure its growth.The afore mentioned strain gives rise to reverted colonies when expose to carcinogen substance (Sodium Azide).Data obtained from this assay indicated that mother's milk significantly reduced the viability of NB4 cells and inhibited cell growth in a dose dependent manner. In Ames Test Mother's Milk prevented the reverted mutations and the hindrance percent of mother's milk was 46% in Antimutagenicity test and this value in anticancer test was 53%. Findings from the present study indicate that mother's milk is highly cytotoxic to human leukemia cells.These results have revealed antimutagenicity and anticancer effect of mother's milk.

Limitations in management of neuroblastoma in children - a retrospective analysis

***E. Boeriu**[1], M. Puiu[2], M. Cucuruz[2], A. Chirita Emandi[3], E. Badescu[3], S. Arghirescu[2], M. Serban[2];*
[1]University of Medicine and Pharmacy, Timisoara, Romania, [2]University of Medicine and Pharmacy „Victor Babes", Timisoara, Romania, [3]Emergency Hospital for Children „Louis Turcanu", Timisoara, Romania.

Background: Last decades have brought great improvement in survival rate in neuroblastoma (NB) in children, due to precocious diagnosis and a multimodal approach. Still, several limitations remain in current practice. Aim: To evaluate factors that influenced survival rate in children with NB. Material and method: We proposed a retrospective analysis of cases admitted to our clinic between 1996-2011. Thirty-four children diagnosed with NB were selected. Onset age was between 11 months and 12 years, sex ratio male:female was 1:1. We performed a retrospective analysis of medical charts. Kapplar-Meier survival curve were calculated. Citostatic (protocol NBL 98) and surgical treatment were performed in all patients. Results: Statistic data regarding localization of primordial tumor, stabilization, regional and distance metastasis spread; along with paraclinical data: histological analysis, vanilmandelic acid, LDH, feritin levels are discussed. Molecular biology and DNA index cannot be assessed in our clinic. Complications related to disease were: distance metastatic spread in half of children; locoregional metastasis in 29,16% cases, intestinal occlusion in 4,1%, blindness in 4,1%, paraplegia in 4,1%. Two cases presented relapse of disease. Survival at 3 years was seen in 45,8% cases, 41.6% deceased and 12.5% were lost to follow-up. Conclusions: NB was diagnosed late and with advanced stage, in our population and this correlated with unfavorable evolution and complications related both, to disease and treatment. Genetic assessment is very important in guiding treatment differentiation, which finally prolongs survival rate in patients with NB. Improvement in this area is much needed in our department.

The proinflamatory cytokine, tumor necrosis factor- α (TNF-α) plays a important role in diverse cellular events such as septic shock, induction of other cytokines, cell proliferation, differentiation, necrosis, Malaria, AIDS and apoptosis. In response to TNF therapy several cell signaling pathways activated in ells that in different manner can lead to apoptosis or necrosis. However induction of witch of them is dependent on the receptors that occupied with TNF-α and subsequently activation molecules. Tumor necrosis factor- related apoptosis- inducing ligand (TRAIL) and specially the DR5 one, is generating considerable interests as a possible anticancer therapeutic agent because of is selective activation of apoptosis of this receptor as a superior affinity to ligands (TNF) show up and injected to separate hens to achieve high affinity IgY that can recognize DR5 specially and start exclusively apoptotic signaling in the cell.

Background /Aim: Gastric cancer (GC) is the second most common malignancy worldwide, with a high mortality rate. The incidence of GC has declined in the western countries during the last decades. The Glutathione S-transferases comprise a group of enzymes that are critical in the detoxification of carcinogens. In this study we aimed the relationship GSTP-1 methylation in patients with intestinal metaplasia with and without helicobacter pylori infection, gastric cancer and controls.

Methodology: The methylation status of GSTP1 gene between September 2009 to November 2011was analyzed by Methylation Specific PCR after bisulfate modification in H. pylori (+) (n=25) and (-) (n=25) intestinal metaplasia (IM) patients, GC (n=25), and control subjects (n=15) who underwent endoscopic examination were included into the study

Results:When we considered the GSTP1 gene methylation profile in all of the groups; 26 (28%) patients had methylated GSTP1 gene, 31 (34%) patients had unmethylated GSTP1 gene and 33 (36%) patients had heterogeneously methylated GSTP1 gene.

There was no significant difference in the methylation profile between the four groups (p>0.05).Unmethylation in the control group was more prevalent than GC and H.Pylori (+) IM (p=0.015).Unmethylation in H.Pylori (-) IM was more prevalent than H.Pylori (+) IM (p=0.00004). Heterogeneous methylation in GC and control group was more prevalent than H.Pylori (-) IM (p=0.00002, 0.025).

The relationship between H.pylori and GSTP1 methylation profile, there was no significant difference in metyhlation, unmethylation and heterogeneous methylation between the groups.

Conclusion: GSTP1 gene methylation profile is not appropriate for early diagnosis of cases with gastric cancer.

Molecular genetic characterization of intratumoral heterogeneity in invasive ductal NOS breast carcinoma

E. V. Denisov[1], *L. A. Tashireva*[1,2], *T. S. Dultseva*[2], *M. M. Tsyganov*[3], *N. V. Litviakov*[1], *M. V. Zavyalova*[1,2], *V. M. Perelmuter*[1,2], *N. V. Cherdyntseva*[1];
[1]*Cancer Research Institute, Tomsk, Russian Federation,* [2]*Siberian State Medical University, Tomsk, Russian Federation,* [3]*Tomsk State University, Tomsk, Russian Federation.*

Aim: To characterize the different types of morphological structures, previously demonstrated in tumors of invasive ductal breast carcinoma not otherwise specified, NOS (Zavyalova et al., 2011), and their local microenvironment with cancer-associated SNPs and expression of multidrug resistance (MDR) genes.

Materials and methods: Tubular, alveolar, trabecular morphological structures and their local microenvironment were isolated by laser microdissection from 10 micron-thick sections of FFPE breast tumor. The isolated and whole amplified DNA and cDNA (RNA) were used for analysis of SNPs with the Cancer SNP Panel (Illumina) and assessment of expression of MDR genes: ABCB1, ABCC1, ABCC2, ABCC5, GSTP1, and MVP.

Results: SNP array emerged as an effective tool to detect somatic alterations. Despite of low microarray call rate, probably caused by degradation of DNA during formalin fixation, the Cancer SNP Panel demonstrated significant differences in genotypes both among the different types of morphological structures and their local microenvironment. In particular, the genotype variations affected rs6179 (GHR gene), rs3740616 (LMO2), rs717620 (ABCC2), rs4623993 (k-Ras), rs1050008 (MX1), rs569421 (GATA3), and rs529359 (PGR). MDR genes expression acts as indispensable hallmark of cancer. Similar to the SNP results, their expression was significantly differed between both the studied types of morphological structures and their microenvironment. The differences were displayed in both number (type) of expressing genes and level of expression.

Conclusion: Data obtained here show that the different types of morphological structures of breast tumor may be independent tumor clones with own specific microenvironment.

The study was supported by the Russian Federation President grant (MK-1259.2012.7).

Origin and clonality of primary multiple superficial bladder cancers

A. Babayan[1,2], *Y. Andreeva*[3], *D. Zaletaev*[1,4], *M. Nemtsova*[1,4];
[1]*Research Institute for Molecular Medicine, Moscow, Russian Federation,* [2]*Institute of Tumor Biology, University Medical Center Hamburg Eppendorf,, Hamburg, Germany,* [3]*Moscow Herzen Oncological Research Institute, Moscow, Russian Federation,* [4]*Sechenov Moscow Medical Academy, Moscow, Russian Federation.*

Primary multifocality is a common phenomenon in superficial bladder cancer (SBC). According the monoclonal theory, coexisting primary tumors arise from a single malignant transformed cell, which proliferates and spreads throughout the urothelium or might be spread during the intravesical manipulations. Another theory explains multifocality as subsequent events secondary to a field-cancerization effect, so tumors are expected to be genetically non-identical. The question weather coexisting tumors arise from the same tumor clone or develop independently has a great clinical relevance to surgery and treatment approaches. Molecular analysis of alterations patterns in each of coexisting tumors may give us an answer.

We examined tumor samples from 22 patients with primary multiple SBC (PMSBC) (2-5 tumors/patient). Genomic DNA samples were prepared from formalin-fixed, paraffin-embedded sections. Our panel included LOH analysis at 9p21 and 17p13 (microsatellite assay).

Three out of 22 (13.6%) patients had non-informative state of microsatellite markers. In nine out of 22 patients (40.9%) was shown concordant pattern of LOH in at least one of loci. In ten out of 22 (45.5%) patients we showed discordant patterns of allelic alterations. Moreover, in 5 of these 10 cases (50%) tumors of the same patient differed from each other by presence or absence of allelic misbalance, while in other 5 cases (50%) LOH of different allele in tumors of the same patient were revealed.

Our results show that coexisting multiple tumors show in almost equal proportion either concordant of discordant pattern of molecular alterations, which might mean monoclonal or oligoclonal origin correspondently.

Investigation of microRNA expression changes in HepG2 cell line in presence of URG4/URGCP and in the absence of URG4/URGCP suppressed by RNA interference

Y. Dodurga[1], *N. G. Yonguc*[2], *C. Biray Avci*[3], *G. Bagci*[4], *C. Gunduz*[3], *L. N. Satiroglu-Tufan*[4];
[1]*Pamukkale University School of Medicine Department of Medical Biology, Denizli, Turkey,* [2]*Pamukkale University School of Medicine Department of Anatomy, Denizli, Turkey,* [3]*Ege University School of Medicine Department of Medical Biology, İzmir, Turkey,* [4]*Pamukkale University School of Medicine Department of Genetics, Denizli, Turkey.*

Hepatocellular carcinoma (HCC) originates from liver cells and is one of the most common malignant cancers in the world. MicroRNAs (miRNA), are single strand non-coding RNA molecules with the length of 18-25 nucleotides. miRNAs play an important role in the development of HCC, briefly miRNAs have a significant impact on multistep hepatocellular carcinogenesis including cellular migration and invasion. URG4/URGCP (Up-regulated gene-4/ Upregulator of cell proliferation) is up-regulated in the presence of HBxAg and has been identified and characterized by Satiroglu-Tufan et al. The full-length URG4/URGCP clone is 3.607 kb. Overexpression of URG4/URGCP in the presence of HBV X protein may function as a putative oncogene that contributes importantly to multi-step hepatocarcinogenesis. In this study, we aimed to investigate potential miRNA expression changes in HepG2 cell line model system in the presence of URG4/URGCP and in the absence of URG4/URGCP which was suppressed by RNA interference. To functionally characterize URG4/URGCP, independent cultures of HepG2 cells were stably transfected with pcDNA3 or pcDNA3-URG4/URGCP. Relative quantification of whole genome miRNAs was analyzed by Light Cycler 480 Real Time PCR using Human Whole Genome miRNA qPCR Profiling Kits. Among the 1034 human miRNAs investigated by the arrays, 77 miRNAs were up-regulated and 9 miRNAs were down-regulated in the presence of URG4/URGCP. In conclusion, we have comprehensively analyzed miRNA profiles in the HepG2 cells with the presence or absence of URG4/URGCP gene. Some of these miRNAs may play roles in the URG4/URGCP gene related disease development through the regulation of different signaling pathways.

Differentially methylated genes in breast cancer

N. A. Skryabin[1], *I. N. Lebedev*[1], *N. V. Cherdyntseva*[2];
[1]*Institute of Medical Genetics, Tomsk, Russian Federation,* [2]*Institute of Oncology, Tomsk, Russian Federation.*

Breast cancer (BC) is characterized by abnormal DNA methylation. To date the methylation status of many oncogenes and tumor suppressor genes has been investigated. However the genome-wide analysis of methylation status of many genes is necessary for identification of pathogenetic pathways of cancer development. This study was aimed to identify the functional groups of genes abnormally methylated in BC. We analyzed 16 samples with BC and 6 control histologically normal epithelium samples from women with BC using Illumina GoldenGate Cancer Panel I (Illumina, USA). Differential methylation was observed at 318 CpG-sites. Among them 252 (79.2%) were hypermethylated and 66 (20.8%) were hypomethylated. The identified differentially methylated genes were analyzed using Gene Ontology Enrichment Analysis. Hypermethylated genes belong to two functional groups: positive regulation of cell differentiation (n=8) and regulation of cell proliferation (n=12). Hypomethylated genes belong to two groups as well: cell migration (n=2) and the protein amino acid phosphorylation (n=3). Hypermethylation of genes involved in positive regulation of cell differentiation and proliferation may indicate the important role of their epigenetic inactivation in BC development. Hypomethylation of genes involved in cell migration and phosphorylation of proteins may promote invasiveness, metastasis of cancer cells, and inhibition of tumor suppressor proteins by phosphorylation. Thus, the abnormal methylation status of these functional groups of genes may play a significant role in breast cancer development.

Elucidation of SALL4 oncogenic role in colorectal cancer; the first report

M. M. Forghanifard[1], *R. Raeisossadati*[2], *M. Moghbeli*[2], *A. Tavassoli*[3], *M. Montazer*[4], ***M. Gholamin***[5], *M. R. Abbaszadegan*[1];
[1]*Department of Biology, Mashhad Branch, Islamic Azad University, mashhad, Islamic Republic of Iran,* [2]*Division of Human Genetics, Immunology Research Center, Avicenna Research Institute, Mashhad University of Medical Sciences, mashhad, Islamic Republic of Iran,* [3]*Endoscopic and Minimally Invasive Research Center, Qaem Hospital, mashhad, Islamic Republic of Iran,* [4]*Department of Pathology, Omid Hospital, Mashhad University of Medical Sciences, mashhad, Islamic Republic of Iran,* [5]*Division of Human Genetics, Immunology Research Center, Avicenna Research Institute, Mashhad University of Medical Sciences, Mashhad, Islamic Republic of Iran.*

Human cancer cells resemble stem cells in expression signatures leading to share some features notably self-renewal. A complex network of transcription factors and signaling molecules are required to continuance of this trait. SALL4 is zinc finger transcriptional activator crucial for maintenance of self-renewal in stem cells which its expression rate is not yet elucidates in colorectal tumor cells. To clarify this rate and probable clinicopathological consequences, an expressional analysis was performed. Freshly tumoral and distant tumor-free tissues of thirty eight colorectal samples were enrolled to comparatively examine the expression level of SALL4 by real-time PCR. Compare to normal tissues, greater than two-fold expression of SALL4 was interestingly detected in 89.5% of related tumors. SALL4 expression was significantly correlated with the number of involved lymph nodes especially in moderately differentiated tumor samples (P<0.05). Furthermore, higher levels of SALL4 mRNA expression was significantly associated with older age of patients whom their tumor cells were being in the lower stages (I/II) (P<0.05). These results elucidate the direct impact of SALL4 overexpression on the process of tumor cell metastasis to lymph node and consequently development of tumors into advanced stages (III/IV). Along with the promising evidence of its role in self renewal in various cancers, SALL4 is introduced as potentially interesting therapeutic targets to reverse a number of aberrations that promote colorectal tumor maintenance and development. In conclusion, we presented the first evidence for mRNA overexpression of oncogene SALL4 in cancerous colorectal samples which might enlighten new approaches for cancer therapy.

Gene-gene interaction predicts chemotherapy response in multiple myeloma patients

Z. Rossokha*, S. Kyryachenko, N. Kostukova, S. Vydyborets, N. Gorovenko;*
National Medical Academy of Post-Graduate Education, Kyiv, Ukraine.

Background. Multiple myeloma (MM) is plasma cell neoplasm with low sensitivity to alkylating agent-based chemotherapy. The aim of study was to evaluate gene-gene interaction in the development of drug resistant cases.
Methods. We examined 51 newly diagnosed patients treated alkylating agent-based chemotherapy. 30 patients had clinical response and 21 patients had no response.
The deletion polymorphism of *GSTT1, GSTM1* genes and *A313G* of *GSTP1, C3435T* of *MDR1* genes polymorphism were detected using PCR and RFLP analysis. Statistical analysis was performed to investigate the influence of all analyzed genes and their combinations (MDR_2.0 Programme).
Results. The main effect was found for *GSTM1* deletion polymorphism [Table 1]. The interaction model including *GSTT1, GSTM1, MDR1* genes had higher Testing Balance Accuracy - 83,10.
Table1. Testing balanced accuracy and cross validation consistency for the best MDR models for the prediction of chemotherapy resistance

Gene	Testing Bal. Acc.	Permutation test	CV consistency
GSTM1	0,8286	0,001	10/10
GSTT1/GSTM1	0,7476	0,05	8/10
GSTT1/GSTP1/MDR1	0,8310	0,001	10/10
GSTT1/GSTM1/GSTP1/MDR1	0,7918	0,05	10/10

Conclusion: We propose to evaluate gene-gene interaction for drug resistance prediction in MM patients. Further research may develop new methods of chemotherapy resistance prevention.

Examination of UVR-Induced DNA damage and repair and its association with apoptosis in human keratinocytes and fibroblasts

M. Karbaschi[1], *M. D. Evans*[1], *S. Macip*[2], *M. S. Cooke*[1];
[1]*Department of Cancer Studies and Molecular Medicine, University of Leicester, Leicester, United Kingdom,* [2]*Department of Biochemistry, University of Leicester, Leicester, United Kingdom.*

Skin cancer has an increasing incidence in countries with large populations of white skinned individuals. UVR, by initiating the DNA damage, can lead to mutagenesis and is regarded as the prime cause of most skin cancers. As a result, UVR protection is of primary importance to prevent UVR-induced skin cancers. Cyclobutane pyrimidine dimers (CPD) are an important form of DNA damage induced by both UVA and UVB and removed by nucleotide excision repair. The persistence of CPDs, compared to other forms of DNA damage, is understood to be a major contributory factor to their mutagenicity. Using the T4endonuclease V-modified comet assay on human keratinocytes and fibroblasts, we noted that there was rapid initial repair of CPDs over the first 6h post-irradiation, following either UVA or UVB treatments, but whilst this slowed significantly in the UVB-irradiated cells, it continued to be rapid in the UVA-treated cells with levels approaching baseline within 36h. This confirmed the widely accepted slow repair of UVB-induced cyclobutane thymine dimers, but we uniquely noted far more rapid repair of UVA-induced cyclobutane thymine dimers. There were no significant differences in cell viability between the two treatments over the first 6h post-irradiation, but at 24h post-irradiation viability had decreased significantly only in the UVB-irradiated cells. These data suggest that for at least the first six hours following UVB irradiation, the majority of cells were viable and capable of repair, after that time increasing numbers of cells enter apoptosis, and therefore fail to repair the damage.

Symmetric nuclei support PMN chemotaxis and reflect genomic order

J. P. Chaudhuri[1], *J. U. Walther*[2];
[1]*Genzyme Genetics / LMU Kinderklinik, Munich, Germany,* [2]*LMU Kinderklinik, Munich, Germany.*

Segmentation, condensation and bilateral symmetry of the nuclei of polymorphonuclear leukocytes seem related to their function. Segmentations of the nuclei into two or more lobes and their condensation facilitate their passage (diapedesis) through the endothelial layer of blood vessels to the extravasal space and subsequent locomotion through the interstitial compartment of different tissues. Bilateral symmetry of these nuclei along with their association to the cytoskeletal fibres contribute to their efficiency in locomotion by alignment of the axis of nuclear symmetry to the axis of cellular polarity, which orients towards the direction of locomotion in response to cytokines and other stimuli. Moreover this same mechanism may maintain genomic order in spheroid nuclei of mononuclear cells all through the cell cycle and support and coordinate the allelic functions. Our observations of the cytogenetic facets of intranuclear order in blood and bone marrow cells support these assumptions.

J07.02

Complex chromosomal clones in hematological malignancies: Study on 50 cases

B. B. Ganguly;
Genetics Center, Navi Mumbai, India.

Hematological malignancies are well understood with the consequences of chromosomal alterations and likelihood of treatment outcome. Employment of advanced technologies in the field facilitates better understanding of diseases with an aim in drug development. However, conventional cytogenetics plays an important role for primary diagnosis, monitoring and relapse management. During January 2012, chromosomal analysis was carried out on 50 cases with leukemia and myelodysplastic syndrome by employing conventional bone marrow culture and G-banding. Karyotypic analysis by using IKAROS had detected multiple clonal abnormalities with rare chromosomal rearrangements including numerical and structural alterations (Table). Normal karyotype and classical abnormalities were recorded in 32% and 42% cases respectively whereas 26% cases were detected with multiple complex rearrangements. Two AML cases were recorded with t(9;22) in association with monosomy 7. One case with provisional diagnosis of AL showed three double minutes in cells with varying numerical abnormalities. Case wise detail description on chromosomal rearrangements and numerical alterations will be presented with clinical and hematological expressions. Such complex structural and numerical or both rearrangements might indicate poor prognosis and interfere in treatment outcome. The study highlights the importance of conventional cytogenetics in management of hematologic malignancies and strongly recommends its application in the field.
Table: Data on chromosomal analysis on 50 leukemia cases

Radiation-induced modification of human somatic cells' chromosomes sensitivity to testing mutagenic exposure of bleomycin in vitro in lung cancer patients in delayed terms following Chernobyl accident

M. A. Pilinskaya, *S. S. Dibskiy, Y. B. Dibskaya*;
National Research Centre of Radiation Medicine, Kijiv, Ukraine.

With the help of modified „G2-bleomycin sensitivity assay" above background level of cytogenetic effect which considered as the marker of hidden chromosome instability (HCI) in 4 groups - liquidators of Chernobyl accident, liquidators of Chernobyl accident with lung cancer, unexposed healthy persons, patients with lung cancer who denied conscious contact with ionizing radiation were cytogenetically observed. In all groups significant interindividual variations of cytogenetic effects induced by bleomycin in vitro in testing concentration 5.0 mcg/ml and lack of positive correlation between background and above background frequencies of chromosome aberrations were found. It was established that group of Chernobyl liquidators with lung cancer had been the most aggravated as by expression of above background cytogenetic effects (77.3 aberrations per 100 metaphases) as by number of persons with HCI (66.6%) in comparison with 14.3, 42.4, 53.4 aberrations per 100 cells; 33.3, 46.7, 53.3% hypersensitive persons in unexposed healthy donors, unexposed patients with lung cancer and Chernobyl liquidators without cancer, accordingly. The data obtained not only confirmed possibility of radiation-induced modification of genetically determined susceptibility of human somatic cells' chromosomes to mutagenic exposure, but also permit to suggest existence of an association between radiation-induced increase of individual sensitivity to testing mutagenic exposure and realization of cancer in persons exposed to ionizing radiation. The results obtained showed acceptability of «G2-bleomycin sensitivity assay» under cytogenetic monitoring of irradiated contingents for determining HCI as one of the informative markers of human predisposition to oncopathology.

J07.04

Identification of a new rearrangement involving chromosomes 6 and 11 in a juvenile myelomonocytic leukemia with mutation in CBL gene

E. Tassano, *E. Tavella, M. Lanciotti, C. Micalizzi, C. Cuoco, C. Morerio*;
IRCCS Giannina Gaslini, Genova, Italy.

Juvenile myelomonocytic leukemia (JMML) is a rare and aggressive clonal myeloproliferative disorder of infants and young children, refractory to chemotherapy and responding only to hematopoietic stem cell transplantation. Somatic or germinal mutation in *PTPN11*, *RAS*, or *NF1* and monosomy 7 are known to be the essential genetic or chromosomal abnormalities in this disease. Missense *CBL* mutations, mutually exclusive of other *RAS* activating mutations, have been recently found in JMML, arising de novo or inherited with invariable loss of the normal *CBL* allele in leukemic cells. A 3-month-old boy was referred to us for hepatosplenomegaly, fever, leucocytosis with monocytosis, presence of myeloid precursors, bilinear cytopenia, and normal level of HbF. Hypersensitivity to GM-CSF was observed in the colony assay. A diagnosis of JMML was made. Molecular studies showed no *NRAS*, *KRAS2*, or *PTPN11* mutations, but a c.1246 T>C heterozygous missense mutation in exon 9 of *CBL* gene was found, resulting in p.416C>R amino acid sostitution.

Likely, the homozygous mutation was not detected since bone marrow with low level of leukemic cells was used for analysis. The chromosome analysis on BM and peripheral blood showed 46,XY,t(11;16)(p15;q23)/46,XY karyotype. FISH analysis with specific probes for *NUP98* gene (11p15) excluded the involvement of this gene in the breakpoint. The cases of JMML characterized by chromosomal translocations as sole cytogenetic abnormality are rare and described in individual cases. The importance of *CBL* in hematopoiesis has been demonstrated, however the effect of this chromosomal rearrangement on the propensity to develop JMML has to be clarified.

Association polymorphisms of IL-18 genes (137G/C, 607C/A,133C/G) in patients with allergic rhinitis in the Iranian population

S. Ramazi[1], *m. Motovali bashi*[2], *M. Hashemzade chaleshtori2*[2];
[1]*Cellular and Molecular Research Center, Shahrekord University of Medical, Shahrekord, Islamic Republic of Iran,* [2]*Cellular and Molecular Research Center, Shahrekord University of Medical, shahrekord, Islamic Republic of Iran.*

Background: Allergic rhinitis (AR) is an inflammatory disease of the nasal mucosa induced by an IgE-mediated reaction, following exposure to an allergen. Inflammatory reactions in allergic rhinitis are regulated by many cytokines.The. IL-18 is a member of the IL-1 family.It was originally described as IFN-γ -inducing factor (IGIF),and is known to influence the balance of Th1/Th2 immune response. The *IL18* gene has two promoter regions, promoter 1 and promoter 2. Three SNPs are located in promoter1, two are in exon 1, and three are in the promoter 2. This study aimed to examine the association of three different (SNPs) located in IL-18 gene (-607 C/A, -137 G/C and-133 C/G) on chromosome 11q22 with allergic rhinitis.
Methods : Genomic DNA was obtained from the blood samples of 300 AR patients and 200 healthy control volunteers. The IL-18 polymorphism was analyzed by polymerase chain reaction and restriction fragment length Polymorphism (PCR -RFLP) analysis.
Results: The frequency of the GG genotype of the IL-18/-137 gene polymorphism was greater in allergic rhinitis patients than in control. The data of the IL-18(-607C/A and -133 C/G) gene polymorphisms will be analyse to determine the distributions of alleles.
Conclusions: This study suggests that IL-18 gene variants may be participate as a risk factor in the pathogenesis of AR or in intermediary phenotypes. So Further studies are needed to reveal the associations between the IL-18 promoter polymorphism and allergic diseases in other populations.

Study for association between the polymorphism rs10046 of the gene CYP19 A1 and the risk of premature coronary artery disease

K. Babali[1], *M. Georgoutsou*[1], *D. Babalis*[2], *A. Mouzarou*[2], *K. Agiannitopoulos*[1], *K. Lamnissou*[1];
[1]*Department of Genetics & Biotechnology, Faculty of Biology, University of Athens, Athens, Greece,* [2]*KAT General Hospital, Athens, Greece.*

Objective: It is well documented that sex hormones influence the risk of developing cardiovascular disease. Several genes are involved in the synthesis of sex hormones. The CYP19A1 gene encodes the enzyme aromatase (P450aro) that is involved in the production of oestrogens from androgens. In the present study, we investigated whether the rs10046 single nucleotide polymorphism (SNP) of the CYP19A1gene is associated with developing premature coronary artery disease (CAD).
Methods: A total of 168 Caucasian CAD patients, documented by coronary angiography, aged less than 58 years and 120 healthy
controls were studied. To genotype the subjects we used the PCR-RFLP method.
Results: The frequencies of CC, CT, TT genotypes were 0.278, 0.481, 0.240, respectively, in the patient group and 0.266, 0.522, 0.212, respectively, in the control group. The frequencies of T and C alleles were 0.518 and 0.481in the patient group and 0.527 and 0.473 in the control group. Statistical analysis indicated no significant differences in genotype or in allele frequencies between the patient and the control group.
Conclusion:
The results of this study suggest that there is no association of the rs10046 polymorphism of the CYP19A1 gene with the risk of developing premature coronary artery disease. Therefore, we may conclude that this polymorphism cannot be used as genetic marker for CAD risk assessment in our Caucasian population.

Investigation and validation of five different microsatellites in HLA-DRB1 region in the Iranian population

M. Shaykholeslam Esfahani, ***S. Vallian Broojeni***;
University of Isfahan, Isfahan, Islamic Republic of Iran.

Association between HLA-DRB1 and a large number of diseases such as multiple sclerosis and rheumatoid arthritis has been demonstrated. In the present study, we attempted to identify and characterize some potential microsatellites in HLA-DRB1 gene region with the aim of identification of specific markers for this gene. STR markers located next to or within HLA-DRB1 including M2_3_22, M2_2_36, D6S2878, D6S2805, D6S2879 and D6S2880 were selected from Major Histocompatibility Complex database (dbMHC). *In silico* analysis revealed that among all investigated markers, only M2_3_22 was specific for HLA-DRB1. M2_3_22 existed as single copy in all MHC haplotype sequences and located next to the HLA-DRB1. The presented primers for this STR marker at dbMHC and uniSTS were not compatible with some of the last published MHC haplotype sequences. Therefore, a new set of primer pair was designed and used to amplify this marker in 164 DNA samples obtained from Iranian unrelated individuals. M2_3_22 was successfully amplified in all DNA samples, and three different alleles were identified. The marker was found in Hardy-Weinberg equilibrium (P>0.05) in the studied population. Together, the findings suggested that M2_3_22 could be introduced as a specific locus among all the markers present in the HLA-DRB1 gene region for linkage analysis and disease association investigations.

Genetic variation in the CYP19 gene and recurrent spontaneous abortions

C. Koutsothanasi[1], *K. Agiannitopoulos*[1], *D. Pantos*[2], ***K. Lamnissou***[1];
[1]*Dept of Genetics & Biotechnology, Faculty of Biology, University of Athens, Athens, Greece,* [2]*"Genesis Athens Clinic", Center for Human Reproduction, Athens, Greece.*

Background. The CYP19 gene encodes aromatase, a key cytochrome P450 enzyme that converts androgens to estrogens in the ovarian tissues of premenopausal women. Polymorphic variations in the CYP19 gene result in modified estrogen levels through augment aromatase activity. In the present study, we investigated the association between the C/T single nucleotide polymorphism (SNP) of the CYP19 gene and the risk of recurrent spontaneous abortions (RSA).
Methods: In this prospective case-control study 120 RSA patients and 100 healthy controls were studied. All cohors were Greeks. The PCR-RFLP method was used in order to genotype the subjects.
Results: The frequencies of CC, CT, TT genotypes were 0.275, 0.500, 0.225, respectively, in the patient group and 0.262, 0.532, 0.206, respectively, in the control group. The allele frequencies were 0.525 and 0.475 for C and T, in the patient group and 0.528 and 0.472 for C and T, respectively, in the control group. The data between the two groups were analyzed by chi-square test. The results showed that there are no significant differences in genotype or in allele frequencies between the patient and the control group.
Conclusion: The CYP19 C/T polymorphism cannot be used as genetic marker for RSA risk assessment in our Caucasian population.

Association analysis of the Alu-element Ya5NBC51 with the level IL1RA of serum

I. Nikolaev, *E. Vasileva, E. Vorobjeva, V. Gorbunova;*
Bashkir State Pedagogical University name of M.Akmulla, Ufa, Russian Federation.

INTRODUCTION: Cytokine System is one of the major body systems. Alu-element Ya5NBC51 localized in the third intron of the gene interleukin-1 receptor accessory protein IL1RAP. This protein serves as a coreceptor of proinflammatory cytokines, forming, together with IL1R receptor complex.
MATERIALS AND METHODS: We studied DNA samples from 178 people aged 18-65 years living in the Republic of Bashkortostan. ELISA was performed IL1RA level in blood serum. Analysis of gene polymorphisms was performed using polymerase chain reaction (PCR). Assessing the impact of Alu-insertion in a gene on the data IL1RAP linked ELISA was performed by ANOVA.
RESULTS: Genotype IL1RAP *I/*I is associated with increased levels of serum IL1RA and allele IL1RAP*D with decreased (F = 4,68; p = 0,032). Thus, Alu-element in IL1RAP gene associated with susceptibility to inflammation.

J08.06
Association of vitamin D receptor gene BsmI polymorphisms with bone mineral density in a population of Iranian women

J. Jamshidi, F. Pouresmaeili;
Department of medical genetics, faculty of medicine, Shahid Beheshti university of medical science, Tehran, Islamic Republic of Iran.

OBJECTIVE: To investigate the association of vitamin D receptor (VDR) gene BsmI (rs1544410) polymorphisms with bone mineral density (BMD) in a population of Iranian women. METHODS: Blood samples were obtained from 146 pre- and/or postmenopausal Iranian women, aged 35-80 years, stratified for BMD into normal and osteoporotic groups. Anthropometric parameters including age, body height and weight were all recorded. BMD of the lumbar spine (L1-4) and femoral neck were measured using dual energy x-ray absorptiometry. Polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) technique was used to detect and analyze VDR gene BsmI polymorphisms distributions of our study groups. RESULTS: The frequency of AA and GG genotypes were significantly different in normal and osteoporotic groups ($P < 0.05$), frequency of AA was higher in patients and GG was higher in normal group. Also the GG genotype was significantly associated with increased BMD in the lumbar spine ($P < 0.05$). This association was not significant in femoral neck ($P > 0.05$). CONCLUSION: VDR gene polymorphisms have an association with the BMD in lumbar spine and may have a less effect on proximal femur BMD in women.

Specific risk factors predisposing to adolescent alcohol dependence: genetic pilot study in a Belarusian population.

I. Halayenka[1], A. Kapytau[2], H. Kandratsenka[1], N. Danilenko[1], O. Davydenko[1];
[1]Institute of Genetics and Cytology of National Academy of Sciences of Belarus, Minsk, Belarus, [2]Belarusian Medical State University, Minsk, Belarus.

Adolescent alcohol abuse is the real problem of contemporary society. Belarus, according WHO, is among nine countries with extremely high alcohol consumption. About 17000 adolescents younger than 18 are included in state preventive list. The aim of the investigation: the search of molecular-genetic markers predisposing to regular alcohol consumption of adolescent. The influence of genetic factor and “family climate”: presence of relatives with alcohol abuse, parental attention and physical punishment was also taken into consideration. Four male groups were analyzed, namely, those who started regular alcohol consumption at: 12-18 years old (125 patients); 18-25 (110) ; 3) after 25 (104); controls (103) , all 442 persons from the Republican research and practice center of mental health. 74,4 % adolescents, who started regular alcohol consumption before 18, had relatives with alcohol abuse comparing to control group (42 %, p=0,0002), and two groups of elder patients (55,5% and 53,8%, p=0,001). We revealed that the proportion of DRD2 A1A2 heterozygotes was significantly increased among youngsters that suffered from frequent physical punishment comparing with the control group (p=0,009), we did not observe this effect for elder patients. Genotype A1A2 conditions the effect of poor parental attention on regular alcohol consumption for the youngest test group (p=0,018) but not for “18-25” and “after 25” groups. Alcohol dependence is a result of specific interplay between the genetic and environmental factors that differ between adolescents and adulthood.

J09.02
Screening of Alpha Galactosidase A gene mutations in patients with Hypertrophic Cardiomyopathy phenotype

L. Emrahi Govar[1], N. Karimian[1], M. Ziadi[1], **T. Moharrami**[1], H. Saadatian[1], J. Gharesouran[1], M. Toufan Tabrizi[2], M. Mohaddes Ardebili[1];
[1]Department of Genetic,Faculty of Medicine , Tabriz University of Medical Science, Tabriz, Islamic Republic of Iran, [2]Cardiovascular Research Center of Madani Hospital, Tabriz University of Medical Science, Tabriz, Islamic Republic of Iran.

Fabry disease is an inherited storage disorder caused by a defect in the lysosomal enzyme alpha galactosidase A. GLA gene encoding alpha galactosidase A is located on the X-chromosome and more than 300 mutations have been reported in all 7 exons. This deficiency leads to accumulation of glycosphingolipids throughout the body including heart, kidney and nervous system. Cardiac involvement leads to progressive concentric, asymmetrical or apical left ventricular hypertrophy that is the most frequent cause of death in fabry disease in both genders. Fabry diseases may resemble sarcomere-gene associated hypertrophic cardiomyopathy. On routine echocardiography and electrocardiogram (ECG), there are no characteristic patterns useful for differentiation between hypertrophic cardiomyopathy (HCM) caused by sarcomere gene mutations and fabry disease. The aim of this study was to screen GLA gene mutations in patients with HCM phenotype for a disease-specific treatment with enzyme replacement therapy (ERT). 106 patients with HCM phenotype were examined. Alpha galactosidase A level was evaluated in 57 men. Patients with reduced level of alpha galactosidase A and 49 women underwent GLA gene mutation screening by PCR-SSCP method. It is, however, apparent that further expression and genetic association work is necessary to try and clarify the mixed findings that have been reported until now.

J09.03
ApoE gene polymorphism in rheumatoid arthritis patients

M. Siniauskaya[1], S. Vakyla[1], M. Shaptyrenko[1], L. Maslinskaya[2], T. Tyabut[2], O. Davydenko[1];
[1]Institute of Genetics and Cytology, National Academy of Sciences Belarus, Minsk, Belarus, [2]Belarusian Medical Academy of Post-Graduate Education, Minsk, Belarus.

Objective:Many studies indicate the importance of genetic polymorphism as factors predisposing for cardiovascular diseases and rheumatoid arthritis. Cardiovascular complications associated with atherosclerotic vessel lesions - one of the leading reason of life -time shortening in RA. ApoE allele types determine plasma lipid levels and could be the factor of relative atherosclerosis risk, also facts testified the importance ApoE alleles in Alzheimer‘s disease (AD) and immunoregulation. So possibly ApoE isoforms could influenced disease progress in RA and also could serve as predisposing marker for further atherosclerosis development.
Method: 74 rheumathoides arthritis patients and 107 healthy control were included in research. PCR-RFLP was carried out in order to check allelic frequencies investigated gene polymorphism.
Results: ApoE E3/E3 genotype was less common in RA group comparing to control - 57,5% and 72 % correspondingly (P<0,05). ApoE E2/E3 together with E2/E4 allele composed 28,7% in RA patient group, whereas in controls - 17,8% (P<0,05).
Conclusions: it should be some link between key genes in RA and cardiovascular disease, so separation of some loci could help in subdividing special patient group more sensitive for cardiovascular disease- it will be the purpose of future work.

J09.04
TNF-alpha gene promoter polymorphisms: lack of association with susceptibility to asthma in Romania

O. M. Popa[1], C. E. Berghea[1], M. I. Dutescu[2], M. Meirosu[3], C. Bara[1], L. O. Popa[4];
[1]University of Medicine and Pharmacy, Bucharest, Romania, [2]National Institute of Blood Transfusion, Bucharest, Romania, [3]University of Bucharest, Bucharest, Romania, [4]Grigore Antipa National Museum of Natural History, Bucharest, Romania.

Asthma is a complex disease characterized by chronic airway inflammation and bronchial hyper-responsiveness. Tumor necrosis factor (TNF)-alpha is a pro-inflammatory cytokine that has been implicated in many aspects of the pathology in asthma, but a clear understanding of the exact role in asthmatic patients is yet to be determined.
Objectives: The aim of this study was to investigate the association of TNF-alpha gene single nucleotide polymorphisms (SNPs) with susceptibility to asthma in Romania.
Methods: Three SNPs from TNF-alpha gene promoter (-308G/A, -238G/A and -857C/T) were examined for association and linkage disequilibrium in a sample of 106 Romanian asthmatic patients and 147 ethnically match healthy controls. The genotyping method was TaqMan Allelic Discrimination with SNP Genotyping Assays C_7514879_10, C_2215707_10 and C_11918223_10 (Applied Biosystems, USA). All the statistic tests were performed with the software package PLINK v 1.07.
Results: Patients and controls groups were in Hardy-Weinberg equilibrium for all polymorphisms. The minor allele 857*T was overrepresented in patients versus controls (23.1% vs 19%), but not statistically significant (p=0.2). Three main haplotypes were constructed based on the studied SNPs, the most frequent being 857C/308G/238G, 58% in patients versus 64% in controls. We found that neither alleles or genotypes among all three SNPs nor reconstructed haplotypes were associated with susceptibility to asthma in our population.
Conclusion: TNF-alpha gene promoter polymorphisms are not a risk factor for asthma in the Romanian studied population.

J09.05
Study of clinical significance of genetic variant c.2808G>T in CFH gene in Russian population

E. V. Mymrikov[1,2], N. N. Babenko[1], M. M. Kaabak[1], E. V. Zaklyazminskaya[1];
[1]Russian Research Centre of Surgery named by Petrovski, Moscow, Russian Federation, [2]Lomonosov Moscow State University, School of Biology, Department of Biochemistry, Moscow, Russian Federation.

Background. Atypical hemolytico-uremic syndrome (aHUS) is a rare inherited disease characterized by progressive renal failure requiring renal transplantation, thrombocytopenia, and microangiopathic hemolytic anemia. Number of genes is linked with this syndrome, but the most common genes involved into aHUS pathogenesis are CFH, CFI, and MCP genes. Mutation detection in responsible genes predisposes to higher risk of transplant dysfunction and should be taken into account in making decision related with transplantation.
Methods: Sequencing of coding and contiguous intronic areas of CFH, CFI, and MCP genes of patients with aHUS. Detection of SPNs of interest in 103 adult healthy individuals by allele-specific PCR.
Results: We did perform screening of those three genes in two patients with clinical manifestation of aHUS. We revealed the same genetic variant in both patients in 19th exon of CFH gene (rs1065489, NM_000186.3:c.2808G>T) leading to p.E936D substitution. None of genetic variants of apparent or unclear clinical significance were found in three major genes. One patient was heterozygote, and another one was homozygote carrier of this missence variant. This SNP was previously described in UniProt database as a polymorphism associated with aHUS and basal laminar drusen. To elucidate the clinical significance of this genetic variant we screened 103 healthy adult Russian individuals without any signs of renal pathology (206 chromosomes). We detected 31 heterozygous (G/T) and 3 homozygous (T/T) carriers. The frequency of minor allele (c.2808T) was 18%. We suspect that means that clinical significance of missence variant c.2808G>T in aHUS developing is low, at least in Russian population.

J09.06

Association analysis schizophrenia, Alzheimer‘s disease and alcoholism susceptibility gene polymorphisms relationship to psychodiagnostic traits in the West Siberian population

A. V. Marusin[1]*, A. N. Kornetov*[2]*, M. G. Svarovskaya*[1]*, K. V. Simonova*[1]*, E. S. Pavlenyk*[2]*, V. A. Stepanov*[1]*;*
[1]*Institute for Medical Genetics, Siberian Branch of the Russian Academy of Medical Sciences, Tomsk, Russian Federation,* [2]*Siberian State Medical University, Tomsk, Russian Federation.*

Natural selection plays an important role in maintaining genetic variation for mental constitution. Currently, the behavior genetic variability remains poorly understood. The purpose of this study: association analysis of Alzheimer‘s disease, schizophrenia and alcoholism susceptibility genes polymorphism with mental, psychodiagnostic traits, intelligence and anxiety.
The effect of the *GAB2, CLU, PICALM, DISC1, rs13219354, ZNF804A, GABRA2, SLC6A4, ADCY3, MIR9-2, CBX7* loci polymorphisms on psychodiagnostic traits was investigated in students of Siberian State Medical University (Tomsk). All individuals (n=141) completed IQ, Cattell's, Spilberger anxiety scale, Leonhard **personality inventory** tests**.** *GABRA2* and *GAB2* gene polymorphisms were associated with „histrionic“ on the Leonhard **personality inventory**. *SLC6A4* locus revealed the relationship with the scale “B”, *GABRA2* with the scale “E”, *PICALM* and *CLU* with “Q4” and “Q3” scales and the *CBX7* gene polymorphism was associated with the “A” scale by Cattell's test. For the *ZNF804A* locus we identified associations with the „emotiveness“ (high, excessive emotionality), „histrionic“ and „disequilibrium“ accordingly to Leonhard **personality** questionnaire. For the same test the relationship of *PICALM* with the „disequilibrium” and *DISC1* polymorphisms with the „excitability” was revealed.
The greatest number of statistically significant associations were observed for *MIR9-2* polymorphism with the “C”, “F”, “H”, “F2” Cttell's scales, “hyperthymia” and “dysthymia” on Leonhard **personality inventory**, personal and situational anxiety on Spielberger test. Possibly the identified associations suggest substantial contribution of genetic variability in individual mental constitution.
This work was supported by the Russian Foundation for Basic Research (project no. 11-04-98069-r_sibir'_a).

Association of MDR1, ADRB2, IL4 and IL13 polymorphisms with therapy-resistant bronchial asthma in Russian patients

A. S. Ulitina[1,2]*, Z. A. Mironova*[1]*, V. I. Trofimov*[1]*, M. V. Dubina*[1]*, E. D. Yanchina*[1]*;*
[1]*I.P.Pavlov State Medical University, Saint-Petersburg, Russian Federation,* [2]*Almazov Federal Heart, Blood and Endocrinology Centre, Saint-Petersburg, Russian Federation.*

Background. Bronchial asthma (BA) is a wide-spread polygenic disease.
Aim. To assess severity of BA and effectiveness of BA pharmacotherapy (glucocorticosteroids, beta-2-adrenergic agonists) in patients with different genetic background.
Methods. Genomic DNA was extracted from peripheral leukocytes. We investigated 5 SNPs by PCR-RFLP in 122 BA patients and in 103 healthy controls.

Gene	SNP, common designation	dbSNP	Restriction Enzyme
Multidrug resistance 1 (MDR1)	C3435T	rs1045642	MboI
Beta-2-adrenergic receptor (ADRB2)	Gly16Arg	rs1042713	NcoI
Gln27Glu	rs1042714	BseXI	
Interleukin 4 (IL4)	C-589T	rs2243250	BsmFI
Interleukin 13 (IL13)	Arg130Gln	rs20541	AluI

Results. Distribution of genotypes was similar to other European populations. We revealed numerous associations of genotypes 3435CC, 27GluGlu and alleles 16Gly, -589T, 130Gln with increased risk of BA progression and with unfavorable therapy-resistant BA course.

Allelic variant	Clinical finding	Statistics
3435CC	Increased risk of BA	OR=3.92 (95%CI 1.74-8.79)
3435CC	Increased risk of severe BA	OR=5.22 (95%CI 2.11-12.92)
3435CC	Increased risk of therapy-resistant BA	OR=6.12 (95%CI 2.42-15.48)
16Gly	Increased risk of respiratory failure	OR=17.31 (95%CI 2.01-149.28)
27GluGlu	Increased risk of therapy-resistant BA	OR=3.35 (95%CI 1.16-9.66)
-589T	High rate of BA complication	p=0.002
-589T	High dose of intravenous glucocorticosteroids	p=0.033
130Gln	Increased risk of moderate BA	OR=2.76 (95%CI 1.35-5.63)
130Gln	Increased risk of therapy-resistant BA	OR=2.09 (95%CI 1.01-4.30)

Conclusion. Analysis of MDR1, ADRB2, IL4 and IL13 polymorphisms is useful for both preventive care (revealing subjects with increased predisposition to BA) and BA treatment (pharmacotherapy optimization due to prediction of BA severity at the beginning of disease).

Calreticulin mutations in major psychiatric disorders

M. Ohadi*, A. Mirabzadeh, S. Farashi;*
Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran.

Development- and tissue-specific expression of the calreticulin (CALR) gene in the gray matter in late adolescence and early adulthood coincides with the expression of psychosis. To identify novel mutations in the regulatory regions of the CALR gene in major psychiatric disorders.We report novel low frequency mutations in the CALR promoter and intronic sequence that co-occur with the spectrum of major psychiatric disorders including schizophrenia, schizoaffective disorder and bipolar disorder type I, which did not exist in the control pool (pA increases gene expression in human and mouse neuroblastoma cell lines. This mutation is the first instance of a functional cognition-deficit mutation reversing a human gene promoter to the primitive type. We found that VPA increases gene expression in the cells with the wild-type -220C construct, whereas a dramatic decrease in gene expression was observed in the cell lines with the mutant construct (p<0.000004). A novel 1-bp insertion was also detected in intron 1 at IVSI-310, in a case of amphetamine-induced psychosis. As for the psychosis-linked CALR promoter mutations identified to-date, the IVSI mutation was not detected in the control pool. This mutation creates a RREB-1 transcription factor binding site within the first intron.We propose that major psychiatric disorders are, at least in part, a collection of low frequency mutations with possibly large effect, each contributing a small fraction of the disorders. Re-sequencing of the candidate gene regulatory regions will further clarify this model.

J09.09

Study of gene Caveolin3 in Latvian population.

J. Stavusis*, B. Lāce, I. Inashkina, E. Jankevics, I. Radovica;*
LR Biomedical Study and Research centre, Riga, Latvia.

A research was carried out in order to find out more about neuromuscular diseases in Latvia. As a part of this project a certain gene - CAV3 was researched in Latvian control population of one hundred seemingly healthy people. The particular gene was never before researched in any of Baltic states. Methods of genomic sequencing were being used. Since gene is conservative, changes in the nucleotide sequence are quite rare, but can cause severe muscular diseases, like Limb Girdle Muscular Dystrophy - LGMD 1C, isolated HyperCKemia - H-CK, rippling muscle disease - RMD and Distal myopathy - DM.
The results found were quite interesting. Six polymorphisms (rs1974763,

rs1008642, rs11922879, rs57159780, rs13087941, rs139985460) and one deletion (rs116840772) already existing in databases were found. Frequencies of some of them differed from ones found in databases. The deletion had a sequence mismatch in comparison with one found in database, being shorter by two nucleotides. In addition to that five new polymorphisms were found. Two in the 5' untranslated region (1-44G>A, 1-36G>A) without any obviously possible impact on health. However three of them (220C>A, R74S, 220C>T, R74C, 257T>C, L86P) were found in protein coding region and after *in silico* testing by PolyPhen2 were acknowledged as possibly damaging.
Further work is needed to verify these results. This research is quite meaningful for our society, since the data acquired have become a basis and are being used to help treat people with neuromuscular diseases.

J09.10

The polymorphism of hemostasis system genes in newborns with neurologic abnormalities from Russia.

O. E. Gromyko[1], *E. N. Arsenieva*[1], *N. V. Zhurkova*[1], *O. B. Kondakova*[1], *A. N. Evdokimova*[1], *G. V. Yatsyk*[1], *I. A. Belyaeva*[1], *V. G. Pinelis*[1], *A. Y. Asanov*[1,2];
[1]*Scientific center of Children's Health, Russian Academy of Medical Sciences, Moscow, Russian Federation,* [2]*I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation.*

Neurologic abnormalities in newborns with cerebral ischemia (CI) including intraventricular hemorrhages and thrombosis have become a focus of attention, as it is associated with neurodevelopmental disabilities and mortality. There are limited data on the predisposing risk factors of the neurologic abnormalities in newborns regarding an influence of the polymorphism of hemostasis system genes on its development.
In present work the allele and genotype frequencies of polymorphisms of six genes (*-455G/A* of *FBG*, *G20210A* of *FII*, *G1691A* of *FV*, *T1565C* of *GPIIIa*, *4G/5G* of *PAI-1* and *C677T* in *MTHFR*) were studied in newborns with CI.
The total of 50 patients with CI including 28 newborns with thrombosis and hemorrhages (group I) and 22 newborns having no hemorrhages and thrombosis (group II) and 50 healthy controls were followed. DNA was extracted from peripheral blood samples and hybridization with biochips was performed for the detection of each polymorphism.
Significant differences in the allele frequencies between the group I and controls were found for *FV Leiden* mutation (0.540 versus 0.00, respectively; p=0.019). The frequency of *MTHFR 677C* allele was higher in the group I compared to the group II (0.286 versus 0.125, respectively; p=0.045), but not significantly higher compared to the controls (p= 0.123). The distributions of genotypes and alleles for other gene polymorphisms were not significantly different between studied groups and controls.
Thus our data obtained suggest that *1691A* of *FV* and *677T* of *MTHFR* alleles may contribute to the higher risk of intraventricular hemorrhages and thrombosis development in newborns with CI.

Influence of Dopamine D2 receptor (DRD2) gene polymorphisms on childhood obesity.

N. Col-Araz[1], *M. Nacak*[2], *S. Oguzkan Balci*[3], *N. Benlier*[2], *S. Pehlivan*[3], *A. Balat*[4], *M. Araz*[5];
[1]*University of Gaziantep, School of Medicine, Department of Pediatrics, Gaziantep, Turkey,* [2]*University of Gaziantep, School of Medicine, Department of Pharmacology, Gaziantep, Turkey,* [3]*University of Gaziantep, School of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey,* [4]*University of Gaziantep, School of Medicine, Department of Pediatric Nephrology, Gaziantep, Turkey,* [5]*University of Gaziantep, School of Medicine, Department of Endocrinology and Metabolism, Gaziantep, Turkey.*

Objectives: Feeding is associated with dopamine release in the dorsal striatum and the degree of pleasure from eating correlates with the amount of dopamine release. The number of striatal Dopamine D2 receptor **(**DRD2) receptors has also been related to obesity and increased body mass index (BMI). The purpose of the present study was to examine the association between common polymorphisms of the DRD2 gene and chilhood obesity.
Methods: Eighty six obese and 100 healthy children were included in the study. Two polymorphisms (Taq1A and Taq1B) in DRD2 gene were genotyped by PCR-RFLP method.
Results: For DRD2 Taq1A polymorphism, the distribution of A1/A1, A1/A2, and A2/A2 genotypes was 3.5%, 29.1% and 67.4% in obese children compared with 4%, 31% and 65% in controls. The allele frequency of A1 and A2 was 0.180, 0.820 in cases compared with 0.195, 0.805 in controls (p=0.4). The distribution of B1/B1, B1/B2 and B2/B2 genotypes for Taq1B polymorphism was 3.5%, 22.1% and 74.4% for cases and 3%, 27% and 70% for the controls. The allele frequency of B1 and B2 was 0.145, 0.855 in cases compared with 0.164, 0.836 in controls (p=0.2). Genotype distribution did not differ significantly from those predicted by the Hardy-Weinberg Equilibrium distribution (p>0.05).
Conclusion: According to our preliminary results, Taq1A and Taq1B polymorphisms in the DRD2 gene were not associated with Turkish chilhood obesity susceptibility. Further researches are needed to confirm the exact role of DRD2 gene polymorphism on chilhood obesity.

J09.12

Possible additional effect of rare SNP rs35995925 of the *FAS* gene on predisposition to preeclampsia

Z. Lasabova[1], *V. Janusicova*[1], *I. Svecova*[2], *A. Stanclova*[3], *P. Zubor*[2], *M. Telkova*[1], *K. Biskupska-Bodova*[2], *G. Szabo*[4], *J. Rigo*[4], *B. Nagy*[4], *J. Danko*[2];
[1]*Comenius University, Jessenius Faculty of Medicine, Dept. of Molecular Biology, Martin, Slovakia,* [2]*Comenius University, Jessenius Faculty of Medicine, Dept. of Obstetrics and Gynecology, Martin, Slovakia,* [3]*Comenius University, Jessenius Faculty of Medicine, Dept. of Pathological Anatomy, Martin, Slovakia,* [4]*Semmelweis University, Dept. of Obstetrics and Gynecology, Budapest, Hungary.*

The polymorphism of the *FAS* gene rs1800682 (-670 A>G) is a common SNP with a MAF of 0.4777. The G allele was shown to be associated with preeclampsia. Within the 100 bp region surrounding rs1800682, there are three rare SNPs - rs150130637, rs2234768 and rs34995925, which is 8 bp upstream. The aim of the study is the analysis of possible additional effect of rare variants pooled with common variant on genetic predisposition to preeclampsia. The study cohort was made up of 112 patients with preeclampsia and 90 from women with physiological pregnancy. For genotype analyses, the HRMA and dideoxysequencing were performed on DNA extracted from peripheral blood. For *FAS* expression, RNA was extracted from 19 placental tissues and the deltadeltaC method was applied. The presence of G allele was observed in 88 patients (78.6%) compared to the 63 (70%) individuals from control group. The OR for subjects carrying genotypes GG and GA was 1.5417 (95%CI 0.830-2.974). The preliminary sequencing data of 37 preeclamptic and 45 control samples confirmed the HRMA results for rs1800682. Additionally, two preeclamptic patients with rs1800682 AA alleles were heterozygous for rs34995925 and none in the control group. The relative gene expression in placental samples showed none association with the genotypes. We have detected rare alleles in preeclamptic women close to the

STAT1 binding site with possible additional effect on predisposition to preeclampsia. Following this we plane to perform allele-specific transcript analyses to study the effect of these rSNPs in placental tissue.

Angiotensin-converting enzyme gene I/D polymorphism and fibromyalgia in a Turkish population

N. Karakus[1], *A. İnanır*[2], *S. Yigit*[3], *S. İnanır*[4], *S. Okan*[5], *A. Rustemoglu*[6];
[1]*Ondokuz Mayis University, Faculty of Medicine, Department of Medical Biology, Samsun, Turkey,* [2]*Gaziosmanpasa University, Medical Faculty, Department of Physical Medicine and Rehabilitation, Tokat, Turkey,* [3]*Gaziosmanpasa University, Faculty of Medicine, Department of Medical Biology, Tokat, Turkey,* [4]*Gaziosmanpasa University, Faculty of Medicine, Department of Psychiatry, Tokat, Turkey,* [5]*Gaziosmanpasa University, Faculty of Medicine, Department of Physical Medicine and Rehabilitation, Tokat, Turkey,* [6]*Gaziosmanpasa University, Medical Faculty, Department of Medical Biology, Tokat, Turkey.*

Fibromyalgia (FM) is a multifactorial disease, characterized by a clinical history of generalized muscle pain for more than three months and by specific tender points. The aim of the present study was to examine the possible role of angiotensin-converting enzyme (ACE) insertion/deletion (I/D) gene polymorphism as a risk factor in the development of FM. This study comprised 150 FM patients, 137 females and 13 males, and 199 healthy controls, 127 females and 72 males. Peripheral blood samples were genotyped using polymerase chain reaction (PCR) analysis.
The frequency of D allele was 60.6% in patients and 55.5% in controls (x2=1.65, p=0.19). The distribution of ACE DD, ID, and II genotypes in FM patients were 40; 41.3 and 18.7%, respectively; the corresponding numbers for the control group were 29.1; 52.8 and 18.1%, respectively. The distribution of the ACE gene genotypes frequencies weren't statistically significant between patient and controls groups (x2=5.33, p=0.07). But the percentage of DD genotype is relatively higher in patient group than control group.
Many studies showed that the ID and DD polymorphism is strongly associated with the increased plasma or serum ACE levels. Thus the ID and DD polymorphism favors high ACE expression and activity, hence may predispose individuals to FM and its complications. In this study we have demonstrated that genotype and allele frequencies of ACE gene I/D polymorphism were not statistically association with FM. Further studies with a larger number of patients are needed.

J09.14
Association of the TPO gene in petrochemical women workers with autoimmune thyroid diseases

***O. Kochetova**, T. Viktorova;*
Institute of Biochemistry and Genetics, Ufa, Russian Federation.

Autoimmune thyroid diseases (AITD) are common, with important epidemiological data, supporting a strong genetic background on the etiology of AITD. It is known that the formation of the AIT affect toxic substances. The aim of this study was to assess the relationship between two polymorphisms of Thyroid Peroxidase gene (TPO) serum level of Anti-TPO titer and serum level of hormones TTG and T4 in petrochemical women workers. A sample of 159 participants from the "Gazprom neftekhim Salavat" was selected as the case (N=61) and control healthy women (N=98). Inclusion criteria for cases were Anti-TPO 30U/L with a history of hypothyroidism. Anti-TPO level in subjects was measured by the ELISA kit. Genomic DNA was extracted using Salting-out/Proteinase K method. Two single nucleotide polymorphisms (SNPs) (rs4927611 and rs732609) were tested in TPO. These two markers were chosen considering that the polymorphism changes the encoded amino-acid and a minor allele frequency, MAF, ≥0.3. SNP typing was carried out by means of PCR-RFLP and ARMS-PCR methods. Deviations from the HWE were not observed. D'=0.36, r2=0.11. Association of frequent variant AA polymorphic locus rs732609 C>A TPO gene with AITD occurred only at overweight women p interact=0.044). Variant CC was associated with increased levels of anti-TPO (TT 173±288.4 pmol/L; vs. CC 374.6±407.4 pmol/L; P = 0.029) and increased levels of T4 (TT 14.19±2.77 vs. CC 15.79±5.23 pmol/L; P =0.027). The selected polymorphism of exon 7 has no effect on increased levels of Anti-TPO and hormones.

J09.15
Association of a single nucleotide polymorphism in the adiponectin gene (ADIPOQ) with gestational diabetes mellitus in Bulgarian population

***O. Beltcheva**[1], M. Boyadzhieva[2], I. Atanasova[2], O. Angelova[1], R. Kaneva[1], V. Mitev[1];*
[1]Molecular Medicine Center, Dept. of Medical Chemistry and Biochemistry, Medical University-Sofia, Sofia, Bulgaria, [2]University Hospital of Endocrinology , USBALE "Acad. Iv. Pentchev", Medical University-Sofia, Sofia, Bulgaria.

Gestational diabetes mellitus (GDM) is characterized with impaired glucose tolerance with onset during pregnancy. It is a multifactorial disease, which affects between 3% and 10% of all pregnant women (data from different surveys). GDM is associated with adverse health outcomes for both mother and baby - newborns larger than normal for their gestational age, preeclampsia, higher risk of developing diabetes following the pregnancy, etc.
There is accumulating evidence that adiponectin plays a role in the pathophysiology of diabetes. In patients with type 2 and gestational diabetes lower levels of the protein have been observed. Several common single nucleotide polymorphisms (SNP) in the adiponectin gene (ADIPOQ) have been associated with predisposition to type 2 diabetes. One of those, rs266729 in the promoter of ADIPOQ, has been proposed to affect its transcription. The aim of the present study was to check if this variant was associated with GDM in Bulgarian population.
The study involved 260 pregnant women, 130 with GDM and 130 controls, recruited from local antenatal clinics in Sofia, Bulgaria. Genotyping was carried out using TaqMan assay and statistical analysis with Plink. The genotyping success rate was over 98% and there was no deviation from Hardy-Weinberg.
The rare allele (G) was found in 22% of the affected and 30% of the non affected women and the difference was statistically significant (p= 0.027, OR= 0.64).
To the best of our knowledge this is the first study identifying an association of the rs266729 polymorphism in the adiponectin gene with gestational diabetes.

J09.16
Differences in IL28B promoter region rs12979860 variants in healthy Hungarian Caucasian and healthy Hungarian Roma patients versus with Hepatitis C Virus infected ones.

***P. Kisfali**[1], B. Duga[1], G. Par[2], B. I. Melegh[1], A. Pár[2], B. Melegh[1];*
[1]Department of Medical Genetics and Child Development, Pécs, Hungary, [2]1st Department of Internal Medicine, University of Pecs, Pecs, Hungary, Pécs, Hungary.

It is estimated that about 3% of the world's population is living with chronic HCV (hepatitis C virus). HCV infection may cause acute **hepatitis**, which is self-resolving in 20 to 50% of cases but does not confer permanent immunity. In 50 to 80% of cases, HCV infection becomes chronic and might result in chronic **hepatitis**, cirrhosis, and hepatocellular carcinoma. Recently rs12979860 in the *19q13* region has been shown to have impact on sustained virological response (SVR) following peginterferon alfa-2a and ribavirin (PEG-IFNalfa-2a+RBV) therapy and the wild TT genotype at *rs12979860* is a negative predictor of response to PEG-IFNalfa-2a+RBV therapy. A similarly unexpected observation is that a T allele at *rs12979860* is more common in HCV infected patients.
We analyzed total of 475 Roma, 453 healthy control and 853 HCV patients by Taqman SNP Genotyping Assay. Total of 393 HCV patients have been treated with PEG-IFNalfa-2a+RBV for at least 24 weeks. The rs12980275 *CC* genotype in HCV patients occurred with lower frequency than in healthy controls (24.6% vs. 49.2%; OR=2.56; p=0.0252). Treated patients with the CC genotype achieved SVR in higher rate, than those who have TT alleles (56.9% vs. 36.6 %; OR=2.57; p=0.0482). The Roma and Caucasian population show similar genotype distribution.
As the IL28B polymorphisms are one of the essential contributing factors for high SVR in chronic HCV patients, genetic data may be used to select the optimal treatment regimes in IFN-based therapy.

J09.17
The search for new candidate genes associated with hypertension advancement in children of Northwest Russia

***M. Kanaeva**[1], A. Glotov[1,2];*
[1]Saint-Petersburg State University, Saint-Petersburg, Russian Federation, [2]The D.O.Ott Research Institute of Obstetrics and Gynecology, Saint-Petersburg, Russian Federation.

The risk of hypertension in children is associated with renin-angiotensin genetic system as was earlier demonstrated in our studies. In the present study 7 other polymorphic genetic markers were analyzed in group of children with hypertension (100 samples) and in the control group of children (100 samples). The frequencies of genotypes and alleles have been recorded for 3 genes involved in arachidonic acid turnover - biologically active substance possessing both vasodilatation & vasoconstriction properties and thus most probably involved in hypertension progression. The following SNPs of relevant genes were studied: *CYP4A11 (*rs1126742 T>C), *CYP2J2* (rs890293 G>T) and *prostaglandin-I synthase* (rs6090996 G>A). Comparative analysis did not revealed any significant differences between genotypes or alleles frequencies of these genes in the studied groups (X-squared<1.64, p>0.43). Four other SNPs (rs11191548 T>C (intergenic variant), rs17367504 A>G (*MTHFR)*, rs4977574 A>G (*CDKN2BAS)*, rs11646213 A>T (*CDH13*)), identified by GWAS in adult hypertension patients could not be confirmed in the present study (X-squared<2.44, p>0.29). Different metabolic pathway in infant and adult hypertension syndrome could be suspected.

J09.18
Prevalence and spectrum of MYBPC3 gene mutations in patients with hypertrophic cardiomyopathy from north-west of Iran

*M. Mohaddes Ardebili[1], **L. Emrahi Govar**[1], M. Toufan Tabrizi[2], J. Gharesouran[1];*
[1]Department of Genetic,Faculty of Medicine ,Tabriz University of Medical Science, Tabriz, Islamic Republic of Iran, [2]Cardiovascular Research Center of Madani Hospital,Tabriz University of Medical Science, Tabriz, Islamic Republic of Iran.

Hypertrophic cardiomyopathy (HCM) is the most common genetic cardiovascular disease with a prevalence of 1 in 500 normal populations. The disease is the major cause of sudden cardiac death in the young and morbidity in the elderly individuals. HCM is inherited as an autosomal dominant single gene disease, characterized by unexplained ventricular myocardial hypertrophy. cMYBC is a sarcomeric thick filament protein that interacts with titin, myosin and actin to regulate sarcomeric assembly. Mutations in MYBPC3 gene are one of the most frequent genetic causes of the HCM disease. The aim of the present study was to investigate the frequency and kind of MYBPC3 gene muations in the population of north-west of Iran. DNA was extracted from 60 HCM patients by salting out method. All exons and exon-intron flanking regions of MYBPC3 gene were evaluated by PCR-SSCP assay. It is, however, apparent that further expression and genetic association work is necessary to try and clarify the mixed findings that have been reported until now.

J09.19
IL1B and IL8 polymorphisms involvement in recurrent corneal erosion in patients with hereditary stromal corneal dystrophies

***A. Kucherenko**[1,2], V. Pampukha[2], G. Drozhzhina[3], R. Gulkovskyi[1,2], L. A. Livshits[2];*
[1]Taras Shevchenko Kiev National University, Educational and Scientific Centre „Institute of Biology", Kyiv, Ukraine, [2]Institute of Molecular Biology and Genetics of the National Academy of Sciences of Ukraine, Kyiv, Ukraine, [3]SI "The Filatov Institute of Eye Diseases and Tissue Therapy, AMS of Ukraine", Odesa, Ukraine.

Deposits accumulation in patients with hereditary stromal corneal dystrophies (HSCD) leads to impaired attachment of epitheliocytes to basement membrane - corneal erosion. Proinflammatory microenvironment in the region of wound is crucial for its healing, inducing cell migration, neutrophils attraction etc. Two main inflammatory cytokines genes *IL1B* and *IL8* are upregulated in injured corneal epithelium. *IL1* gene -511 / and *IL8* gene -781C/T variants influence these genes expression in epithelium.

To establish possible involvement of -511 /T and -781C/T polymorphisms in corneal erosion development we investigated them in 2 groups. Case group - lattice HSCD typeI (n=46) and IIIA (n=23) patients with confirmed presence of *TGFBI* Arg124Cys or Hys626Arg mutations respectively. This group consisted of individuals with history recurrent erosion (n=56) and without it (n=13). Control group - healthy individuals (n=105) from Ukraine. Genotyping for both studied polymorphisms and *TGFBI* mutations was performed by PCR followed by RFLP analysis.

No significant differences in *IL1B* -511 /T genotype or allelic frequencies between patients with erosion and without it were found. Whereas a trend to decrease of -511TT genotype frequency in group with erosion (3,7%) comparing to control (6,7%) was observed.

Frequency of *IL8* -781TT genotype was significantly ($P<0,05$) lower in group with erosion (10,7%) comparing to patients without erosion (30,8%) and control (25%).

Our results revealed possible involvement of *IL8* -781C/T polymorphism in corneal erosion development. *IL8* -781TT genotype is associated with negative prognosis for recurrent erosion in patients with HSCD.

J09.20

Genetic Polymorphism TNF-α 308G>A and Ischemic Stroke in Northern Romania

F. M. Petrisor*;*
Department of Medical Genetics U.M.F "Iuliu Hatieganu", Cluj-Napoca, Romania, Cluj-Napoca, Romania.

Background. TNF-alpha is a proinflamatory cytokine. Evidence in support for a role for TNF-alpha in this respect is emerging as evidence on de novo upregulation of TNF-alpha following ischemia is now well established.

Objectives. The aim of the present study is to evaluate the connection between TNF-alpha polymorphism and ischemic stroke in a group population from Northern Romania and to determine whether it has an influence on the risk of cerebral events .

This is a cross-sectional, randomized, case-control study for the evaluation of the frequency of TNF-α 308G>A polymorphism alleles among patients with ischemic stroke.

Material and methods. The study included 100 cases of patients diagnosed with ischemic stroke (neurological and CT scan examination), and 86 healthy unrelated controls.

TNF-α 308G>A genotyping was carried out using PCR amplification of relevant gene fragment was followed by restriction enzyme digestion. Detection of TNFα 308G>A alleles was determined through analysis of resulting restriction fragment length polymorphism (RFLP) followed by gel electrophoresis.

Results. Molecular analysis did not reveal an increased frequency of GA mutant genotype in the study group compared to the control group ($p = 0.744$, OR = 1.174, CI = 0.6183 - 2.229). The AA genotype was not present in any subjects, probably because of the smaller number of AA carriers present in the population, since the A allele is very rare.

Conclusions. We found no significant difference in distribution of the TNF-α 308G>A polymorphism between the ischemic stroke and control groups.

J09.21

Investigation of the Asporin gene polymorphism as a risk factor for knee osteoarthritis in Iran

R. Jazayeri[1]*, S. Qoreishi*[2]*, M. Babanejad*[1]*, H. Seyyed Hoseinzadeh*[2]*, H. Najmabadi*[1]*, S. Jazayeri*[2]*;*
[1]*. Genetics Research Center, University of Soscial Welfare and Rehabilitation Science, Tehran, Islamic Republic of Iran,* [2]*Medical School, Shahid Beheshti University of Medical Sciences & Health Services, Orthopedic Surgery Center of Excellence, Health Services & Medical Education of Akhtar Hospital,, Tehran, Islamic Republic of Iran.*

Osteoarthritis (OA) is a degenerative disease of the joints characterized by degradation of the hyaline articular cartilage and remodeling of the subchondral bone with sclerosis. Asporin (ASPN) gene encodes a cartilage extracellular protein that is member of the small leucine-rich proteoglycan family. Polymorphisms in the aspartic acid repeat region in the second exon of this gene, that is consist of GAT repeats, are associated with a susceptibility to osteoarthritis. The D14 allele (an allele containing 14 D repeats) is associated with increased OA susceptibility in Japanese and Han Chinese, but is not an important factor in OA etiology among Caucasians, although the D15 allele is considered a risk allele for Greek population. To apprise the possible association, that seems controversially, we explored the ASPN effect in Iranian patients with knee OA. The D repeat polymorphism was genotyped in 100 knee OA patients and 100 control subjects, and the allelic association of the D repeat was examined. Our data suggest that the D15 allele could be considered a risk allele significant only for females ($p=0.045$) of Iranian population. This association is partially similar to Greeks, that D15 allele was considered a risk allele.

J09.22

Interleukin-1 β Gene Polymorphisms in Iranian Patients With Uterine Fibroid, A Case- Control Study

f. taghizade mortezai*, s. Miraj, M. Hashemzade Chaleshtori, E. Farrokhi, S. Khairi;*
Cellular and Molecular Research Center, Shahrekord Univ. of Med. Sci. Shahrekord Iran, shahrekord, Islamic Republic of Iran.

Background and abjective: Uterine leiomyoma or fibroid is currently the most common estrogen- dependent reproductive system tumor. Almost a quarter of women of reproductive age are affected with this benign tumor. These tumors are the most common reason of hysterectomy and women surgery and seriously affect women health. The aim of this study is investigation of IL-1β-511and IL-1β 3954 Polymorphisms association with uterine leiomyoma between in Iranian women of Charmahal & bakhtiari province.

Method of investigation : In this study , 276 patients with uterine leiomyoma and 157 healthy women as control are studied. The genetic polymorphisms for IL-1β-511and IL-1β 3954 were analyzed by polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP). and the results analyzed with SPSS software and χ^2 test

Finding: genotypes and allelic frequencies compared are two groups. A significant difference in the allele frequencies of the IL-1 β -511 C>T polymorphism in leiomyoma groups and normal controls was found ($P < 0.05$). No difference was found in the IL-1 β -3954 polymorphism in studied cases.

Conclusion: Our findings indicated that there is a significant association between IL-1 β -511C>T promoter Polymorphism and risk increase of uterine leiomyoma on the women of our study and this polymorphism might participate in developed this disease.

Keyword: leiomyoma, polymorphism, IL-1β

Association between MDR1 gene polymorphisms and its expression in Iranian CRC patients.

S. Samanian[1]*, F. Mahjoubi*[1]*, B. Mahjoubi*[2]*, R. Mirzaee*[3]*;*
[1]*Department of Clinical Genetic, National Institute of Genetic Engineering and Biotechnology (NIGEB), Tehran, Islamic Republic of Iran,* [2]*DHAZRAT RASOOL Hospital, Iran University of Medical Sciences, Tehran, Islamic Republic of Iran,* [3]*HAZRAT RASOOL Hospital, Iran University of Medical Sciences, Tehran, Islamic Republic of Iran.*

Increase expression of multidrug resistance gene (MDR1) gene is one of the mechanisms responsible for drug resistant to chemotherapy.

There are different mechanisms such as polymorphism that result in MDR1 over expression.

It has been reported that the C1236T and C3435 polymorphisms of the MDR1 gene have substantial impact on expression or activity of P-glycoprotein (Pgp).

In this study, we investigated the possible association between MDR1 gene C3435 and C1236T polymorphisms and its expression in Iranian CRC patients.

ARMS and RFLP PCR were used for the detection of this single nucleotide polymorphism in 60 CRC patients and 60 healthy individuals.

We concluded that there was no significant association between MDR1 expression and polymorphism in patients; the results of the present study demonstrate that these polymorphisms may not play a role in inducing drug resistance by altering the expression level of MDR1 gene.

Current experiences with newborn screening & case finding in Iran

S. Farshidi*, S. Gafari, B. Farokhi;*
Hope gene center, Tehran, Islamic Republic of Iran.

This review presents the current experiences with newborn screening & case finding in Iran. Iranian population is about 70 million, with high birth rate and an estimated 1 million per year. The population is characterized by a high consanguinity (25-70%) . Inherited metabolic disorders common among the population. Although research spending is rather soft in the region, there are numerous pilot studies that highlighted the high incidence of genetic defects and the need for newborn screening programmers.

1 : we searched for IEM in ill infant & children admitted in clinics or hospitals (2007-2010).

Mass screening using tandem mass spectrometry(MS/MS) and selected testing was initiated to determine IEM.

From April 2007 to March 2010, 13,500 infants and children were screened for organic, amino and fatty acid metabolism disorders and aminoacidopathies. In these group we had 2% positive result (264). Out of 264 patients , the spectrum included OA (98), aminoacidopathies (78) ,UCD (54), neurotransmitter conditions (12) and lysosomal disorders mainly MPS (14) , with a sensitivity of 97.67%, a specificity of 99.28% .

2: we searched for IEM in 5000 newborns (2009-2010), *by* Tandem mass spectrometry (MS/MS) for >20 markers of disease in a single assay. Limited information is available for setting the marker cutoffs and for the resulting positive predictive values.

We identified 22 babies with aminoacidophaties (5), OA (10) and FAO(7).

The Future of Migraine Genetics

L. A. Rudkjoebing[1,2], *A. Esserlind*[1], *J. Olesen*[1];
[1]*Danish Headache Center, Department of Neurology, Glostrup, Denmark,* [2]*Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark.*

Background

Migraine is a commonly occurring, neurological disorder with a substantial genetic component. With the exception of the rare monogenic forms of migraine, current technology has not proved efficient in revealing the underlying genetics of migraine. Recent genome-wide association studies (GWAS) have identified four single nucleotide polymorphisms significantly related to migraine. However, these polymorphisms explain only a small part of the heritability. The missing heritability might be hidden in rare variants, calling for a more detailed sequencing to be applied and developed. Sequencing the entire genome by exome sequencing and whole genome sequencing (WGS) are techniques undergoing an enormous development and might help to reveal the genetic mystery of migraine. We aim to explore future possibilities for migraine genetics given by the new developing technologies.

Methods

Since the technology evolves much faster than the literature, the study is predominantly based on interviews with genetics experts. Also, we evaluated studies regarding migraine genetic and next generation sequencing, which were identified using PubMed search.

Conclusion

The future research in migraine genetics will be dominated by the next generation sequencing. However, at the present time, prices and analyzing tools limit its use, and in cases with sporadic migraine, GWAS appear to be the best choice. Conversely, in cases with familial migraine, exome or whole genome sequencing will be the preeminent choice. In order to gain insight in the heritability of migraine, studies in the upcoming years will require large sample sizes and cooperation between migraine genetic consortia.

J09.26

May quantity of low functionality alleles of folic acid metabolism genes be important?

H. Makukh, *L. Chorna, H. Akopyan, D. Zastavna, O. Hnateyko;*
State institution "Institute of Hereditary Pathology of Academy of Medical Science of Ukraine", Lviv, Ukraine.

MTHFR, MTRR and MTR genes SNPs polymorphisms have been associated with many disorders, however, findings have been inconsistent.

DNA of 274 studied cases (55 female with neural tube defect fetuses (MNTD), 35 mother children with Down syndrome (MDS), 35 mother children with cleft lip and/or palate (MCL/P), 84 women with RSA (recurrent spontaneous abortion), 35 CL/P patients, 35 chorion villi from miscarriages (CV)) and 225 control subjects was isolated using the salting out method and the analysis of SNPs polymorphisms was performed by PCR-RFLP assay.

The differences of the MTHFR 677C→T and 1298A→C, MTR 2756A→G and MTRR 66A→G allele and genotype frequencies between studied and control groups were not significant besides higher incidence of MTRR 66G allele in MDS group (p=0.009; OR=2.10; CI:1.20 - 3.70).

As all the studied conditions are polygenic we attempted to calculate the quantity of MTHFR 677T, 1298C, MTR 2756G and MTRR 66G as low functionality alleles. We speculate that accordingly to obtained results for four analyzed loci person could have from 0 to 8 low functionality alleles. Interestingly, no one case with the presence more that six low functionality alleles was detected.

The accumulation in the female genotype of 5/8 alleles: MTHFR 677T, MTHFR 1298C, MTR 2756G and MTRR 66G in homo-/heterozygous state is associated with significantly increased risk of delivering child with NTD (OR=5.90; CI:1.11 - 31.43, p=0.032); CL/P (OR=9.08; CI:1.58 - 52.2, p=0.014) and RSA (OR = 9.83; CI:2.14 - 45.20, p=0.0004). These observations were not found in MDS, CL/P and CV groups.

J09.27

Replication of the results of genome-wide association study for Parkinson's disease in patients and controls from Bashkortostan Republic of Russia

G. Akhmadeeva[1], *I. Khidiyatova*[1], *I. Gilyazova*[1], *A. Safiullina*[2], *D. Baizigitov*[2], *E. Khusnutdinova*[1];
[1]*Institute of biochemistry and genetics Ufa Scientic Centre RAS, Ufa, Russian Federation,* [2]*Bashkir State University, Ufa, Russian Federation.*

The purpose of the investigation was to replicate the results of genome-wide analysis (GWAS) of Parkinson's disease (PD) on DNA samples of patients and controls - residents of Bashkortostan Republic. The analysis of alpha-synuclein (SNCA) gene polymorphisms at three loci (rs356219, rs356165, rs2737020) in 382 PD patients (143 - Russians, 157 - Tatars, 72 - Bashkirs, 10 - other ethnic origin) and 530 healthy individuals, matched for sex and age (133 - Russians, 307 - Tatars, 88 - Bashkirs, 2 - other ethnic origin) was performed. The association with PD development was found for loci rs356219 and rs356165. A comparison of total cohorts of patients and controls revealed genotypes and alleles associated with the disease in each locus: the genetic marker of the increased risk for PD development at rs356219 was allele *G (OR=2,02), the frequency of which was 0,45 and 0,39 in patients and controls, respectively; the protective markers for PD development were genotype * A * A (OR = 0,71) and allele * A (OR = 0,73); at rs356165 - allele * G (OR = 1,36) and genotype * G * G (OR = 1,51) increased and allele * A (OR = 0,73) decreased risk of PD development. The comparison of ethnically devided PD patients samples and controls demonstrated similar statistically significant associations (p <0,05) only in Bashkirs, while Russians and Tatars showed only a trend of such associations.

J09.28

Analysis of LRRK2 and parkin gene mutations in Slovak Parkinson disease patients

C. Bognár[1], *M. Baldovic*[1], *A. Zatkova*[2], *L. Kadasi*[1,2];
[1]*Department of Molecular Biology, Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia,* [2]*Institute of Molecular Physiology and Genetics, SAS, Bratislava, Slovakia.*

The Parkinson's disease (PD) is the second most common progressive neurodegenerative brain disorder caused by loss of nigrostriatal dopaminergic neurons, which affect the control of body movements, with inclusion formation (Lewy bodies) in surviving neurons. It affects 1-2% of the global population above 65 years and its prevalence increases to approximately 4% in those above 85 years. Parkinson's disease is a complex neurodegenerative movement disorder characterized by bradykinesia, resting tremor, rigidity and postural instability.

To detect the most common mutations in selected exons of LRRK2 and parkin genes responsible for late and early onset form of disease, respectively, we applied a gene scanning approach using dHPLC method. In this study, we evaluated the prevalence of LRRK2 mutations in exons 31, 35, 41, 48 and of parkin (PARK2) mutation in exons 2, 6 and 7 in a cohort of 216 consecutive, unrelated Slovakian patients with familial or sporadic PD, including early and late onset patients.

We have found one exonic, eight intronic polymorphisms and a heterozygous point mutation p.Arg275Trp (c.823C>T, rs34424986) in exon 7 of parkin gene in one patient with age at onset 62 years. In the exons 31 and 41 of gene the LRKK2, and in exon 6 of the gene parkin we did not observe any variant chromatographic profile after DHPLC analyses.

J09.29

Tumor Necrosis Factor Alpha, Interleukin-2 and Interleukin-2 Receptor Beta Gene Polymorphisms in Patients with Psoriasis and Psoriatic Arthritis

A. Gulel[1], *H. S. Inaloz*[1], *S. Pehlivan*[2], *T. Sever*[2];
[1]*University of Gaziantep, Faculty of Medicine, Department of Dermatology, Gaziantep, Turkey,* [2]*University of Gaziantep, Faculty of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey.*

In this study, our aim is to investigate association between TNF-α, IL-2 and IL-2RB gene polymorphisms/expressions and susceptibility for psoriasis and psoriatic arthritis.

Seventy four patients with psoriasis and 74 healthy volunteers were enrolled in the study. In all study subjects, the genes analysed by PCR-RFLP method. Then, data compared between the study groups.

AA genotype in TNFα(-308) (high expression), AA genotype in TNF-α(-238) and GG, TT genotypes in IL-2(-330) are significantly increased in patients with psoriasis in comparison with control group. However, GG genotype in TNF-α(-238) and GT genotype in IL-2 are significantly decreased in patients with psoriasis in comparison with control group. Also gene polymorphisms were analyzed according to the clinical characteristics of the psoriasis patients. IL-2/GG genotype frequency was significantly decreased and the frequency of IL-2/TT genotype was significantly increased among patients with psoriatic arthritis in comparison with psoriasis patients. The frequency of IL-2/TT genotype was significantly increased in mild psoriasis pattient according to moderate-severe psoriasis patients. Also IL-2RB/CC genotype was significantly increased, among patients with late-onset psoriasis in comparison with early onset psoriasis group. IL-2RB/TC genotype frequency was significantly decreased and TT genotype frequency was significantly increased in patients with positive family history of psoriasis according to negative family history patients.

In conclusion, polymorphisms of TNF-α (-238 and -308/high expression) and IL-2 genes may contribute to susceptibility to psoriasis. Also, the IL-2/TT genotype may be a risk factor for the development of psoriatic arhritis, whereas the GG genotype may be a protective factor against psoriatic arthritis.

J09.30

The study and comparison of serotonin gene receptor (5HT3A) expression profiles in rheumatoid arthritis and systemic Lupus erythematous patients

M. Sadeghi Koupaei[1], *s. nazari*[2], *g. ahangari*[3];

[1]Department of Basic Sciences, Paramedical Sciences School, Shaheed Beheshti University of Medical Sciences, Tehran, Islamic Republic of Iran, [2]Department of Hematology & Oncology, Mofid Hospital, Shaheed Beheshti University of Medical Sciences,, Tehran, Islamic Republic of Iran, [3]Department of Medical genetic, National Institute for Genetic Engineering and Biotechnology (NIGEB),, Tehran, Islamic Republic of Iran.

Background and Aims: Rheumatoid arthritis (RA) and Systemic lupus erythematous (SLE) are both autoimmune disease that their causes are still unknown. Serotonin (5HT) plays roles as a neurotransmitter and a neuromodulator with functions in brain and peripheral tissues. Recent studies reveal that in addition to the CNS, immune cells synthesis neurotransmitters such as serotonin can regulate immune functions. The aim of this study is to evaluate the serotonin receptor gene expression level on peripheral blood mononuclear cells of RA and SLE patients compared to normal individuals.

Material and Methods: In the present study, we investigated serotonin receptor gene expression in PBMCs of 40 RA and SLE patients and 20 healthy individuals using Real Time-PCR. The specificities of the obtained Real time PCR products for the respective serotonin receptors fragments were confirmed by sequenced analysis capillary system (ABI3700, Applied Bio system, USA).

Results: The results showed that 5HT3A receptors mRNA Expression significantly altered in PBMC of RA and SLE patients. Compared to normal individuals, statistics analysis shown that 5-HT3A expression level in RA patients decreased while this level in SLE patients increased.

Conclusion: It appears that both genetic and environmental factors play a role in pathogenesis of RA and SLE diseases. In this study it is suggested that serotonin and its receptors possibly can have an effective role in pathophysiology of RA and SLE diseases.

Keyword: Serotonin receptor gene expression, Rheumatoid arthritis, Systemic lupus erythematous

Association between ACE, AGTR, Factor II and Factor V gens with Stroke Subtypes in an Persian Population

A. Sadr-Nabavi[1], *M. Ghasemi*[1], *M. Pirhoushiaran*[1], *P. Zargari*[1], *P. Sasannejahad*[2], *M. Azarpajooh*[2];

[1]Medical Genetic Institut Mashhad University of medical Since, Mashhad, Islamic Republic of Iran, [2]Neurology Institut Mashhad University of medical Since, Mashhad, Islamic Republic of Iran.

Background and aims: Stroke is the third cause of death in the world after the cancer and cardiovascular disease. In Persian population, Ischemic stroke incidence was also considerably greater than reported in other regions. It is the first gene-association study, which determines the relationship between ACE, AGTR, Factor V Leiden, Factor II variations and stroke. A stroke Database bank was design for this project. Matched controls were randomly selected from the same geographically area. The aim of this study was to determine the association between mentioned gene ′s variations and stroke.

Method: 153 patients of stroke and 153 healthy controls were matched for age and sex. Additionally, control subjects were matched in some stroke risk factors such as diabetes mellitus, low-density lipoprotein, high-density lipoprotein, triglyceride, total Cholesterol hypertension and ischemic heart attack. The gens were determined by Multiplex ARMS- PCR, Real Time PCR, and PCR-RFLP.

RESULT: Statistically significant differences found between ACE II genotypes: 26.8% II in patients versus 15% II in controls. There were a high frequency of AA genotype and very low frequency of CC genotype in both groups for the AGTR. There was no correlation between Factor V, Factor II variations in case and control groups.

Conclusion: Statically significant different was found between ACE II genotype in both groups ($p<0.05$).Our results suggest that ACE II genotype is responsible for stroke susceptibility in Persian Population. We report that Insertion/Insertion genotype of ACE gene was an independent risk factor for Persian stroke patients in contrast to verified studies.

Estrogen receptor α gene polymorphisms and reproductive history in women with systemic lupus erythematosus

S. Andonova[1], *R. Robeva*[2], *D. Tanev*[3], *M. Nikolova*[4], *M. Stoycheva*[5], *A. Tomova*[2], *P. Kumanov*[2], *R. Rashkov*[3], *A. Savov*[1], *Z. Kolarov*[3];

[1]National Genetic Laboratory, Sofia, Bulgaria, [2]Clinical Center of Endocrinology and Gerontology, Medical University, Sofia, Bulgaria, [3]Clinic of Rheumatology, Medical University, Sofia, Bulgaria, [4]Clinic of Nephrology, Medical University, Sofia, Bulgaria, [5]Department of Social Medicine and Health Management, Medical University, Sofia, Bulgaria.

Background: Systemic lupus erymathosus (SLE) is an autoimmune disease that affects predominantly females. Estrogens could modulate the immune system functions through an estrogen receptor dependent mechanisms. However, the influence of the estrogen receptor alpha (ERα) gene polymorphisms on the reproductive function in autoimmune disorders (and especially in women with SLE) is not clarified.

Objectives: The aim of the study was to investigate whether two ERα-gene polymorphisms were related the reproductive history in SLE-women.

Methods: A total of 103 women with SLE were genotyped for ERα polymorphisms PvuIIT/C and XbaIA/G by RFLP analysis. The absence of PvuII and XbaI restriction sites were indicated by „P“ and „X“ and their presence by „p“ and „x“, respectively. The presence of menstrual disorders, pregnancies, miscarriages and live births as well as the age of menarche were registered in all women.

Results: XbaIA/G and PvuIIT/C polymorphisms were not significantly related to the frequency of pregnancies, miscarriages or live births in SLE patients ($p>0.05$). Menstrual disturbances were reported less frequently by women with Xx genotype than by patients with XX or xx genotypes (8% vs. 24.5%, $p=0.033$). The age of menarche was not influenced by the ERα polymorphisms ($p>0.05$).

Conclusions: XbaIA/G and PvuIIT/C polymorphisms of the ERα-gene were not related to the reproductive outcome in women with lupus. Further studies are needed to confirm and explain the relationships between the XbaIA/G polymorphism and menstrual disorders in women with lupus and other autoimmune diseases.

The study was granted by research grant 26/2010 from MU-Sofia, Bulgaria

Attitude and controversial aspects in systemic lupus erythematosus onset

C. Daescu[1,2], *I. Maris*[1], *O. Margineanu*[1,2], *T. Marcovici*[1,2], *A. Militaru-Somogy*[1,2], *A. Craciun*[1,2], *O. Belei*[1,2], *D. Chiru*[1,2], *M. Puiu*[1,2];

[1]"Victor Babes" University of Medicine and Pharmacy, Timisoara, Romania, [2]"Louis Turcanu" Children's Emergency Hospital, Timisoara, Romania.

Introduction: Systemic lupus erythematosus (SLE) is a multi-organic autoimmune disease with numerous immunological and clinical manifestations. A genetic predisposition in SLE disease is well documented. Material and method: We present a 12 years old girl referred to our hospital for SLE as presumptive diagnosis. Results: The patient's family history is highly significant for SLE: a maternal aunt died at age 26, due to SLE complications. Her daughter (patient's cousin) was also diagnosed with SLE. Her evolution was unfavorable, despite extra-renal epuration. She presented important cardiovascular comorbidities, but the cause of death was renal failure, at 16 years. In these circumstances, the onset of malar rash and photosensitivity demands further evaluation of other markers of SLE, in our case. Complete investigation ruled out the following diagnostic criteria: discoid rash, serositis, oral ulcers, arthritis, hematological disorders, renal involvement, antinuclear antibodies, immunologic phenomena and neurological pathology. Two out of the eleven diagnostic criteria were serially present during follow-up. Discussion: The presence of HLA-A1, B8, DR, the null complement alleles and congenital deficiencies of complement (especially C4, C2, and other early components) increase the risk of SLE in this case. If a mother has SLE, her daughter's risk of developing the disease is estimated at 1:40. For this girl, the risk is even higher, due to SLE family aggregation. Conclusions: Genetic testing should be performed to clarify the diagnosis of SLE in this case. Psychosocial aspects and genetic counseling can influence patient and family quality of life.

J09.34

The prevalence of genes *HLA-DQ* in children with diabetes type 1 of Krasnodar region

N. V. Tarasenko[1]*, E. I. Kondrat'eva*[2]*, I. J. Chernjak*[3]*;*
[1]*State Research Institute of Medical Genetics, Tomsk, Russian Federation,* [2]*GBOU VPO KubGMU Minsravsocravitiya Rossii, Krasnodar, Russian Federation,* [3]*Children's Regional Clinic, Krasnodar, Russian Federation.*

Objective: study of the frequency of polymorphic genes alleles *HLA-DQA1* and *HLA-DQB1* in children and adolescents with type-1 diabetes (T1D) in the Russian population living of the Krasnodar region.
Methods: examination of 110 patients with T1D and 34 healthy siblings. Defining gene alleles HLA-DQA1 (8 specificities) and HLA-DQB1 (12 specificity) was performed using sets of „DNA-Technology".
Results: the data were analyzed protecting and predisposing alleles for T1D for the genes *HLA-DQA1* (*0301, *0501, *0102, *0103, *0201) and *HLA-DQB1* (*0201, *0302, *0304, *0401, *0301, *0602). Patients with T1D revealed the following relationship of diabetogenic alleles: the presence of four predisposing alleles *HLA-DQ* was observed in 39% of patients with T1D; 2 to 3 alleles was observed in 42%, and <1 allele was detected in 19%. In healthy siblings we observed the following: 4: 6%, 2-3: 50%, and <1: 44%. The most common haplotype, which includes four predisposing allele, was encountered in 72% of T1D. Haplotype DQA1*0301-DQB1*0201 was observed in 43% of patients, haplotype DQA1*0501-DQB1*0201 was observed in 51%. Preventing alleles were observed in 41% of patients with T1D, of which 8% with the observed combination of alleles DQA1*0102 and DQB1*0602. In 74% of healthy siblings we identified protecting alleles, of which haplotype DQA1*0102-DQB1*0602 was observed in 18%.
Conclusions: T1D patients in the Russian population of the Krasnodar region are characterized by a „classic" for European populations, protecting and predisposing for T1D alleles *HLA-DQ* genes.

J09.35

Association of two IL-23R gene variations with ulcerative colitis in Iran

N. Naderi[1]*, A. Farnood*[2]*, **T. Dadaei***[1]*, H. Balaii*[1]*, M. Habibi*[1]*, H. Mirtalebi*[1]*, M. Zali*[1]*;*
[1]*Research Center for Gastroenterology and Liver Disease, Shahid Beheshti M.C, Tehran, Islamic Republic of Iran,* [2]*Imam khomeini Hospital, Keshavarz Blvd, Tehran, Islamic Republic of Iran.*

Background and aim: Ulcerative colitis (UC), a chronic inflammatory bowel disease, occurs in genetically susceptible individuals who mount inappropriate immune responses to endo-luminal antigens. Interleukin 23 receptor (IL23R) gene has been reported as a genetic factor associated with ulcerative colitis and other autoimmune-mediated diseases. This study was performed to evaluate two interleukin-23 receptor (IL-23R) polymorphisms association with UC in Iranian patients.
Material and methods: A number of 102 patients with ulcerative colitis and 152 sex- and age-matched healthy controls from the same origin were participated. The PCR-RFLP method was used to evaluate IL23 R SNPs, rs 10889677 (Exon-3' UTR) and rs 11209026 (Arg 381 Gln), of IL23R gene in our population.
Results: The frequency of mutant allele of rs10889677 was 46.5% in UC and 45.7% in controls. The frequency of rs11209026 mutant allele was 2.9% and 5.2% in UC and controls, respectively. None of the evaluated polymorphisms of IL23R gene were more frequent in UC patients, compared to healthy controls.
Conclusions: Our results demonstrated that rs10889677 and rs11209026 mutations of IL23R are not associated with UC in Iranian patients. Additional variants in this gene might play a role in UC disease susceptibility in Iran.

J09.36

Valuation of inherited venous thromboembolism risk within two clinically unrelated populations

N. Lojo - Kadric*, L. Kapur - Pojskic, J. Ramic, K. Radic, K. Bajrovic;*
Institute for genetic engineering and biotechnology, Sarajevo, Bosnia and Herzegovina.

Venous thromboembolism is disease where a blood clot is formed in human venous system. This disease includes deep venous thrombosis (DVT) and pulmonary embolism (PE). Venous thromboembolism results as a combination of hereditary and acquired factors. Acquired factors include surgery, trauma, cancer etc, while common hereditary factors are F5 (coagulation factor V Leiden) 1691G-A gene mutation, F2 (coagulation factor II, prothrombin) 20210G-A gene mutation and MTHFR (methylenetetrahydrofolate reductase) thermolabile polymorphism (677C-T mutation.
In this study, 100 individuals were genotyped: 70 grouped by their clinical background (40 individuals on hemodialysis (HP) and 30 individual with breast cancer (BC)), and 30 healthy volunteers with no clinical background as control group. All samples were genotyped for MTHFR 667C-T, F2 20210G-A and F5 1691G-A mutation using in-house optimized Sybr® green method.In all three groups we found one heterozygote (GA) for F5 Leiden mutation. All other samples had wild type genotype. Only in control group we found one homozygote (AA) for F2 20210G-A mutation, and one heterozygote (GA). We also found one heterozygote in HP group and two in BC group. MTHFR genotypes in HP group are 45% of CC - wild type genotype, 37,5% of CT genotype and 17,5% of TT genotype. BC and control group had the same percentage - 60% of CC, 37% of CT and 3% of TT genotype.

J09.37

The association between VEGF -2578C/A polymorphism and amyotrophic lateral sclerosis in Russian population.

E. V. Lysogorskaia*, N. I. Abramycheva, M. N. Zakharova, S. N. Illarioshkin;*
Research Center of Neurology, Russian Academy of Medical Sciences, Moscow, Russian Federation.

Background. The association of -2578C/A, -1154G/A, and -634G/C SNPs with ALS was found in some European populations (Lambrechts et al., 2003). However, there was no such association in different other populations (Brockington et al., 2005; Del Bo et al., 2006; Van Vught et al., 2005; Zhang et al., 2006). We suppose the important role of VEGF in ALS pathogenesis. The aim of this study was to investigate the association between VEGF -2578C/A polymorphism and ALS in Russian population.
Methods. The peripheral blood was extracted from 197 patients with ALS and 156 controls. The ALS group included 54% (107/197) males and 46% (90/197) females aged from 20 to 83 years (51,2 ±13,4) and was comparable with controls. All of persons were the Slavs. TaqMan PCR was used for detection of -2578C/A SNP.
Results. The significant difference of the distribution of -2578A allele in ALS cases and controls was observed (p=0,014). The VEGF -2578A/A genotype increased ALS risk to an adjusted odd of 1,58 (95% CI, 0,04-0,95). There was no increased risk for males (OR=1,84, 95% CI, -0,06-1,27). The association between VEGF genotype and clinical characteristics of ALS wasn't detected. But the patients before 45 years old had a weakly increased risk of ALS (OR=1,27, 95% CI, -0,47-0,95).
Conclusions. Our data showed that VEGF genotype isn't a major cause of motor neuron degeneration in ALS, but it can modulate the risk of ALS in Russian population. Thereby VEGF genotype could be useful in choice of ALS pathogenetic therapy.

J09.38

Investigation of mitochondrial tRNA^{Thr} and tRNA^{Pro} genes mutations in autism

F. Piryaei*, M. Houshmand, Z. Piryaei;*
National Institute of Genetics Engineering and Biotechnology, Tehran, Islamic Republic of Iran.

Objectives: Autism as one of three recognized condition in the autism spectrum disorders (ASDs) is a neurodevelopmental, multifactorial disorder. Autism is noticeably reported to be affected by mitochondrial dysfunction which impairs energy metabolism. mtDNA encodes 22 tRNAs working as amino acid transporters for synthesis of the respiratory chain enzymes. Involvement of mutations within tRNA genes have been well documented in mitochondrial disorders. In this study, tRNA^{Pro} and tRNA^{Thr} were investigated to find mutations which are related to autism pathogenesis, as these two genes mutations have been reported to be involved in some neurological disorders.
Methods: In this study, a cohort of 24 unrelated idiopathic patients and 100 ethnically-matched Persian control individuals were obtained. PCR sequencing of mtDNA fragments was employed to investigate the involvement of mitochondrial variations in autism.
Results: A substitution , G15928A, was identified in two groups without a significant difference (P = 0.179, P> 0.05). A new homoplasmic substitusion, A15973G, was identified within the T-loop of tRNA^{Pro} gene in 1 patient as it had not been reported before. This variation is moderately conserved (75 %) among species and also, was not detected in blood sample from the patient's mother.
Conclusion: Investigation on mitochondrial varations may strengthen the role of genetics in association with autism. To reveal the relation of A15973G

and autism, more delicate molecular methods could be done for determining the percentage of heteroplasmic mtDNA in mother's sample of the patient.

J09.39

The BDKRB2 gene I/D polymorphism in Russian athletes

L. J. Mustafina[1], *Y. I. Timshina*[2], *I. V. Astratenkova*[2], *I. I. Ahmetov*[1];
[1]Kazan State Medical University, Kazan, Russian Federation, [2]St Petersburg Research Institute of Physical Culture, St Petersburg, Russian Federation.

Background

Bradykinin is a potent endothelium-dependent vasodilator and acts via the bradykinin B2 receptor (encoded by BDKRB2). The absence (-9), rather than the presence (+9), of a 9 bp repeat sequence in exon 1 has previously been shown to be associated with increased gene transcription, higher BDKRB2 mRNA expression and higher efficiency of muscular contraction (Williams et al. 2004). Studies suggest that insertion-deletion (I/D) polymorphism in BDKRB2 gene is associated with aerobic capacity and elite endurance athlete status. The aim of our study was to investigate the association between the BDKRB2 -9/+9 polymorphism and athlete status in Russians.

Methods

One thousand three hundred and seventy nine athletes from different sporting disciplines and 507 controls were involved in the study. The athletes were prospectively stratified into 5 groups according to the event duration and distance, covering a spectrum from the more endurance oriented to the more power oriented. Genotyping was performed by PCR.

Results. Analysis of distribution of allele frequencies revealed no significant differences between a whole group of athletes and the control group (-9 allele: 47.8 vs 45.9%; P=0.319). However, the frequency of the -9 allele was significantly higher among endurance-oriented athletes and athletes with mixed activity (endurance, power/strength): long distance running (P=0.014) and long distance swimming (P=0.022), wrestling (P=0.009) and archery (P=0.002).

In conclusion, our results are in agreement with the previous studies and indicate that the BDKRB2 -9 allele is favourable for endurance performance.

J09.40

The PPARG gene Pro12Ala polymorphism is associated with power athlete status

E. S. Nasibulina, *A. A. Arkhipova, A. V. Kuznetsova, A. V. Borisova, I. I. Ahmetov;*
Kazan State Medical University, Kazan, Russian Federation.

Peroxisome proliferator activator receptor gamma (PPARG) gene regulates the expression of genes involved in lipid and carbohydrate metabolism, differentiation of adipocytes and myoblasts, insulin sensitivity and glucose homeostasis. The 12Ala variant of the PPARG gene Pro12Ala polymorphism is associated with decreased receptor activity [Deeb et al., 1998], leading to insulin hypersensitivity and enhanced glucose utilization [Ek et al., 2001]. As a consequence, the carriers of the 12Ala allele show better glycaemic response to exercise training [Adamo et al., 2005], higher rates of skeletal muscle glucose uptake [Vanttinen et al., 2005] and greater cross-sectional area of muscle fibers [Ahmetov et al., 2008]. In a study of Russian power-oriented athletes a higher frequency (23.8 vs. 15.1%, P < 0.0001) of the PPARG 12Ala allele compared with controls has been reported [Ahmetov et al., 2008]. The aim of the present study was to investigate the association of the PPARG Pro/Ala polymorphism and athlete status in an independent cohort of Russian athletes. Two hundred and fifty eight athletes and 1174 controls were involved in the study. The frequency of the 12Ala allele was not significantly different between a whole cohort of athletes and controls. However, in accordance with the previous study, we found statistically significant differences in genotype distribution (weightlifters: Pro/Pro - 71.2%, Pro/Ala - 22.0%, Ala/Ala - 6.8%; controls: Pro/Pro - 72.1%, Pro/Ala - 26.0%, Ala/Ala - 1.9%; P = 0.043) and Ala/Ala frequency (P = 0.013) between weightlifters and controls. Thus, the PPARG gene Pro12Ala polymorphism is associated with power athlete status.

J09.41

Apolipoprotein E polymorphisms statues in Iranian patients with Multiple Sclerosis

M. Rafiei[1], *M. Zarif Yeganeh*[2], *S. Sheikhol Eslami*[2], *E. Gozalpour*[3], ***M. Hedayati***[2];
[1]1. Reference Health Laboratory, Ministry of Health and Medical Education, Tehran, Iran, Tehran, Islamic Republic of Iran, [2]Obesity Research Center, Research Institute for Endocrine Sciences, Shahid Beheshti University of, Tehran, Islamic Republic of Iran, [3]Dept of Pharmacology and Toxicology, Radboud University Nijmegen Medical Centre, Nijmegen Centre for Molecular Life Sciences, The Netherlands, Nijmegen, Netherlands.

Background: Multiple sclerosis (MS) is a chronic inflammatory demyelinating disorder in the central nervous system. Evidences linking Apolipoprotein E (APOE) to myelin repair, neuronal plasticity, and cerebral inflammatory processes suggest that it may be relevant in MS. The main goal of this study was to determine whether the APOE genotypes and alleles are associated with MS patients.

Materials&Methods: Totally,147 MS cases and 168 control subjects from Iranian population were genotyped for APOE gene using PCR-RFLP method. Genotype and allele frequencies for APOE gene were calculated and compared between MS cases and control subjects by Chi2 or Fisher's exact test.

Results:The frequency of APOE-ε2ε3 genotype was significantly higher in control subjects than MS patients (14.3%vs.6.1%,*P*=0.009,OR=0.39) whereas APOE-ε3ε4 genotype frequency was significantly higher in MS cases compared with control subjects (8.2%vs.3.6%,*P*=0.03,OR=2.4). APOE-ε2 allele frequency in cases was significantly lower than that of control subjects (4.4%vs.8.0%,*P*=0.03,OR=0.52). Also male controls were significantly more likely to have APOE-ε2 allele (7.8%vs.1%, *P*=0.01,OR=0.11). APOE-ε4 allele frequency in cases was significantly higher than control group (4.8%vs.2.1%,*P*=0.03,OR= 2.35).

Conclusion: The allele frequency of APOE-ε4 in our population is lower than the general population (3.5%vs.15-20%). It seems that individuals carrying APOE-ε4 allele and/or APOE-ε3ε4 genotype develop MS two times more than non-carriers. Also APOE-ε2ε3 genotype or APOE-ε2 allele may have a protective role against MS development in Iranian population. Further investigation would be warranted to understand the role of APOE alleles and genotypes and risk of MS.

J09.42

Research association of polymorphic markers of candidate genes with ischemic heart disease with the development of oxidative stress in elderly and senile patients living in the Rostov region

T. Nguyen;
Southern Federal University, Rostov on Don, Russian Federation.

The study selected patients with ischemic heart disease (n = 300). The control group (n = 280) consisted of a random sample of both sexes with no significant signs of ischemic heart disease. It was found that the development of coronary heart disease in elderly and senile patients living in the Rostov region, increases the rate of production of activated oxygen species, nitric oxide metabolite levels, the intensity of lipid peroxidation in plasma and red blood cells, reduces the activity of the enzymes superoxide dismutase, catalase in erythrocytes increases the oxidase activity of ceruloplasmin in the blood plasma and violates the stability and the structural organization of erythrocyte membranes. It was also found that residents of elderly, a manifestation of coronary artery disease is associated with polymorphic markers T174M gene AGT; L33P gene ITGB3; L28P gene APOE; C3238G APOC3 gene and the C786T gene eNOS. It is more common combination of two or more polymorphic alleles in the heterozygous and homozygous states. Identified polymorphisms in genes that regulate hemostasis and endothelial function are associated with the development of oxidative stress and impaired structural homeostasis of erythrocyte membranes.

J09.43

Haplotypes in IL-8 Gene are Associated to Age-Related Macular Degeneration

t. lepre[1], *f. taglia*[1], *r. cascella*[1], *f. missiroli*[2], *c. de felici*[2], *a. cusumano*[2], *s. zampatti*[1], *c. eandi*[3], *g. staurenghi*[4], *f. ricci*[2], *g. novelli*[5], *e. giardina*[1];
[1]Department of Biopathology, Centre of Excellence for Genomic Risk Assessment in Multifactorial and, rome, Italy, [2]UOSD Patologia retinica Fondazione PTV "Policlinico Tor Vergata", rome, Italy, [3]Department of Clinical Physiopathology, Eye Clinic, University of Torino, Torino, Italy, [4]Luigi Sacco Hospital, Milan, Milan, Italy, [5]Agenzia di Valutazione del Sistema Universitario e della Ricerca (ANVUR); San Pietro – Fatebenefratelli Hospital, Rome, rome, Italy.

Age-related macular degeneration (AMD) is the main cause of blindness in the developed world. The etiology of the disease is multifactorial, due to the interaction between genetic and environmental factors. Genetic and functional studies have confirmed that inflammation plays a pivotal role in the development of the disease. It's well known that interleukins mediate many of the effector phases of immune and inflammatory responses. Moreover activated macrophages secrete many proteolytic enzymes able to fragment Bruch's membrane leading to the neovascularisation. In our study, we show the association between IL-8 gene and age-related macular degeneration. We performed a case-control association study, testing for the Single Nucleotide Polymorphism rs2227306 a total of 1381 Italian subjects: 721 cases and 660 controls. On the basis of our positive preliminary results (p-value: 4.15*10-5; OR for T allele: 1.39 [1.19-1.62]), we also sequenced the entire IL-8 regulatory and coding regions of 60 patients and 30 controls stratified for their genotype at rs2227306. We identified two different haplotypes involving rs4073 (A/T), rs2227306 (C/T), rs2227346 (C/T) and rs1126647 (A/T): A-T-T-T (p-value: 2.08*10-9; OR: 1.68 [1.43-1.97]) and T-C-C-A (p-value: 7.07*10-11; OR: 0.60 [0.51-0.70]). Expression analysis on RNA extracted from whole blood of 50 donors failed to reveal evidence of correlation between genotype/haplotype and RNA expression. Our results suggest the association between IL-8 gene and the development of the disease, although further studies should be encouraged to clarify the functional effects as well as the causative variants.

J09.44

Influence of metabolic gene polymorphisms on athletic performance

O. N. Fedotovskaya[1], *D. V. Popov*[2], *E. V. Lyubaeva*[2], *L. J. Mustafina*[3], *O. L. Vinogradova*[2], *I. I. Ahmetov*[1,2,3];
[1]*Saint-Petersburg Institute of Physical Culture, Saint-Petersburg, Russian Federation,* [2]*Institute for Biomedical Problems of the Russian Academy of Sciences, Moscow, Russian Federation,* [3]*Kazan State Medical University, Kazan, Russian Federation.*

Genetic factors play important role in determination of functional physiological, biochemical characteristics and athletic performance. Regular intensive training helps elite athletes to be at the peak of human physical performance, which makes them the best objects for studying molecular mechanisms of energy supply for muscular activity. The aim of this study was to discover whether polymorphisms of genes involved in metabolic pathways (*AMPD1* C/T rs17602729, *CKMM* A/G rs8111989, *G6PC2* G/A rs560887 and *MCT1* A/T rs1049434) are associated with elite athlete status and common phenotypes related to sports performance. DNA samples of 996 Russian athletes and 1389 non-athletic Russian controls were analyzed for four gene polymorphisms by PCR-RFLP analysis. Sporting intermediate phenotypes were assessed in subgroups of athletes by measuring of aerobic capacity, strength, anthropometric parameters, muscle fiber characteristics, blood lactate and glucose concentrations. Four 'endurance alleles' were overrepresented in a group of endurance athletes compared with controls: *AMPD1* C (*P*=0.01), *CKMM* A (*P*=0.001), *G6PC2* G (*P*=0.0004), *MCT1* A (*P*<0.0001). The frequency of four 'power alleles' was higher in strength/power athletes compared with controls: *AMPD1* C (*P*<0.0001), *CKMM* G (*P*=0.007), *G6PC2* G (*P*=0.14), *MCT1* A (*P*=0.004). Associations of polymorphic variants with predisposition to certain types of physical activity (endurance and strength/power) were consistent with results of correlation analysis of these polymorphisms with measured physiological, morphometric and biochemical parameters of skeletal muscle. Thus, *AMPD1, CKMM, G6PC2* and *MCT1* genotypes are associated with sporting intermediate phenotypes as well as with athletic status.

No major clinical impact of a common variant in Toll-like receptor 4 gene on Temporal Lobe Epilepsy.

I. Manna[1], *A. Labate*[2], *L. Mumoli*[2], *G. Palamara*[2], *E. Ferlazzo*[3], *U. Aguglia*[3], *A. Gambardella*[1];
[1]*Institute of Neurological Sciences - CNR, Mangone (CS), Italy,* [2]*Institute of Neurology, University Magna Graecia, Catanzaro, Italy,* [3]*Regional Epilepsy Centre,Hospital of Reggio Calabria, Reggio Calabria, Italy.*

Evidences support the hypothesis that inflammation and neurogenesis play an important role in the pathogenesis of temporal lobe epilepsy (TLE). Coding variants in Toll-like receptor 4 (TLR4) gene have been reported to be associated with inflammatory diseases, so TLR4 may represent a reasonable functional candidate gene for TLE. The aim of this study was to determine whether a functional single nucleotide polymorphisms (SNPs), an A>G base transition at position 896 from the transcriptional start site of TLR4 (referred to as Asp299Gly), contributes to TLE. We also investigated whether this variant may influence the TLE phenotype. We used a case-control approach comparing the frequencies of Asp299Gly polymorphism between unrelated TLE patients and matched controls. In the second step, we evaluated the patient group in terms of the major clinical variables related to the epileptogenic process.
The study group included 345 patients (189 women and 156 men; mean ± SD age: 47.43±18.24) with a diagnosis of non-lesional TLE, based on comprehensive clinical, electroencephalographic, and magnetic resonance evaluations, and 370 (186 women and 184 men; mean ± SD age: 48.46±20.96) healthy controls. All individuals were genotyped for the SNP Asp299Gly in the TLR4 gene using a TaqMan 5' allele discrimination assay. Analysis of genotype and allelic frequencies between patients and controls showed no statistically significant difference. Moreover, the Asp299Gly variant did not influence age of epilepsy onset, duration of epilepsy, and response to medication. Our results illustrates that a major clinical impact of variant as a disease modifier in TLE is probably unlikely

J09.46

Extensive mutational analysis of CDK5 and CDK5R1 in patients with non-syndromic mental retardation reveals novel variants in CDK5R1 3'-UTR

S. Moncini[1], *P. Castronovo*[1], *A. Murgia*[2], *S. Russo*[3], *M. F. Bedeschi*[4], *P. Riva*[1], *M. Venturin*[1];
[1]*University of Milan, Milan, Italy,* [2]*University of Padua, Padua, Italy,* [3]*Istituto Auxologico Italiano, Milan, Italy,* [4]*Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy.*

CDK5 and its activator p35, encoded by CDK5R1 gene, are highly expressed in CNS where they have a fundamental role in neuronal migration and differentiation during CNS development. Their fundamental role in CNS development and function, and their involvement in the pathogenesis of neurodegenerative disorders makes CDK5 and CDK5R1 strong candidate genes for the onset of mental retardation. We carried out the mutation screening of CDK5 and CDK5R1 coding regions, as well as of CDK5R1 3'-UTR, on a cohort of 344 patients with non-syndromic mental retardation (NS-MR). In fact, we recently demonstrated that 3'-UTR has a key role in the post-transcriptional regulation of CDK5R1 expression, through the binding of protein factors and microRNAs belonging to miR-15/107 family, and this evidence prompted us to include this region in the mutational analysis. We found one silent mutation in CDK5, and three silent and two missense conservative mutations in CDK5R1 coding region. Four novel variations in intronic regions of CDK5 were also found but never predicted to cause splicing defects. Interestingly, we found nine heterozygous variations in CDK5R1 3'-UTR: among these, six were single base substitutions and three were small deletions. None of these variations was present in 450 healthy controls. Of particular interest is the deletion of one predicted miR-15/107 family binding site, found in one patient. Luciferase constructs containing the mutations observed in CDK5R1 3'-UTR will be used to verify if these variations have an effect on CDK5R1 expression levels and therefore constitute susceptibility variants for NS-MR.

Introduction: The main factor for atherosclerosis development is high LDL cholesterol (LDLc) levels. Majority of hypercholesterolemia cases are due to complex interactions gene-environment being the most common cause the polygenic hypercholesterolemia (PH).
Aim: Our objective was to identify candidate gene variants as contributors to de genetic cause of PH.
Methodology: 378 unrelated subjects, without mutations in *LDLR* and *APOB* genes, were selected according to the following criteria: LDLc ≥ 90th percentile and Tryglyceride levels ≤ 200 mg/dl. Moreover, a control group with 525 normolipemic subjects from the *Aragon Working Health Study* (AWHS) was analysed. All subjects were genotyped using Solexa (Illumina®) technology for 18 SNPs located in 5'UTR region of the *APOE*, *APOB*, *PCSK9*, *NR5A2*, *SREBF1* and *LDLR* genes.
Results: We have observed different allelic distribution between the PH population and the normolipemic subjects within 5 genetic variants. Our results have shown a higher frequency of the minor allele in PH versus control population of the *APOB* SNPs: rs51235 (0.497 vs 0.444, p<0.0250), rs617314 (0.333 vs 0.272, p<0.0055) and rs58429712 (0.092 vs 0.027, p<0.0001); while a lower frequency was observed in the PH group for the NR5A2 polymorphism rs9427440 (0.260 vs 0.387, p<0.0001) and the *LDLR* variant rs17248720 (0.087 vs 0.164, p<0.0001), are inversely related to PH.
Conclusion: We have identified 5 SNPs associated with the phenotypic expression of PH disease. The 3 *APOB* SNPs are directly related to PH phenotype while the *LDLR* and *NR5A2* polymorphisms seem to be protective to the hypercholesterolemia development.

Armenian HLA profile in the genetic context of Middle East

A. Margaryan[1], Z. Khachatryan[1], A. Harutyunyan[1], A. Khudoyan[2], L. Yepiskoposyan[1];
[1]Institute of Molecular Biology, Yerevan, Armenia, [2]Institute of Man, Yerevan, Armenia.

Armenians are an indigenous people of the South Caucasus with strong and distinct ethnic and cultural characteristics. Despite the important geographic location of historical Armenia in terms of ancient migrations and spread of Indo-European languages and agriculture, the genetic profile of the Armenian population is not well studied yet. In this work, we aimed to answer the following questions: i) is the Armenian population geographically stratified based on HLA markers despite their ethnic unity, and ii) what is the place of the Armenians on the genetic landscape of the Middle-East? To answers these questions we analyzed the genetic structure of three large Armenian territorial groups, Karabakh, historical Western Armenia, and Iran, as well as ethnically different populations from Middle East, Europe, Africa and Far East. Initial information on HLA typings were taken from published papers and analyzed relying on low resolution genotyping results of HLA-A, HLA-B and HLA-DRB1 loci. All the three Armenian territorial groups were assessed for haplotype frequencies estimated by the EM (Expectation-Maximization) algorithm using Arlequin software package. It was shown that the three Armenian subpopulations despite their ethnic homogeneity are geographically stratified which is in compliance with the results based on the Y-chromosomal markers. The pattern of genetic relatedness between the three Armenian groups and the comparative data sets revealed that the Armenians along with Mediterranean ethnic groups form a distinct cluster on a Principal Coordinate plot and Neighbor-Joining tree based on standard genetic distances, which is supporting the Mediterranean origin of Armenians.

Monitoring of congenital malformations in population of Republic of Moldova

V. V. Egorov, N. Barbova, M. Stratila, E. A. Halabudenco;
National Center of Human Reproduction and Medical Genetics, Chisinau, Republic of Moldova.

In Republic of Moldova congenital malformations (CM) occupies second place in structure of infantile mortality. Monitoring of CM in our country acts since 1991, and since 2009 they carry out work jointly with EUROCAT.

The aim of present study was evaluation of prevalence and structure of CM in Republic of Moldova based on genetic monitoring during the period 2006 - 2010.

The system of genetic monitoring in Moldova based on registration of all the range of congenital pathologies in live newborns, stillborn and children dead after birth with weight less than 500 g. on term of 22 weeks and more. CM registered in children during first year of life.

In the territory of Moldova during the period 2006 - 2010 was born 195837 children, including 3562 with CM. During this period there were 144 pregnancies terminated conform medical indications due to congenital or hereditary pathology (such as CM, chromosomal aberrations), revealed prenatal before 22 weeks of gestation. Overall prevalence of CM was 18,92 for 1000 newborns. Maximal prevalence of CM was in 2006 - 22,19 for 1000 and minimal in 2007 - 16,38 for 1000.

In structure of CM in Moldova first place occupies anomalies of musculoskeletal anomalies, cardio-vascular and multiple anomalies.

The prevalence of individual forms of CM (esophageal atresia, palate/lips clefts, omphalocele, Down syndrome) corresponds to indexes of EUROCAT. Anal atresia, spina bifida and polydactyly were more rare than in EUROCAT, and reductional anomalies were more frequent.

J10.03

A combined influence of TNFα and GSTs genetic variants in pathogenesis of COPD

M. Stankovic[1], A. Nikolic[1], N. Petrovic-Stanojevic[2], V. Dopudja-Pantic[2], M. Andjelic-Jelic[2], M. Mitic-Milikic[3], L. Nagorni-Obradovic[3], D. Radojkovic[1];
[1]Institute of Molecular Genetics and Genetic Engineering, Belgrade, Serbia, [2]Zvezdara University Medical Center, Belgrade, Serbia, [3]Institute for Tuberculosis and Lung Disease, Belgrade, Serbia.

The etiology of chronic obstructive pulmonary disease (COPD) is multifactorial, including genetic and environmental factors, as well their interactions. Increased inflammation and oxidative stress are the most prominent features of COPD. Since that, variants of genes involved in inflammatory response and protection from oxidative stress, which may alter these processes, might initiate and/or progress COPD.

We performed a case-control study in order to examine the role of functional variants of tumor necrosis factor α (TNFα) and glutathione-S-transferases (GSTs) in. Total number of 86 COPD patients and 100 controls were genotyped for TNFα G-308A, GSTM1 null, GSTT1 null and GSTP1 Ile105Val variants.

Statistical significance was observed for TNFα -308GG genotype (82.5% *vs* 69%, OR=2.13, p=0.04) in COPD *vs* controls. The statistically significant results were also obtained for combination of TNFα -308GG and GSTM1 null (48.8% *vs.* 31.0%, OR=2.12, p=0.016), as well for combination of TNFα -308GG, GSTM1 null and GSTP1 105Val/ (Val) (30.2% *vs.* 15.0%, OR=2.46, p=0.014).

This is the first study in which TNFα -308GG genotype was associated with pathogenesis of COPD. In addition, TNFα -308GG genotype in combination with GSTM1 null and GSTP1 105Val/(Val) was associated with the disease, that further confirmed importance of -308GG genotype for COPD pathogenesis.

Single and complex genotypes revealed in this study indicate the importance of the analysis of larger number of candidate genes which might contribute to elucidation of COPD pathogenesis and might be valuable in prevention of the disease.

Genetic polymorphism and haplotypes of HLA-A,-B,-DRB1 loci distribution analysis in North-West region of Russian Federation

E. Kotelevskaya[1,2], S. Smirnova[1,2], K. Shunkina[2], A. Smolyaninov[1,2];
[1]Reseach laboratory of cell technologies of the North-Western State Medical Academy named after I. I., St. Petersburg, Russian Federation, [2]Stem Cell Bank „Pokrovski", St. Petersburg, Russian Federation.

Umbilical cord blood contains hematopoietic stem cells and can be used as an alternative to bone marrow transplantation in certain cases. The most important factor of effective transplantation is the degree of HLA matching. There is a great genetic variety in HLA among representatives of different nationalities. The aim of given investigation is to determine the major histocompatibility complex antigens of umbilical cord blood samples from public bank, by a molecular-genetic method, to analyze loci and haplotypes HLA-A,-B,-DRB1 polymorphism of the North-West region of Russia residents. During the work 500 samples of cord blood were analyzed using polymerase chain reaction (PCR) with sequence specific primers (SSP).

It was identified that the most frequent alleles are: HLA-A*02 - 28,3%, *03 - 15,8%, *24 - 13,6%; HLA-B*07 - 12,6%, *35 - 11,4%, *44 - 8,2%, HLA-DRB1*15 - 15,8, *13 - 15,0%, *03 - 12,5%. The most frequent haplotypes are: HLA-A*01-B*08-DRB1*03 - 0.55%, HLA-A*03-B*07-DRB1*15- 0.45%, HLA-A*03-B*35-DRB1*01- 0.45%.

Obtained results of genetic polymorphism of HLA-A,-B,-DRB1 loci distribution in the North-West region of Russia inhabitants can complement existing information database on population genetics and associated diseases.

Sequence analysis of the GJB2 gene in Romanian children with hearing impairment

C. Dragomir[1], A. M. Stan[1], L. Savu[1], E. Severin[2];
[1]Genetic Lab, Bucharest, Romania, [2]Univ Med Pharm, Bucharest, Romania.

Congenital hearing loss is one of the most common sensorial impairments in human, affecting approximately one in 1000 children. DFNB1 locus, comprising GJB2 and GJB6 genes, is responsible for up 50% of cases with congenital nonsyndromic prelingual deafness in many population. More than 100 mutations have been reported in exon 2 of the GJB2 gene, whereas two mutations has been described in the donor splice site of intron 1.

In this respect, the purpose of the study was to investigate genetically children with prelingual nonsyndromic hearing loss. Here we report the first study of GJB2 gene sequencing performed in Romania.

The study was carried out on a group of 11 children with prelingual hearing loss. The children were previously found negatives for the three most common mutations involved in nonsyndromic deafness in Europeans namely 35delG GJB2 gene, del(GJB6-D13S1830) and del(GJB6-D13S1854). To amplify the entire coding exon 2 we used three primer sets. The primers for non-coding exon1 were chosen so as to include the donor splice site of intron 1.

The sequence analysis of the GJB2 gene revealed the recessive splice site IVS1+1G>A (-3172G>A) mutation. This variant was homozygous in two subjects. The mutation was also confirmed by MPLA analysis. The other deaf children were found negatives for the mutations in the GJB2 genes.

The results are promising and continuing the study will make possible the construction of a data base regarding hearing loss in Romanian population. Molecular diagnosis will also allow timely intervention at children with hearing impairment.

J10.06

Uninterrupted CCTG tracts in the myotonic dystrophy type 2 associated locus - are they really rare?

J. Radvansky[1], *L. Kadasi*[1,2];
[1]*Inst. of Molecular Physiology and Genetics, SAS, Bratislava, Slovakia,* [2]*Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia.*

Myotonic dystrophy represents the most common form of adult muscular dystrophies. The first genetic form of the disease, myotonic dystrophy type 1 (DM1), is caused by expansion of the (CTG)n repeat tract in the DMPK gene. The second genetic form, myotonic dystrophy type 2 (DM2), is caused by expansion of the (CCTG)n repeat tract in the ZNF9 gene. The CCTG tract is generally interrupted in healthy range alleles and is uninterrupted in pathologically expanded alleles. Our study reports the variability of the healthy range DM2 alleles found during a population study in Slovakia. In comparison with previous studies, we identified wider range and higher frequency of healthy range alleles containing uninterrupted CCTG tracts. As uninterrupted alleles were so far reported mainly on larger alleles, they were considered as possible DM2 premutations. Our findings, however, suggest that uninterrupted CCTG parts are not restricted to large alleles and can be found continuously throughout the whole range of healthy range alleles, from the smallest up to the largest ones. This emphasizes the need for further studies aimed partially to the better characterisation of boundaries between meiotically and mitotically stable alleles and those which can be considered as unstable DM2 premutation alleles.

J10.07

Development and validation of a methodology to analyze the molecular phylogeny of the family Piperaceae, Piper genus, of species found in the Western Brasilian Amazon

D. Delani;
Universidade Federal de Rondônia, Porto Velho, Brazil.

Family Piperaceae, especially Piper genre, presents a fascinating array of plant species for the study of natural products in organic chemistry, pharmaceuticals and ethnobotany. The best use of these species and handling the genre can be provided with the incorporation and association studies of genetic variability. Therefore, knowing the distribution of genetic variability among and within this population is essential for the establishment of appropriate use, as well as better enforcement. Thus, this study aims to evaluate, from the DNA, the genetic structure of natural populations found in the western Brazilian Amazon, with a view to advancing knowledge and manipulation of species, favoring the development of conservation strategies and stimulating the application of a breeding program to actively participate. Preliminary data from our lab established the best methodology to be applied in this analysis. The results show that the method described by Doyle & Doyle (1990) and modified by Faleiro et al. (2003) was the most efficient in obtaining DNA of better quality and in sufficient concentrations to be used in studies of genetic diversity in plants. To molecular analysis in this population, in a comparison with different techniques, RFLP, RAPD, AFLP and SSR, the results indicates that RAPD (random-amplified polymorphic DNA) can be successfully used (Powell, 1996). This reinforces the use of this technique in studies of genetic variability. It is worth emphasizing that in this work we shall present our findings and especially focus on the recommendations that were the conclusion of this part of the investigation.

Distribution of MEFV Gene Mutations among Turkish Patients with Crohn's Disease and Ulcerative Colitis:Preliminary Results

H. Salifoglu[1], *G. Kilciler*[2], *M. Karkucak*[1], *A. Tuzun*[2], *Y. Tunca*[1], *S. Bagci*[2];
[1]*Departments of Medical Genetics, Gulhane Military Medical Academy, School of Medicine, Ankara, Turkey,* [2]*Department of Gastroenterology, Gulhane Military Medical Academy, School of Medicine, Ankara, Turkey.*

Inflammatory bowel disease (IBD) and Familial Mediterranian Fever(FMF) may share some clinical and biological features; they are both inflammatory disorders characterized by the same chronic relapsing behaviour, infiltration by neutrophils at the site of injury, and abnormal regulation of apoptosis. There is a few studies about Mediterranean Fever (MEFV) gene mutations in Turkish patients with Crohn's disease(CD) and Ulcerative Colitis(UC). In this study, we aimed to investigate the frequency and distribution of MEFV mutations in Turkish adult patients with IBD. Twenty-two patients with UC and 18 patients with CD (totally 40 patients) included in the study. The most common 10 MEFV mutations detected by using microarray method after PCR amplification of DNA samples. MEFV mutations found in 14 patients. In CD patients E148Q mutation allele, in UC patients M694V mutation allele was found to be signaficantly more frequent. In conclusion, our study is important in terms of showing distribution of MEFV allele among Turkish patients with UC and CD. MEFV mutation allele frequency is higher in CD patients than UC patients.

J10.09

Prevention of mutagenic effects in human populations

P. Izhevskij;
Burnasyan Federal Medical Biophysical Center, Moscow, Russian Federation.

The human genome is constantly exposed to attacks by environmental mutagens. The permissible levels of exposure and the concentration of mutagens are established on the basis of preventing acute effects. It does not take account of possibility of long-term (stochastic) effects - unfavorable pregnancy outcomes (UPO) in exposed individuals. Requires a quantitative assessment of risk of stochastic effects, and measures for their prevention.
To determine the external dose doubling the incidence of UPO's in the families of exposed persons and the development of preventive measures long-term effects of radiation in human populations. Results: During the 1985-2006 years based on the data about outcomes of pregnancies and the health of the offspring in populations exposed to ionizing radiation over a wide dose range, defined as follows:1. Frequencies UPO's in 226 populations exposed to radiation after the Chernobyl accident. Additional to the natural background radiation dose were calculated for the period from 1986 to 1992 ranged from 4 to 152 mSv. 2. The radiation dose, doubling the incidence of UPO's in the 1st-generation offspring of exposed individuals. 3. The frequency of congenital anomalies among infants in the population and families of personnel of industrial enterprises are constantly contact with mutagens. 4. It is proposed package of measures for prevention UPO's in the families of personnel continually exposed to mutagens, and the population living near industrial plants - the sources mutagens.

J10.10

Index endogamy in Republic Tatarstan, Russia

G. I. Elchinova, *P. S. Igumvov*, *R. A. Zinchenko*;
Research Centre for Medical Genetics, Russian Academy of Medical Sciences, Moscow, Russian Federation.

In 13 areas of Tatarstan on the basis of total sample of marriage records for 1990-2000 (N=31837 after an exception of marriages of persons of postreproductive age and inhabitants of other regions registering marriage on the historical native land) the index endogamy is counted up that appeared to be lowest in the Pestrechinsky area (0,45) like Kazan (between Pestretsy and Kazan there are 28 km), the highest (0,74) - in Aktanyshsky (to Kazan of 307 km), the most remote from Kazan from all 13 studied areas. We will noticed while endogamy index calculating for representatives of the various ethnoses occupying these areas, distinctions in migratory activity of representatives of various ethnoses are not revealed. Rural endogamy has appeared low enough - from 0,06 in the Old Drozhzhanoe to 0,25 in Menzelinsk. In cartographical extrapolation the minimum values of endogamy are found out near to big cities - Kazan and Nizhnekamsk, and maximum - in marginal areas: Drozhzhanovsky (0,70), Baltasinsky (0,69), Kukmorsky (0,67), Alkeevsky (0,70) and Aktanyshsky (0,74). These results show high degree of isolation of rural populations of Russia.

Application of 52 Autosomal SNPs (SNP*for*ID) to Forensic Casework in Malaysia

S. Alimat[1,2], *W. Goodwin*[1];
[1]*School of Forensic and Investigative Sciences, Faculty of Science and Technology,University of Central Lancashire, Preston, United Kingdom,* [2]*Forensic Division, Department of Chemistry Malaysia (KIMIA), Ministry of Science and Technology, Petaling Jaya, Malaysia.*

The analysis of degraded DNA can be problematic. Recent advances in the identification and analysis of single nucleotide polymorphisms (SNPs) have demonstrated the advantage of these markers over short tandem repeats (STRs) in that they only require small amplicons. However, before applying to casework, it is important to develop allele frequency databases from three Malaysian major ethnic groups; Malay, Chinese and Indian.
In order to genotype the population samples reliably and robustly, four sets of 13-plex SNPs were developed for 52 autosomal SNP markers (that have been identified in the SNP*for*ID project). A total of 150 DNA Malaysian samp-

les were genotyped using this multiplex assays and full, complete and clear profiles were generated. Data were collected and evaluated statistically.
Across the three ethnic groups, few significant departures from HWE were observed in Malay, Chinese and Indian ethnic groups, for example, at marker rs2107612, no heterozygosity was observed at all in Malay group (Ho=0) but the Indian group showed higher heterozygosity (above 80%).The combined mean match probabilities for the 52 SNPs of Malay, Chinese, and Indian are 2.1974^{e-18}, 6.0042^{e-18} and 1.1756^{e-18}, corresponding to a combined power of discrimination of >99.99999999%, respectively. Paired F_{st} values obtained in the study suggest that Malay group is closely related to Chinese compared to Malay-Indian or Chinese- Indian.
As for forensic casework, we have demonstrated these multiplexes with the samples that in some instances the SNPs can generate full profiles from DNA extracts that yielded no or partial STR loci.

J10.12

Prevalence and co-infection of 3 human Torque teno viruses in the Romanian population

S. SPANDOLE[1], D. Cimponeriu[1], N. Panduru[2], P. Apostol[1], M. Toma[1], M. Stavarachi[1], C. Serafinceanu[3], A. D. Ion[2];
[1]Department of genetics Bucharest, Bucharest, Romania, [2]Department of Pathophysiology " Carol Davila" UMP, Bucharest, Romania, [3]NIDNMD N Paulescu, Bucharest, Romania.

The TT viruses (TTVs) recently discover DNA viruses and included in the Anelloviridae family. The strains that infect humans are Torque teno virus (TTV), Torque teno midi virus (TTMDV) and Torque teno mini virus (TTMV).
The aim of the study was to determine the prevalence and distribution of the TT viruses, and the co-infection pattern in several human pathologies.
Materials and Methods: The viral DNA was studied in the blood of patients with diabetic nephropathy, breast cancer, colorectal cancer, thalassemia, healthy controls and in the saliva of healthy subjects using nested-PCR. The amplification products were analyzed by agarose gel electrophoresis. For additional genotyping, high resolution melting (HRM) was performed.
Results: The average frequency of TTV and TTMV was approximately 85% among all the subjects, while for TTMDV was 60%. The average frequency of co-infection was 55%, and the highest rate of triple co-infection (80%) was found among the thalassemic patients. The highest frequency of the viruses was also found among the patients with thalassemia. The most commonly found virus was TTV and least common was TTMDV.
Conclusions: TT viruses' prevalence is the highest among the patients with thalassemia. The co-infection pattern is not correlated to a specific pathology. The viruses can be easily detected in the subject's saliva. The estimated frequency is consistent with the values reported in other populations.
Acknowledgements: This paper is supported by the Sectoral Operational Programme Human Resources Development, financed from the European Social Fund and by the Romanian Government under the contract number POSDRU/89/1.5/S/ 64109.

J10.13

Clinical and genetic spectrum of single gene disorders among Saudi Arab

H. Y. Alabdulwahed, N. A. Al Sannaa;
saudi aramco, Dhahran, Saudi Arabia.

The high consanguinity rate had resulted into increased incidence of rare autosomal recessive disorders in The Kingdom of Saudi Arabia. Some of these disorders had been observed to be more specific for certain tribes and families with an evidence of gene founders. This had facilitated providing a selective genetic testing for this population.
A retrospective review of 1359 patients with single gene disorders seen within our medical facility was done. We found that this population has similarities in the disease-causing molecular mutations with nearby Arabian Gulf countries*. However, novel mutations were detected for the following disorders; Arthrogryposis-Renal Dysfunction-Cholestasis syndrome, Hereditary motor and sensory neuropathy with agenesis of the corpus callosum, Aicardi-Goutieres Syndrome 3, Pelizeaus-Merzbacher-Like Disease 1, Pelizeaus-Merzbacher-Like Disease 1, spondyloconstal dysostosis type 2, h ypophosphatasia*,Gangliosidosis 1, Alstrom syndrome, IRAK4 defeicency , Abetalipoproteinemia, Fabry disease and mucopolysaccharidosis type I. We hope that this data will help to guide researchers and medical professionals within the region in molecular diagnosis of their patients.

J10.14

Characteristics of mitochondrial DNA HVS-1 sequence in patients and aborted fetuses with aneuploidies

V. Pankratov, N. Danilenko;
Institute of genetics and cytology, Minsk, Belarus.

Background: Aneuploidy is strikingly frequent in humans: up to 20% of all zygotes have an abnormal number of chromosomes. Despite intensive research little is known about the origin of aneuploidy and its risk factors. Here we analyze mitochondrial DNA of aneuploid fetuses and patients to reveal whether certain features of mtDNA of primary oocytes make them more prone to non-disjunction.
Methods: Hypervariable segment 1 of mtDNA was sequenced in 48 patients with Down's syndrome, 22 aborted fetuses with DS and 2 aborted fetuses with Edward's syndrome - altogether 72 samples. Previously published HVS-1 sequences of 267 Byelorussians were used as controls.
Results: Attention was focused on frequencies of 16189C and its combination with 16183C as these substitutions create a polyC stretch which interferes with the replication of mitochondrial DNA and is reported to be a risk factor for metabolic syndrome and cancer. 16189C is 1.6 times more frequent in the group of aneuploids compared to the control one (p=0.07), whereas 16183C+16189C haplotype is 3.7 times overrepresented among aneuploids (p=0.005). Another allele, 16300G, shown to be a risk factor for bipolar disorder, was found in 3 cases with DS, although it is absent from the studied population of healthy Byelorussians. 16292T and the rCRS haplotype are significantly underrepresented among aneuploids (p<0.05).
Conclusions: 16189C (and its combination with 16183C) and 16300G in mother's mtDNA may be a risk factor for aneuploid conceptions. 16292T and the rCRS haplotype may be linked with some protective SNPs in the coding region of mtDNA.

FVII R353Q and GP1a C807T polymorphisms in Ukrainian ischemic stroke patients

M. Burlova-Vasylieva[1], S. Kravchenko[2], L. Livshits[2];
[1]Educational and Scientific Centre "Institute of Biology" of National Taras Shevchenko University of Kyiv, Kyiv, Ukraine, [2]Institute of Molecular Biology and Genetics of of National Academy of Sciences of Ukraine, Department of Human Genomics, Kyiv, Ukraine.

Ischemic stroke is a complex pathology, with a variety of genetic and environmental risk factors. The aim of our study was to establish the possible involvement of the FVII R353Q and GP1a C807T polymorphisms into ischemic stroke development.
Case-control study including 179 patients aged 39 to 81 years with ischemic stroke and 88 patients aged 59 to 92 (control I), as well as population control (control II, n=97) without a history of stroke has been performed. Genotyping was performed by the PCR followed by RFLP analysis.
Comparative analysis of genotype distribution in ischemic stroke and control I showed a marginal association of the RR genotype of R353Q polymorphism with stroke (OR=1.79; 95% CI, 0.99-3.23; P=0.05). Also, there was a significant association between RR genotype and stroke compared to control II (OR=2.03; 95% CI, 1.15-3.59; P=0.01). Obesity as one of the stroke risk factors itself showed a strong association with stroke in our study (OR=2.35; 95% CI, 1.51-4.8; P=0.008). Moreover, while analyzing the joint effects of R353Q and obesity, interaction between these risk factors was revealed (Synergy factor=6.9, 95% CI, 1.34-36.39; P=0.02). The RR individuals with obesity had a significant susceptibility to ischemic stroke (OR=4.03; 95% CI, 1.64-9.89; P<0.01). No significant association was found between ischemic stroke and C807T polymorphism.
Our study suggests that RR genotype of R353Q polymorphism may be an additional ischemic stroke risk factor in patients with obesity, while GP1a C807T polymorphism is not associated with a risk of ischemic stroke in Ukrainian patients.

Epigenetic identification of stem cells: From embryonic toadult

A. Tayaranian Marvian[1], S. Esfahani moghaddam[2];
[1]University of Tehran, Tehran, Islamic Republic of Iran, [2]Sari Agricultural Sciences and Natural Resources University, Sari, Islamic Republic of Iran.

Stem cells, like other incredible properties they have, possess unique epigenetic structure. Growing evidence suggests that the potency of these cell to regenerate from low to complete differentiated cell lines is accurately depend on epigenetic processes occurring on DNA and chromatin. DNA methylation and histone modifications are the major contests which lead to the establishment of chromatin states in these cells. It seems that these contests have fundamental regulatory effect on the potency of different stem cells and make embryonic cells to be unique for their stemness characteristics compare to adult cells. Tracing these epigenetic change from embryonic stem cells to adult stem cells would be an appropriate approach to investigate the function of the events in reducing stemness capacity. More study in this field would help to establish new approachs to induce pluripotency in different cell types; especially in multipotent adult stem cells and it would be useful for therapeutic approaches. In this review we summarize current progress in field of embryonic and adult stem cells epigenetics and also we try to illustrate conceptual regard to epigenetic changes during embryonic development and beyond.

Customized DNA microarray fabrication for gene expression analysis of multiple sclerosis

A. Pourjahed[1]*, M. Rabiee*[1]*, M. Sanati*[2]*, M. Ataei*[2]*;*
[1]*Amirkabir University of technology, Tehran, Islamic Republic of Iran,* [2]*Iran National Institute of Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran.*

Multiple Sclerosis (MS) is a complex autoimmune disease, involved many pathophysiological processes which should be considered in designing diagnostic, prognostic studies. In recent years, microarray technology becomes a valuable tool for identifying good biomarkers in diagnostic as well as prognostic processes for all diseases. Also better drug treatments may be obtained by identifying new drug targets and studying drug effects via this technique .

In this work, we designed a customized microarray for 76 susceptible genes in MS, which involved in different pathophysiological processes (e.g. inflammation, demyelination, axonal damage and repair mechanisms) based on peripheral blood analysis. Poly-l-lysine coated glass slides was used to fabricate this microarray by BioRad vers-array spotting robot. Fabricated microarray can be used to study gene expression of MS patients and healthy controls in various clinical conditions.

J11.03

Development and validation of multiplex (4-plex) PCR-based assay to assess DNA degradation

M. S. Nazir*, W. Goodwin, J. Smith;*
School of Forensic and Investigative Sciences, University Of Central Lancashire, Preston, United Kingdom.

To assess the degradation of DNA in the model organisms (pig, rabbit and human), Multiplex (4-plex) PCR- based assay was developed. Sequence data for a nuclear gene; recombination activating gene 1 (RAG-1) from rabbit, pig and human was aligned to identify conserved regions for primer design that would amplify 70 bp, 194 bp, 305 bp and 384 bp amplicons. PCR was optimised so that it worked over a wide range of template amounts (0.03 ng to 75.83 ng). Multiplex (4-plex) PCR assay was validated following the guidelines of Scientific Working Group on DNA analysis Methods (SWGDAM). The multiplex PCR was tested for its specificity, reproducibility, sensitivity and stability using ABI 310 and 3500 genetic analysers (Applied Biosystems). Samples treated with various environmental regimes and DNeasy1 were also included in this study. The multiplex (4-plex) PCR was found to work efficiently in triplicate samples of all three species until 0.3 ng of DNA template, although, partial profile is also obtained with 0.03 ng DNA template.
The result of this validation study promises that this multiplex can be used in forensic analysis to assess DNA persistence in human decomposing bodies following mass disasters and in experimental animals (rabbit and pig) and therefore is recommended for forensic purposes.

VMD DisRg: New user-friendly implement for calculation distance and radius of gyration in VMD program

S. Falsafi Zadeh[1]*, Z. Karimi*[2]*, H. Galehdari*[3]*;*
[1]*Toxicology Research centre, Jundishapur Medical Science University, Ahvaz, Islamic Republic of Iran,* [2]*Bioinformatics unit, Department of Genetics, Shahid Chamran University, Ahvaz, Islamic Republic of Iran,* [3]*Department of Genetics, Shahid Chamran University, Ahvaz, Islamic Republic of Iran.*

Molecular dynamic simulation is a practical and powerful technique for analysis of biopolymers structure. Several programs have been developed to facilitate the mentioned investigation, under them the visual molecular dynamic or VMD is the most frequently used programs. One of the beneficial properties of the VMD is its ability to be extendable by designing new plugin. We introduce here a new and easy to use facility of the VMD for distance analysis and radius of gyration of biopolymers such as protein and DNA. Our plug-in is a user friendly package which calculates mentioned analysis for structure or simulation trajectories with 3D representation center of mass.

Epigenetic aberrations in leukocytes of patients with schizophrenia: Association of global DNA methylation with antipsychotic drug treatment and disease onset

P. A. Melas*, M. Rogdaki, U. Ösby, M. Schalling, C. Lavebratt, T. Ekström;*
Karolinska Institute, Stockholm, Sweden.

Even though schizophrenia has a strong hereditary component, departures from simple genetic transmission are prominent. DNA methylation has emerged as an epigenetic explanatory candidate of schizophrenia's non-Mendelian characteristics. To investigate this assumption, we examined genome-wide (global) and gene-specific DNA methylation levels which are associated with genomic instability and gene-expression activity, respectively. Analyses were conducted using DNA from leukocytes of schizophrenic patients and controls. Global methylation results revealed a highly significant hypomethylation in schizophrenics ($P < 2.0*10^{-6}$) and linear regression among patients generated a model in which antipsychotic treatment and disease onset explained 11% of the global methylation variance (adjusted $R^2 = 0.11$, ANOVA $P < 0.001$). Specifically, haloperidol was associated with higher ("control-like") methylation ($P = 0.001$) and early-onset (a putative marker of schizophrenia severity) was associated with lower methylation ($P = 0.002$). With regard to the gene-specific methylation analyses, and in accordance with the dopamine hypothesis of psychosis, we found that the promoter of *S-COMT* was hypermethylated in schizophrenics ($P = 0.004$). In conclusion, these data support the notion of an aberrant epigenetic regulation in schizophrenia which may be subject to certain antipsychotic treatments. Additionally, blood DNA-methylation signatures show promise of serving as a schizophrenia biomarker in the future.

J11.06

Role of the genes encoding NMDA receptors in the development of neurologic pathologies during influenza infection

M. A. Plotnikova*, S. A. Klotchenko, V. V. Egorov, A. V. Vasin;*
Research Institute of Influenza, St. Petersburg, Russian Federation.

Influenza is one of the most widespread respiratory viral diseases, infecting humans. Influenza virus may cause various neurologic complications which can lead to chronic diseases characterized by different cognitive dysfunctions. However, until recently very little was known about the molecular biological mechanisms of activity disbalance of the central nervous system in case of influenza disease. One of the dominant roles in this process probably belongs to the ionotropic glutamate receptors selectively binding N-methyl-D-aspartate (NMDAR). The main aim of this study was to analyze the expression level of the genes encoding NMDAR during influenza infection. Native NMDARs are thought to function only as heteromeric assemblies containing both NR1 and NR2 subunits. The NR1 family is encoded by a single gene. The NR2 family of subunits consists of four members arising from separate genes (GRIN2A, GRIN2B, GRIN2C, GRIN2D). The novel mRNA which can be encoded by GRIN2B gene was found. We used postmortal human lung tissues from patients who died because of complications against pandemic influenza virus disease. PCR analysis of IL-10 mRNA expression shown that the nonspecific products were irrefutable obtained. Sequence of this amplicon aligns with the intron 2 of GRIN2B. Gene-specific primers for detecting expression level of human and mouse NMDAR were designed using Primer-BLAST program. To test these primers we used total RNA isolated from mice tissues section. We are now planning to investigate the expression of NMDAR genes in cell cultures infected by pandemic and seasonal influenza virus H1N1. The work is supported by RF President's Grant.

J11.07

Cafe Variome: sharing diagnostic sequence variants with the research community

O. Lancaster[1]*, R. Dalgleish*[1]*, D. Atlan*[2]*, A. J. Brookes*[1]*;*
[1]*University of Leicester, Leicester, United Kingdom,* [2]*PhenoSystems, Lillois, Belgium.*

The internet-based Cafe Variome is designed to function as an exchange portal for gene variant (mutation) data produced by diagnostics laboratories, offering users a secure environment through which to announce and discover a comprehensive listing of observed neutral and disease-causing variants in patients and unaffected individuals.

To achieve this, Cafe Variome facilitates the “publication” of data from researchers, diagnostics laboratories, and others, to any stakeholders who may wish to, for example, check for evidence of causal influence upon certain disease states, and/or incorporate the data into locus-specific databases. While data generators generally do not object to disseminating anonymised diagnostic data, they are not motivated to do so because of the effort and time involved. Cafe Variome specifically addresses these issues by:

- Enabling data analysis tools used by research and diagnostic laboratories with a “data submission” function which automatically pushes diagnostic data to Cafe Variome, which acts as a universal data reception and advertisement point
- Offering manual support to laboratories to move their variant datasets into Cafe Variome (legacy data and new data in batches or in real time).

The development of Cafe Variome (based at the University of Leicester) involves the cooperation of diagnostic software companies PhenoSystems (Gensearch) and Interactive Biosoftware (Alamut) as well as academic partners in the Bioinformatics Support Group at Leiden University Medical Centre (LUMC) whose Mutalyzer data-validation tool will allow us to feedback data-inconsistencies to submitters, and at NGRL Manchester who have extensive expertise in diagnostic databases through their development of DMuDB.

J11.08

Mutation screening of *ATP13A2* in early onset Iranian Parkinson‘s disease patients

M. Malakouti Nejad[1]*, A. Alavi*[2]*, M. Hashemi*[3]*, G. Shahidi*[4]*, E. Elahi*[2]*;*
[1]*Science and Research Branch,Islamic Azad University, Tehran, Islamic Republic of Iran,* [2]*School of Biology, University College of Science, University of Tehran, Tehran, Islamic Republic of Iran,* [3]*Tehran medical Branch, Islamic Azad University, Tehran, Islamic Republic of Iran,* [4]*Tehran University of Medical Sciences, University of Tehran, Tehran, Islamic Republic of Iran.*

Parkinson’s disease (PD) is the most common neurodegenerative movement disorder whose average age of onset is 60 years. Individuals in whom symptoms first manifest before age of 40 years are classified as early onset PD (EOPD) cases.

To date, 4 genes responsible for early EOPD have been identified, *parkin*/PARK2, *PINK1*/PARK8, *DJ1*/PARK7 and *ATP13A2*/PARK9. Among these genes, mutations in *ATP13A2* are the least common. Mutations in PARK9 have been reported to cause autosomal recessive early onset Parkinson’s disease (PD). *ATP13A2* is located on chromosome 1p36, contains 29 exons, and codes a transmembrane protein of 1180 amino acids which belongs to the Group 5 P-type ATPase superfamily. The function and substrate specificity of the coded protein remains unknown. Here we present results of mutation screening in 14 Iranian EOPD patients in whom mutations in *LRRK2*, *PRKN*, *DJ1*, and *PINK1* were previously ruled out. The average age at onset of the Iranian patients was 20 years, and the range was 11-31 years. The whole *ATP13A2* coding region (29 exons) and exon-intron boundaries were sequenced from genomic DNA. A novel homozygous variation (**IVS8+19G>A**) was identified in non-coding region in one sporadic patient. To identify the effect of this variation in splicing, NNsplice software was used.The results showed, this variation isn’t effective on splice site. This patient also had a polymorphism (c.1138G>C) in heterozygous state in *PRKN*. Thus we conclude that *ATP13A2* genetic variability is unlikely to cause or influence the development of PD.

J11.09

Effects of PITX2 as a Transcription factor in ocular development on their Target genes

H. Moazzeni[1]*, A. Sadighi gilani*[1]*, H. Paylakhi*[2]*, E. Elahi*[1]*;*
[1]*University of Tehran, Tehran, Islamic Republic of Iran,* [2]*University of Damghan, Damghan, Islamic Republic of Iran.*

The development of the eye comprises a series of inductive events. A number of genes that include transcription factors, growth factors, nuclear proteins and enzymes are involved in multiple cascades of events in ocular development and other developmental processes. These developmental regulatory networks are therefore not only important in the development of the eye but also in the development of the whole embryo as well.

The Pituitary homeobox 2 (PITX2) and Forkhead box C (FOXC1) proteins are examples of such transcription factors.PITX2 is a member of the paired-bicoid family of homeodomain (HD) transcription factors. Pituitary homeobox proteins are actively involved in a wide range of developmental processes, including formation of the pituitary gland, hind limb and anterior segment of the eye. 41 genes for PITX2 were identified by Expression profiles derived using microarray.

Usage of Bioinformatics tools for determination of promoter region, finding PITX2’s Binding sites and conservation of promoters revealed that several genes directly affected by PITX2.among these, promoter of *PLEKHG5* were cloned into PGL4-14 vector then this construct co-transfected into HeLa cells with expression vector of PITX2.

Interestingly Dual luciferase assay revealed that PITX2 transcription factor, which is known to be involve in ocular development, increase the activity of *PLEKHG5* promoter and expression of its downstream gene.

[1]*IGBMC(Institut de Génétique et de Biologie Moléculaire et Cellulaire), ILLKIRCH, France,* [2]*Inserm, U964, Illkirch, France,* [3]*CNRS, UMR7104, Illkirch, France,* [4]*Laboratoire Diagnostic Génétique, Faculté de Médecine, CHRU, Strasbourg, France,* [5]*Département de Neurologie, Hôpital Civil de Strasbourg, Strasbourg, France,* [6]*6Service de Pédiatrie, Centre Hospitalier Universitaire (CHU), Strasbourg, France,* [7]*Faculté de Médecine de Marseille, Université de la Méditerranée, Inserm UMRS 910 Génétique Médicale et Génomique Fonctionnelle, Marseille, France,* [8]*Institut Cochin, INSERM Unité 1016, CNR UMR 1408, Université Paris Descartes, Sorbonne Paris Cité, Paris, France.*

Introduction:

Neuromuscular diseases (NMD) are debilitating disorders with a strong impact on the individuals and society. Despite tremendous research and clinical efforts, the molecular causes of NMD are still unknown for about 40% of patients and additional genes remain to be found. In order to provide a faster and cheaper molecular diagnosis for NMD patients and to detect different types of mutations, we have validated sequence capture, DNA barcoding and next generation sequencing (NGS).

Results:

Using targeted re-sequencing of 267 genes implicated in NMD, we sequenced 16 patients (4 pools of 4 DNAs) with different types of mutations where we knew the mutations in half of them. We could successfully detect all the disease-causing variants in the 8 patients with known mutations (covering point mutations, intronic (-10nt from splice site), a small indel and a large deletion).For patients with unknown mutations, we used a ranking program and we could find the disease-causing mutations in several of them.

Conclusion:

We conclude that NGS is a powerful approach to identify potential disease-causing variants, a prerequisite for genetic counseling and better healthcare. it should allow reducing the diagnosis time and its cost.

It might represent a first screening without the need for detailed clinical criteria for inclusion that may be absent in atypical forms of the diseases or when the disease begins. In addition, the analysis might be proposed before the need of more invasive investigations such as biopsy. This emerging strategy is likely to become a standard tool for routine genetic diagnosis.

J11.11

Mitochondrial Defects in Trisomy 21 Fetuses might contribute to the Down Syndrome Neurological Phenotype

A. Izzo[1]*, F. Bonfiglio*[1]*, R. Manco*[1]*, M. Prisco*[1]*, C. Piccoli*[2]*, F. Gentile*[3]*, G. Calì*[3]*, N. Capitanio*[2]*, A. Conti*[1]*, L. Nitsch*[1]*;*
[1]*University of Naples Federico II, Naples, Italy,* [2]*University of Foggia, Foggia, Italy,* [3]*Institute of Experimental Endocrinology and Oncology, National Council of Research, Naples, Italy.*

Hsa21 trisomy has been associated to mitochondrial dysfunction in Down Syndrome (DS) mouse models and the dysregulation of genes encoding mitochondrial proteins has been demonstrated in human trisomic fetal brains by microarray analysis. Since mitochondrial function has a central role in many neurodegenerative diseases, such as Alzheimer and Parkinson, it has been hypothesized that the mitochondrial defect might contribute to the DS mental retardation.

The aim of this study was to fully characterize the mitochondrial defect in fibroblasts derived from trisomic human fetuses.

Genes mapping to chromosomes different from 21, and implicated in multiple mitochondrial functions such as respiratory chain, mitochondrial biogenesis and structure, were studied by qRT-PCR. Many of the analyzed genes, including PGC-1 α, a gene that plays a key role in mitochondrial biogenesis, were significantly down-regulated in trisomic versus euploid fibroblasts, supporting the hypothesis that Hsa21 trisomy perturbs the expression of mitochondrial genes. Mitochondria ultrastructure, assessed by electron microscopy, revealed morphological abnormalities in trisomic fibroblasts, like giant mitochondria with irregular shape, breaks of both inner and outer membranes and altered cristae pattern. Functional studies demonstrated a significant reduction of oxygen consumption rate and of respiratory chain complex I activity, a decrease of mtDNA copy number and an increased production of reactive oxygen species in trisomic fibroblasts.

These results are indicative of a widespread mitochondrial dysfunction and support the hypothesis that it might contribute to the DS neurological phenotype.

J11.12

Extended comparative analysis of high resolution array platforms for genome wide detection of CNV

A. E. Urban[1], *R. Haraksingh*[1], *M. Haney*[1], *A. Abyzov*[2], *M. Gerstein*[2], *M. Snyder*[1];
[1]*Stanford University, Palo Alto, CA, United States,* [2]*Yale University, New Haven, CT, United States.*

High-density oligonucleotide array CGH is now a widely available tool for the analysis of genomic copy number variation (CNV), in discovery studies, for the validation of CNVs detected with other means (i.e. sequencing) and increasingly in cytogenetic diagnostics.

Various platforms are available from several different suppliers, utilizing either array Comparative Genome Hybridization (aCGH) alone or in combination with SNP genotyping.

Earlier [Haraksingh et al., PLoS One, 2011] we carried out a quantitative comparison analysis of the performances of twelve leading genome-wide CNV detection platforms. We tested the ability of the different array types to accurately detect Gold Standard sets of CNVs in the genome of HapMap CEU sample NA12878. The Gold Standards used were a 1000 Genomes Project sequencing-based set of 3997 validated CNVs and an ultra high-resolution aCGH-based set of 756 validated CNVs.

The arrays that were originally analyzed were the NimbleGen 4.2 M, 2.1 M and 3×720 K Whole Genome and CNV focused arrays, the Agilent 1×1 M CGH and High Resolution and 2×400 K CNV and SNP+CGH arrays, the Illumina Human Omni1Quad array and the Affymetrix SNP 6.0 array. We have since then added the NimbleGen 12-plex and 6-plex platforms, respectively, to the comparative analysis.

We compared the arrays with the criteria of sensitivity, total number detected, size range and breakpoint resolution of CNV. We found that arrays with the genome-wide CNV-focused design principle generally outperformed whole-genome (evenly spaced tiling) designs. Our results should be useful when designing CNV detection strategies in both research and clinical settings.

Ataxia with oculomotor apraxia, type 2 (AOA2) in a Russian family

M. V. Kurkina, *E. Y. Zakharova, G. E. Rudenskaya;*
Medical Genetics Research Centre, Moscow, Russian Federation.

AOA2 is an autosomal recessive ataxia caused by various mutations in *SETX* gene. Typical age of onset is 15-20 years (variability 3-30). Progressing ataxia due to cerebellar atrophy and polyneuropathy are main disabling features. Oculomotor apraxia (OA), inability to coordinate eye movements, is a specific sign seen in half of patients. Serum alpha-fetoprotein raise is helpful. AOA group includes AOA1 (*APRX* gene) with onset in 4-5 years and AOA3 (*PIK 3R5*) described in 2012 in a Saudi family. OA is typical also for Louis-Bar ataxia-telangiectasia. Recently an AOA1 case was confirmed in our laboratory. A first Russian AOA2 case in a 25-year-old male, an only child in the family, is presented. The disease started in 18 years, in 23 years he lost independent walking due to incoordination and weakness; ataxia in hands and dysarthria were moderate. OA was found on neurological examination but produced little symptoms. Sensorimotor axonal polyneuropathy was confirmed by electroneuromyography. MRI showed moderate cerebellar atrophy. Alpha-fetoprotein level was tenfold raised. A hereditary ataxia was considered from the disease onset, and a number of genetic tests were performed, but AOA2 was recognized only seven years later. On direct sequencing of *SETX* exons 6-8 a novel frame-shift mutation c.2623-2626 del 4 in heterozygous state was detected which is sufficient for AOA2 confirmation; the allelic mutation is in search. DNA diagnostics permits genetic counseling and prenatal testing in AOA families. OA should be purposefully searched for in children and young adults suspicious of autosomal recessive ataxias.

J12.02

High expression of IL-10 in Netherton Syndrome

S. Pehlivan[1], *S. Oguzkan Balci*[2], *S. Inaloz*[3], *E. Kucukosmanoglu*[4], *T. Sever*[2], *O. Keskin*[4], *A. Gülel*[3], *K. Erciyas*[5];
[1]*University of Gaziantep, Faculty of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey,* [2]*University of Gaziantep, Faculty of Medicine, Department of Medical Biology and Genetics, GAZIANTEP, Turkey,* [3]*University of Gaziantep, Faculty of Medicine, Department of Dermatology, GAZIANTEP, Turkey,* [4]*University of Gaziantep, Faculty of Medicine, Department of Pediatric Allergy, GAZIANTEP, Turkey,* [5]*University of Gaziantep, Faculty of Medicine, Department of Periodontology, GAZIANTEP, Turkey.*

Objectives: Netherton syndrome (NS) is a rare autosomal recessive disorder, characterized by congenital ichthyosiform erythroderma, trichorrhexis invaginata and severe atopic diathesis. Considering that cytokines are involved in NS pathogenesis and that cytokine gene polymorphism may affect cytokine production, our purpose was to investigate the association between NS and IL-6, IL-10, IFN-γ, TGF-β1 and TNF-α polymorphisms.

Methods: Cytokine genotyping and haplotyping were performed in a family with NS by PCR-SSP method.

Results: We observed GCC GCC haplotypes (high expression) of IL-10 gene polymorphisms (-1082 A/G, -819 T/C, -592 C/A) in proband with NS and no association with IL-6, IFN-γ, TGF-β1 and TNF-α polymorphisms.

Conclusion: GCC GCC haplotypes which leads to high expression levels of IL-10 may be associated with etiopathogenesis of NS.

J12.03

Charcot-Marie-Tooth disease in Republic of Sakha (Yakutia)

P. I. Gurieva[1], *N. R. Maximova*[1,2], *T. Y. Nikolaeva*[1], *A. L. Sukhomyasova*[3,2];
[1]*M.K.Ammosov North-Eastern Federal University, Yakutsk, Russian Federation,* [2]*Yakut Scientific Center of complex medical problems, Siberean Branch of the Russian Academy of Medical Sciences, Yakutsk, Russian Federation,* [3]*Republican Hospital №1 - National Medical Center, Yakutsk, Russian Federation.*

Background: Republic of Sakha (Yakutia) is the largest region in Russia. It is located in the North-East part. Population of republic makes 958,021 persons. The leading place in structure of a genetic pathology in Yakutia is occupied with hereditary disease of nervous system among which one of the most common is Charcot-Marie-Tooth disease (CMT). Prevalence CMT in the world makes 4,7-40 per 100,000 population, in Yakutia prevalence has made 11,8 per 100,000. Methods: the research is carried out by the materials from Republican Genetic Registry of inherited and congenital pathology of Republic of Sakha (Yakutia) in medical-genetic consultation Department of the National Medical Center. The diagnosis was established on the basis of anamnestic data, data of neurological examination, genealogic analysis, electroneuromiography and molecular-genetic analysis with the use of markers 17 dup4, 17 dup5 in gene PMP22 (locus 17 p12-p11.2). Results: we studied 113 medical records of patients with CMT in the age of 6 to 75 (average age is 33,30±1,45), male - 60 (53%), female - 53 (47%). There were 87 Sakha patients (77%), Russians - 22 (20%) and 4 other nations (3%). The CMT1A type was established in 37 out of 113 cases (33 %), the rest of patients had unknown mutations. For CMT1A is characterized by the onset in childhood, the high arch of the foot, the reduction or absence of tendon reflexes, upset sensitivity on polyneuritic type, hypotrophy of peroneal muscles, occurrence of stepping gait.

J12.04

A further case of lamellar ichtyosis having H435Y mutation in CYP4F22 gene

E. Arslan Ates[1], *F. Hazan*[2], *S. Yamacı*[2], *H. Onay*[1], *F. Ozkinay*[1];
[1]*Ege University Faculty of Medicine, Izmir, Turkey,* [2]*Dr. Behçet Uz Children's Hospital, Izmir, Turkey.*

Autosomal recessive congenital ichthyosis (ARCI) is a rare keratinisation disorder with an estimated prevalence 1:100.000-300.000. It is classified into two groups: Lameller Ichthyosis (LI) and congenital ichthyosiform erythroderma (CIE). The major difference between these two forms is scale property. Although plate-like, dark brown scales are common in LI, fine scales are mostly observed in CIE patients. ARCI is a genetically heterogenic disease. To date mutations in TGM1, ALOX12B, ALOXE3, NIPAL4, CYP4F22 and ABCA12 genes have been have been described in ARCI.

We report a five-months-old girl with lameller ichtyosis. Parental consanguinity in this case strongly suggested autosomal recessive inheritance. She was born with collodion membrane and had grayish scaling. There were no mutations in the molecular genetic analysis of TGM1 and NIPAL4 genes. Following this, CYP4F22 gene was sequenced and a homozygous c.1303 C >T (p.H435Y) mutation was found in the index patient. The parents were heterozygous for the mutation.

The case presented here is the first Turkish ARCI case having this particular mutation.

J12.05

Profile of Iranian Genome variation of connexin 31 gene

M. Falah[1], M. Houshmand[2], Y. Ghavami[1], M. Balali[1], M. Farhadi[1];
[1]Department and Research Centre of ENT & Head and, Tehran, Islamic Republic of Iran, [2]National Institute of Genetic Engineering & Biotechnology, Tehran, Iran, Tehran, Islamic Republic of Iran.

Background & Objective: The connexins are a family of at least 20 homologous proteins in humans that form aqueous channels connecting the interiors of coupled cells and mediating electrical and chemical communication. Mutations in GJB3, the gene encoding the gap junction protein Connexin 31 (CX31), have been pathogenically linked to erythrokeratodermia and non-syndromic autosomal dominant (DFNA2) or recessive hereditary hearing impairment (HHI).

In the present study, we aimed to characterize the genome variation of GJB3 in Iranian patients with hearing impairment.

Methods: Twenty five non-syndromic autosomal recessive hearing loss patients who were normal for two major responsible genes of non syndromic hearing loss (GJB2 and GJB6) were tested with direct sequencing of entire coding region of the GJB3 gene.

Results: Single nucleotide sequence alteration was present in 15 out of 25 patients (60%) and 40 % of patients were normal. Five different variations that were detected are: G866A (34%), G798T (20%), C856A (6%), C357T (2%) and C93T (2%).

Conclusions: 60 percent of patients showed single polymorphism in coding and non coding part of GJB3. All patients were normal for sequencing of two well known genes for non syndromic hearing loss (connexin 26 and connexin 30). Therefore this high percentage of genetic variation in GJB3 may have pathogenic effects on Iranian population, but this needs more investigation on normal subjects

Early-onset primary dystonia (DYT1) in Iranian patients

H. Moshiri[1], V. ghodsinejadkalahroudi[1], O. Ariyani[1], M. Houshmand[2];
[1]Special Medical Center, Tehran, Islamic Republic of Iran, [2]National Institutes of Genetic Engineering & Biotechnology, Tehran, Islamic Republic of Iran.

Early-onset primary dystonia (DYT1) typically presents in childhood or adolescence and only on occasion in adulthood. Dystonic muscle contractions causing posturing of a foot, leg, or arm are the most common presenting findings. Dystonia is usually first apparent with specific actions; e.g., writing or walking. Over time, the contractions frequently (but not invariably) become evident with less specific actions and spread to other body regions. No other neurologic abnormalities are present, except for postural arm tremor. Disease severity varies considerably even within the same family .Isolated writer's cramp may be the only sign. DYT1 is inherited in an autosomal dominant manner with reduced penetrance. TOR1A, encoding the protein torsin-1A (torsinA), is the only gene known to be associated with this disease. DYT1 is diagnosed by molecular genetic testing of TOR1A revealing the three-base pair deletion c.907_909delGAG in most affected individuals.

Oral medications are usually tried first and include anticholinergics, baclofen, and others alone or in combination (levodopa, clonazepam and other benzodiazepines, carbamazepine, and dopamine-depleting agents).

We investigated molecularly 12 cases suspected to DYT1 using PCR and sequence analysis of TOR1A gene. C.904_906delGAG heterozygote was found in one patient. This result showed that this alteration was observed in less than %10 of our cases. The rest of cases are being investigated for the other relevant genes for familial dystonia.

Plasmid vector encoding recombinant protein ApoB100(site B) - GFP for measuring functional disruptions of LDL-receptor

V. A. Zhemkov[1], E. A. Vasileva[1], D. S. Polyakov[2], N. A. Grudinina[2], K. V. Solovyov[2], T. D. Aleynikova[2], M. M. Shavlovsky[2];
[1]Faculty of Medical Physics and Bioengineering, Saint-Petersburg State Polytechnical University, Saint-Petersburg, Russian Federation, [2]Department of Molecular Genetics, Institute of Experimental Medicine, Saint-Petersburg, Russian Federation.

Familial hypercholesterolemia (FH, OMIM 143890) is rather widespread autosomal dominant disease leading to increased level of low-density lipoproteins (LDL) what in turn leads to higher risk of atherosclerosis. FH is associated with disorder of LDL-receptor.

Apolipoprotein B100 (apoB) is the only protein component of LDL particles providing their binding to receptor. Sub-clinical diagnostics of FH, such as genetic analysis, is difficult due to large size of LDL-receptor gene. Study of intermolecular interactions between receptor-active domain of apoB (3359-3369) and LDL-receptor gives new opportunities of measuring functionality of LDL-receptor. For this purpose we created the plasmid vector encoding receptor-binding region known as high conservative site-B (3359-3369) of apoB fused to 5'-terminus of GFP gene. Fragment of apoB gene was amplificated through PCR. The template was human DNA. Vector was constructed by direct cloning of apoB gene fragment with SalI and HindIII endonucleases. Also we have inserted sequence encoding polyhistidine tag to 5'-terminus of *apoB* to make the metal chelate affinity chromatography of fusion protein possible. Plasmid was successfully sequenced and studied by restriction analysis. *E.coli* cells transformed with this plasmid vector and incubated in IPTG-containing medium showed presence of fluorescent protein.

Maximums of excitation and emission of fusion protein are equal to GFP characteristics. This protein has been extracted and purified on nickel agarose column. Synthesized fusion protein could become basis for diagnosticum of FH, with which functionalality of LDL-receptor could be measured. Studies of binding of fusion protein to cells receptor in cultures of hepatocytes and fibroblasts are taking place.

To characterize and analyze the haplotypes of normal and "at risk of expansion" FMR1 CGG repeat alleles

M. S. Khaniani, S. M. Derakhshan;
Tabriz university of Medical Science, Tabriz, Islamic Republic of Iran.

The mechanism of instability of FMR1 alleles during transmission from mother to offspring and the exact timing of CGG repeat expansion are still unknown and recently the investigation of instability of the FMR1 gene has been a major goal in Fragile X research.

The haplotypes which are in linkage disequilibrium with these unstable alleles provide not only potential markers of those with the potential to expand but also clues to their inherent susceptibility. This approach is important as it might contribute to understanding the mechanism for instability of CGG repeats in the initial steps of small CGG expansion.

To address this issue and make a contribution to understanding the basis of the mutational process, three flanking microsatellites markers (DXS548-FRAXAC1-FRAXAC2) and two SNPs (ATL1 and FMRb) were genotyped in a large cohort and haplotype associations compared among subgroups of normal and intermediate alleles. It was of special interest whether there were differences in the distribution of haplotypes across the normal and intermediate allele ranges in two different cohorts.

Determination of the nucleotide variations in exon 2 of GJB2 and exan3 of GJB6 genes in central part of IRAN.

s. Asadollahi[1], M. seyedhassani[1], m. neshan[1], s. kalantar[2], f. saeb[1];
[1]Dr.seyedhassani genetic center, yazd, Islamic Republic of Iran, [2]yazd medical science university, yazd, Islamic Republic of Iran.

INTRODUCTION: GJB2 & GJB6 are human genes encoding for gap junction protein. Defects in these genes lead to the most common form of congenital deafness. Some variations are reported in different countries.

METHODS: 120 individuals were evaluated by pcr-sequencing. Some of them were suffering from deafness & others were their relations that were referred for carrier detection.

RESULTS: of the 120 individuais,22 had GJB2 mutations,6 were found to be heterozygous for 35delG,4 were heterozygous for C:127 G>A (R>H),one case was heterozygous & one was homozygous for C:143 C>T (R>W),5 were heterozygous for C:153 A>G (V>I),that 3 of them were deaf & 2 of them were healthy but one case was homozygous for this mutation & he wasn't deaf. One was heterozygous for C:30 A>G & one was heterozygous for 57delT.one individual had a compound heterozygous mutation of 35delG/C:143 C>T. there wasn't any change in exon 3 of GJB6 gene. There was only one silent variant in sequencing of this gene.(G>A (T>T))

CONCLUSION: these results can help genetic counseling & molecular genetition in evaluation of GJB2 & GJB6 variation.

Investigation of EPM2A and NHLRC1 Mutations in Turkish Patients with Lafora Disease

O. Ozdemir[1], F. N. Tuncer[1], I. Karacan[1], S. U. Iseri[1], B. Baykan[2], C. Gurses[2], A. Dervent[2], U. Ozbek[1], N. Bebek[2];
[1]Institute for Experimental Medicine, Department of Genetics, Istanbul, Turkey, [2]Istanbul University, Istanbul Faculty of Medicine, Department of Neurology, Istanbul, Turkey.

Investigation of Lafora Disease Mutations in Turkish Population

The progressive myoclonic epilepsies (PMEs) are composed of a rare group of inherited neurodegenerative diseases with a prevalence of 1% of epileptic syndromes in children and adults around the world.

Among PMEs, Lafora disease (OMIM #254780) has been recognized as the most common and severe form of adult-onset progressive epilepsy with an autosomal recessive form of inheritance. Affected individuals exhibit epileptic seizures with a progressive deterioration to status epilepticus combined with progressive dementia, and starch-like polyglucosans called Lafora bodies detected in skin biopsies. The age of onset usually occurs between ages of 12 and 17 years, and patients usually die within 10 years of onset. Approximately 80% of affected individuals have displayed a mutation in *EPM2A* gene located on chromosome 6q24, which encodes laforin; a tyrosine phosphatase. *NHLRC1* (*EPM2B*) gene, recently mapped to chromosome 6p22, encodes E3 ubiquitin ligase, and was shown to carry mutations responsible for the disease.

The proposed study comprises mutational analysis of 9 patients diagnosed with the Lafora disease after all necessary clinical examinations. All exons and exon-intron boundaries of *EPM2A* and *NHLRC1* genes were PCR amplified from genomic DNA and analyzed for mutations through direct DNA sequencing.

One of the patients' revealed homozygous c.436G>A missense mutation (D146N) in *NHLRC1* gene, which was previously reported in Danish families.

This is the preliminary result of the study which is continuing with a larger group of patients.

Novel deletion c.22-1320_633+1224del in gene CYB5R3 in patients with recessive congenital methemoglobinemia in Russia

N. Galeeva[1], I. Kleymenova[2], S. Nenasheva[3], A. Poliakov[1];
[1]Research Centre for Medical Genetics, Moscow, Russian Federation, [2]Voronezh Regional Pediatric Medical Hospital № 1, Voronezh, Russian Federation, [3]Region Medical genetic consultation of the Samara Oblast, Clinical Hospital MI Kalinin, Samara, Russian Federation.

Recessive congenital methemoglobinemia (RCM) type I and II is a rare autosomal disease, which characterized by deficiency of soluble or soluble and membrane-bound forms of NADH-cytochrome b5 reductase (cytb5r) appropriately. The more severe type II form is characterized by cyanosis with mental retardation, the only symptom for type I is cyanosis. Mutations in gene CYB5R3 is the molecular-genetics cause of both types of disease. We have investigated patient with type II of disease and found deletion of exons 2-7 in homozygous state. Also we have investigated two sisters with type I of RCM and found in two sisters only one mutation p.Val253Met in exon 9 in heterozygosis state, which was previously described. Analysis of haplotypes for 4 markers, which flank gene CYB5R3, detected one general haplotype in patient with type II in homozygous state and in two sisters with type I in heterozygosis state. Then we developed system, which permitted us to detect exact borders of the deletion in introns 1 and 7. The size of deletion formed 12 kb and the name of deletion was c.22-1320_633+1224del. In next step we developed system, which permitted us to detect deletion c.22-1320 _633+1224del in homo- and heterozygosis state, and we revealed this deletion in two sisters. Our patients with type I and II of RCM are not relations but they live in Volga region in Russia.

Screening DFNB59 gene mutation in non-syndromic genetic hearing loss in Iran

f. azadegan, N. Bagheri, M. Abolhasani, E. Farrokhi, M. Hashmzadeh Chaleshtori;
Cell and Molecular Research Center, Shahrekord University of Medical Sciences, Shahrekord, Islamic Republic of Iran.

Background and aim: Hearing Impairment (HI) is the most prevalent Neurosensory disorder which is heterogeneous and can also occur due to environmental causes. The majority of hearing deficiencies are of genetic origin affecting about 60% of the HI cases. A novel gene DFNB59 encods pejvakin has been recently shown to cause deafness. This study aims to determine the frequency of DFNB59 gene mutations in coding region the gene in Iran.

Method: In this descriptive experimental study, we investigated the presence of DFNB59 gene mutations in Exons (2-7) of the gene in 80 deaf subjects. DNA was extracted using standard phenol -chloroform method. The screening of gene mutations was performed by PCR-SSCP/HA procedure. Finally, the possible mutations were confirmed by direct sequencing.

Results: In all, 9 polymorphisms 793C>G were found in 80 non-syndromic, genetic hearing loss subjects studied. However no DFNB59 gene mutation was identified.

Conclusion: We conclude that the association of DFNB59 gene mutations with hearing loss is very low in samples studies.

J12.13

Mutation detection in a large Iranian family with spinocereberllar ataxia type 6 (SCA-6)

S. Ahmadlou[1], M. Keramatipour[1], M. Togha[2];
[1]Department of Medical Genetics, School of Medicine, Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran, [2]Department of Neurology, Sina Hospital, Tehran University of Medical Sciences,, Tehran, Islamic Republic of Iran.

Spinocerebellar ataxia is an autosomal dominant neurodegenerative disorder characterized by slowly progressive ataxia. 30 different loci have been reported to be responsible for cerebellar ataxia. In general SCA 1-7 are the most frequent forms and account for 50-80 % of ADCA in most studies. The mutation associated with these loci is abnormal expansion of CAG repeat. The frequency of SCA subtypes varies in different ethnic groups.

We here investigated a large Iranian pedigree with clinical presentation of ADCA consisting of 13 affected members in three generation.

Genomic DNA was extracted from blood of patients with cerebellar ataxias and unaffected individuals. To amplify a fragment of SCA6/CACNA gene containing the CAG repeat, the polymerase chain reaction (PCR) was performed. PCR products were run on 3% agarose gel, wild-type and expanded alleles were extracted from the gel and were sequenced with both forward and reverse primers. Analysis of the sequence data determined the number of repeats for the normal and expanded allele as 11 and 24 repeats respectively. The results were confirmed by capillary electrophoresis using fluorescent primer labeled with 6-FAM. The size of the normal and expanded alleles were determined as 128 bp and 169 bp respectively with capillary electrophoresis.

Investigating patients in different generation showed a stable number of repeats, with no sign of increase in the number of repeats. This finding was consistent with the clinical findings in patients because no sign of anticipation, such as earlier age of onset and more severe clinical presentation was seen.

Clinical and molecular characterization of two large families segregating severe tooth agenesis

D. Gabrikova, J. Bernasovska, D. Grejtakova, A. Bozikova, I. Boronova, S. Macekova;
Department of Biology, Faculty of Humanities and Natural Sciences, University of Presov, Presov, Slovakia.

Tooth agenesis is the most common abnormality affecting formation of dentition in humans. The absence of six or less teeth is usually referred as hypodontia, while oligodontia is a term used for agenesis of more than six teeth excluding third molars. Tooth agenesis can be found either in isolated form (non-syndromic) or it can be associated with systemic condition or syndrome, such as various types of ectodermal dysplasia (syndromic tooth agenesis). In addition to previously known genes (PAX9, MSX1, AXIN2, EDA, EDAR), mutations in EDARRAD and WNT10 gene were recently found to be involved in isolated forms of tooth agenesis. Here we report unusual cases of two large families of Roma origin segregating non-syndromic oligodontia with very variable phenotype (4-17 missing teeth in family I, 2-12 missing teeth in family II). Molecular analysis of seven suspected genes will be presented.

This work was supported by projects LPP-0331-09 and ITMS 26220120041.

GJB2 caused hearing loss in patients from Belarus

E. A. Bliznetz[1], D. N. Martsul[2], O. G. Khorov[3], T. G. Markova[4], A. V. Polyakov[1];
[1]Research Centre for Medical Genetics, Moscow, Russian Federation, [2]Grodno regional hospital, Grodno, Belarus, [3]Grodno State Medical University, Grodno, Belarus, [4]National Research Centre for Audiology and Hearing Rehabilitation, Moscow, Russian Federation.

Mutations in Connexin 26 gene (*GJB2*) are responsible for more than half of all cases of prelingual nonsyndromic recessive deafness in Caucasians. The carrier frequency of the c.35delG mutation in *GJB2* gene was found to be as high as 1-4% in the European populations. Here a prevalence of *GJB2* caused cases and a mutation spectrum in 112 unrelated probands (and 8 their sibs) with prelingual nonsyndromic deafness from Belarus are shown. Among the probands there were different an ethnic groups including Belarusians (53%), Poles, Russians, Ukrainians, Azerbaijanians. In 50 probands and in all their sibs with hearing loss (45%) biallelic mutations in *GJB2* gene were detected. We revealed 8 pathological defects in the *GJB2* gene: the most common mutation c.35delG (allelic frequency: 84%), c.313_326del14 (7%), c.-23+1G>A (IVS1+1G>A) (2%), p.Met34Thr (2%), p.Glu120del (2%) and less frequent c.235delC, c.167delT and p.Ile82Met. The carrier rate in hearing individuals from Belarus for mutation c.35delG was estimated as 3% (8/234). A prevalence of hearing loss caused by mutations in *GJB2* gene was calculated to be 1/2500 in Belarus.

J12.16

The heterozygous carrier frequency of ABCA4 gene mutations in Russia

***M. T. Bondarenko**, A. Chukhrova, A. Loginova, A. V. Polyakov;*
Research Center for Medical Genetics, Moscow, Russian Federation.

Stargardt disease is the most common hereditary early-onset macular degeneration. It characterized by slowly progressive loss of central vision.

Autosomal-recessive Stargardt desease type 1 (STGD1) is caused by mutations in the ATP-binding cassette transporter gene (ABCA4). ABCA4 gene includes 50 exons, encodes 2273 amino-acid and mapped to 1p22. There are about 500 mutations in the ABCA4 gene have been reported.

882 unrelated control individuals and 100 unrelated STGD1 patients from Russia were screened for the prevalent European ABCA4 gene mutations: Gly863Ala, Ala1038Val and Gly1961Gln by multiplex ligation-dependent probe amplification (MLPA) and subsequent gel electrophoresis. In the control group the allele frequency of Gly863Ala, Ala1038Val and Gly1961Gln were 0.17%, 0.51% and 0.62%, respectively. In STGD1 patients the allele frequency for mutations Gly863Ala, Ala1038Val and Gly1961Gln were 1.0%, 17% and 6.0%, respectively. Heterozygous carrier frequency of mutation Gly863Ala is high in different countries of Europe (up to 1 out of 18 in Northern Europe), but it is significantly lower in Russia (1 out of 294 by our data).

Mutation Ala1038Val is the most frequent in Russian STGD1 patients, but prevailing mutation in control group is Gly1961Gln. The possible explanation is the heterozygous state of Gly1961Gln mutation provokes an age-related macular degeneration (AMD) and reduces this mutations` frequency in the group of STGD1 patient. This reseach is the first attempt to define the heterozygous carrier frequency of ABCA4 gene mutations in Russian population.

J12.17

Homozygosity mapping of a family with a mixed dystonia phenotype

***E. Jaberi**[1], M. Nemati[1], G. Shahidi[2], M. Rohani[2], I. Safari[1], E. Elahi[1];*
[1]School of Biology, University College of Science, University of Tehran, Tehran, Islamic Republic of Iran, [2]Department of Neurology, Tehran University of Medical Sciences, University of Tehran, Tehran, Islamic Republic of Iran.

Introduction: Dystonia results from involuntary concomitant contraction of agonist and antagonist muscles, with overflow of unwanted muscle contractions into adjacent muscles. Several classifications of dystonia are based on topographic distribution, age at onset, cause, or genetics. According to the etiologic classification this syndrome includes primary dystonia, secondary dystonia, dystonia-plus syndromes, and paroxysmal dystonia. Presently, eleven genes and seven additional loci have been reported to be associated with monogenic primary dystonias. We report the mapping of a family from Iran with an autosomal recessive form of dystonia-plus syndrome with severe hearing impairment linked to the chromosome 13.

Materials & methods: Whole genome homozygosity mapping was performed in a consanguineous Iranian family with two dystonia affected children and five unaffected family members using high density single nucleotide polymorphism chips**.** Patients had childhood-onset form of dystonia, muscle atrophy, and severe hearing impairment.

***Results*:** We observed a large homozygosity region of 15 Mega bases on chromosome 13 in all affected individuals of this family but no among the non-affected individuals. Nearly 200 annotated genes exist within the linked region.

Conclusions: These findings indicate that the causative gene exists on chromosome 13. Because these patients are suffering from a mixed phenotype, we have chosen some candidate genes related to dystonia, hearing loss, and muscle atrophy in this chromosomal region. Exome sequencing and mutation screening of candidate genes within the linked region is being performed.

J12.18

Homozygousity mapping in one Iranian pedigree affected with Autosomal Recessive Congenital Ichthyosis (ARCI) reveals linkage to region 17p13 and mutation in *ALOX12B* gene

***A. Alavi**[1], P. Rasooli[2], M. Malakooti Nejad[3], M. Mirshams Shahshahani[4], E. Elahi[1];*
[1]University of Tehran, Tehran, Islamic Republic of Iran, [2]School of Biology, University College of Science, University of Tehran, Tehran, Islamic Republic of Iran, [3]Science and Research Branch, Islamic Azad University, Tehran, Islamic Republic of Iran, [4]Tehran University of Medical Sciences, University of Tehran, Tehran, Islamic Republic of Iran.

Ichthyosis is clinically and genetically heterogeneous group of disorders characterized by abnormal skin scaling over the whole body. Autosomal Recessive Congenital Ichthyosis (ARCI) is a subgroup of ichthyosis that exhibits autosomal recessive inheritance. To date, eight genes and three additional loci have been associated with ARCI. Mutations in these genes account for disease in 70-75% of the patients.

We performed whole genome homozygosity mapping in an Iranian ARCI family using high density SNP chips.

Disease status in the family linked to a homozygous region of 2.2 Mb on chromosome 17. The ALOX12B gene associated with ARCI lies within the region and mutation screening revealed a homozygous mutation causing p.Arg442Gln. The missense mutation p.Arg442Gln (c.1325C>T) in exon 10 just was reported in one Japanese patients as compound heterozygous and p.Arg442Gln mutation was not found in his parents and was thought to be a de novo mutation. But, R442Q mutation in ALOX12B in our patients was homozygous in both patients and heterozygous in their parents. Phenotypic similarities and variations among the mutation carrying patients are detected but, two patients showed a striking palmoplantar hyperlinearity. It seems mutation in ALOX 12B gene is associated with mild form of ARCI and hyperlinearity in palms and soles.

Molecular Genetic Diagnostics of Phenylketonuria in Kazakhstan

*G. Svyatova, G. Berezina, **Z. Makhmutova**, D. Salimbaeva;*
The Scientific Center of the obstetrics, gynecology and perinatology, Almaty, Kazakhstan.

The aim of our study was to determine the spectrum and frequency of the most common mutations of RAH gene in patients with phenylketonuria in Kazakhstan.

Materials and methods. Molecular genetic analysis of mutations in PAH gene (R408W, R261Q, R252W, IVS10-11, IVS12 +1, R158Q, P281L, IVS14 +5) carried out using PCR technique. We studied DNA from blood of 44 patients with phenylketonuria and their parents.

Results. The results of our study showed that in Kazakhstan the most important are the six mutations: R408W with frequency 0,455, mutation R261Q with frequency 0,136, IVS12nt1, IVS10nt546, P2812L, IVS12+1G>A with the same frequency 0,023. Besides, we had neutral polymorphism V245V in 7 exon of a PAH gene that described earlier (Dworniczak et al., 1990).

Conclusions: The examination of mutant alleles in patients and their families or investigation of alleged heterozygous carriers with pathological mutations provided good possibility for prenatal diagnosis of the fetus. This is important factor for prevention of hereditary diseases in families.

Whole exome sequencing combined with linkage analysis identifies novel variations in a large Coronary Artery Disease family

***K. Inanloo Rahatloo**[1], E. Elahi[1], S. Davaran[2], T. Fan[3];*
[1]School of Biology, University College of Science,Tehran University, Tehran, Islamic Republic of Iran, [2]Tehran University of Medical Sciences,University of Tehran, Tehran, Islamic Republic of Iran, [3]Illumina Inc, San Diego, CA, United States.

We sought to use exome sequencing in conjunction with linkage information to identify candidate causative mutations in a large family with CAD. Linkage analysis of this family comprising six affected and 4 unaffected individuals revealed linkage signals at 3 Loci with maximum LOD score of 2.1. We captured exomes of two affected individuals from a family and performed sequencing analysis by a second-generation sequencer with a mean coverage of 30× and sufficient depth to call variants at ~97% of each targeted exome. The shared genetic variants of these two affected individuals in the family being studied were filtered against the 1000 Genomes Project and the dbSNP131 database. After annotation and functional expectation, three variations were found to be candidates for CAD.

Genetic study of demyelinating form of autosomal-recessive Charcot-Marie-Tooth diseases in Russian families

***T. B. Milovidova**, E. L. Dadali, G. E. Rudenskaya, O. A. Schagina, N. V. Punina, A. L. Chuchrova;*
Research centre for medical genetics, Moscow, Russian Federation.

Charcot-Marie-Tooth disease (CMT) is the most common inherited neuropathy. During of the scale analysis of demyelinating form of CMT in Russia the necessity was presented of research of autosomal-recessive CMT (AR-CMT). The aim was focused on molecular analysis of the selected genes associated with AR-CMT and construction of a molecular and genetic diagnostic algorithm in this group of disorders in the Russian population.

We analyzed a group of 92 unrelated patients with probably autosomal recessive inheritance. The studies covered analysis of coding regions of the GDAP1 gene using sequencing and molecular genetic analysis of eight frequent occurrence mutations using two Multiplex Ligation Probe Assay (MLPA) systems. The first MLPA-system contained six of frequent occurrence mutations in four genes: FGD4 (Met298Thr, Met298Arg), FIG4 (Ile41Thr), GDAP1 (Leu239Phe), SH3TC2 (Arg954Stop, Arg658Cys). The second MLPA-system contained two frequency Gypsies mutation in two genes: NDRG1 (Arg148Stop) and SH3TC2 (Arg1109Stop).

In result the cause of AR-CMT was determined in 26% of cases (24 patients). Mutations in GDAP1 gene were most frequent (18,5% or 17 patients). The mutation Arg148Stop of NDRG1 gene was found of three patients (3,2%). Mutations Arg954Stop of SH3TC2 gene and Ile41Thr of FIG4 gene were found of two patients (2,2%).

This is the first study focused on the autosomal recessive Charcot-Marie-Tooth disease in the Russian population, which is essential for molecular diagnostics in CMT disease.

Abnormal Type I Collagen folding and matrix deposition in a Cyclophilin B KO mouse model of recessive Osteogenesis Imperfecta

W. A. Cabral[1]*, E. Makareeva*[2]*, M. Weis*[3]*, A. M. Barnes*[1]*, W. Chang*[1]*, S. Leikin*[2]*, D. Eyre*[3]*, J. C. Marini*[1]*;*
[1]*Bone & Extracellular Matrix Branch, NICHD, NIH, Bethesda, MD, United States,* [2]*Section on Physical Biochemistry, NICHD, NIH, Bethesda, MD, United States,* [3]*Orthopaedic Research Laboratories, University of Washington, Seattle, WA, United States.*

Recessive OI is caused by deficiency of proteins involved in collagen post-translational interactions, including the collagen prolyl 3-hydroxylation complex consisting of CRTAP, P3H1 and PPIB. The function of α1(I) Pro986 3-hydroxylation is unknown, but roles in fibril alignment and matrix cross-linking are speculated. PPIB, a prolyl cis-trans isomerase also known as cyclophilin B, is thought to catalyze the rate-limiting step in collagen helix formation. To further characterize the role of PPIB in collagen folding, Ppib-null mice were generated from a gene-trap ES cell clone with half-normal *PPIB* expression. Homozygous *Ppib*$^{-/-}$ mice were verified by real-time RT-PCR to completely lack transcripts in skin, fibroblasts, osteoblasts and femora. *Ppib*$^{-/-}$ mice weigh one-third less than WT and Het littermates. Ppib protein was absent and P3h1 reduced 50% in *Ppib*$^{-/-}$ cultured fibroblasts and osteoblasts. As expected, α1(I) P986 3-hydroxylation was reduced to 5-11% of WT. In agreement with previously described patients with decreased P986 3-hydroxylation, collagen from *Ppib*$^{-/-}$ cells had delayed electrophoretic mobility on SDS-Urea PAGE. However, thermal stability, 5-lysyl and 4-prolyl hydroxylation of fibroblast collagen were normal. Inhibiting hydroxylation of collagen with α,α'-dipyridyl resulted in Ppib$^{-/-}$ collagen alpha chains with faster elecrophoretic migration than WT chains, suggesting altered conformation due to loss of peptidyl-prolyl isomerization. In *Ppib*-/- fibroblast cultures, collagen deposition was decreased by 70% vs WT cultures, despite only moderate delay of secretion. These data suggest unique roles for Ppib in collagen post-translational processing and extracellular matrix incorporation, in addition to its chaperone function for folding.

Kuskokwim Disease, a recessive congenital contracture disorder, is the third syndrome caused by an *FKBP10* mutation

A. M. Barnes[1]*, M. Weis*[2]*, W. A. Cabral*[1]*, E. Mertz*[3]*, E. Makareeva*[3]*, G. Duncan*[4]*, W. Paton*[5]*, S. Leikin*[3]*, D. R. Eyre*[2]*, S. J. Bale*[6]*, J. C. Marini*[1]*;*
[1]*BEMB, NICHD/NIH, Bethesda, MD, United States,* [2]*University of Washington, Seattle, WA, United States,* [3]*SPB, NICHD/NIH, Bethesda, MD, United States,* [4]*Christchurch Hospital, Christchurch, New Zealand,* [5]*Alaska Native Medical Center, Anchorage, AK, United States,* [6]*Gene Dx, Gaithersburg, MD, United States.*

Kuskokwim Disease (OMIM %208200), found solely among Alaskan Eskimos along the Kuskokwim river delta, is a recessive syndrome characterized by multiple congenital joint contractures, predominantly in knees and ankles. Null mutations in *FKBP10* (Chromosome 17q21.2) have been shown to cause recessive osteogenesis imperfecta (OI), with (Bruck Syndrome 1) or without congenital contractures. Linkage mapping of Kuskokwim Disease to chromosome 17q12-q21, together with contractures as a variable feature of *FKBP10* mutations, led us to sequence this gene. We identified a homozygous 3 nt deletion in *FKBP10* exon 5 (c.875_877delACT), which causes deletion of p.Tyr293, in probands from three Kuskokwim pedigrees. This mutation occurs in the 3rd PPIase domain of FKBP65 and is highly conserved among species. *FKBP10* expression by real-time PCR ranged from 0.75-1.67 of control in five probands, suggesting that the transcripts are not degraded. FKBP65 protein was present in proband fibroblasts at 2.5-7.5% of control levels, demonstrating destabilization of the protein. Steady-state type I collagen biochemistry has near normal migration. Additionally, collagen cross-linking is decreased in probands, with 0-25% hydroxylation of the telopeptide lysine involved in cross-linking and an 80% reduction in mature cross-linked collagen deposited in culture, despite normal collagen secretion. Collagen in extracellular matrix appears more diffuse, perhaps from thinner fibrils, with a normal to decreased collagen:organics ratio shown by Raman micro-spectroscopy. In conclusion, this is the third phenotype caused by mutations in *FKBP10*, adding contractures with osteopenia to the previously described severe OI with and without contractures; the Kuskokwim mutation specifically affects collagen cross-linking.

J12.24

Identification of mutations in PANK2 in Pantothenate kinase associated neurodegeneration (PKAN) patients

M. Ansari Dezfouli[1]*, I. Safari*[1]*, M. Ansari Dezfouli*[1]*, M. Rohani*[2]*, G. Shahidi*[2]*, E. Elahi*[1]*;*
[1]*University of Tehran, Tehran, Islamic Republic of Iran,* [2]*Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran.*

Pantothenate kinase associated neurodegeneration (PKAN) is a rare autosomal recessive genetic disease classified within the group of Neurodegeneration with Brain Iron Accumulation (NBIA) disorders. Its reported prevalence is less than 1/1,000,000. PKAN diagnosis is based on clinical features and magnetic resonance imaging(MRI) and genetic analysis. Its clinical presentations include dystonia, speech defects, dysphangia, and intellectual impairment. Dementia, severe mental retardation and severe movement disability may develop at later stages. In MRI T2 weighted images, all affected individuals exhibit hypodensity in the globus pallidus region. Only in some cases, a region of hyperdensity in the center of the region of hypodensity creates an "Eye of Tiger" sign.

Here, we report first genetic screening of Iranian PKAN patients. The subjects included eight cases. The three patients, all of them presented the Tiger Eye, harbored homozygous mutations. The mutations affected Arg>Trp and Arg>Leu and Arg>Pro . All mutations were checked in 100 control individuals. *PANK2* mutation was not observed in any of the five cases without "Eye of Tiger" sign, consistent with the proposal that there is a tight association between *PANK2* mutations and this imaging feature. The five patients without *PANK2* mutations will be pursued for identification of another causing genes.

The results of KRT5 and KRT14 analysis in Polish patients with epidermolysis bullosa simplex

K. Wertheim-Tysarowska[1]*, A. Giza*[1]*, C. Kowalewski*[2]*, K. Woźniak*[2]*, A. Kutkowska-Kaźmierczak*[1]*, A. Sobczyńska-Tomaszewska*[1]*, J. Bal*[1]*;*
[1]*Medical Genetic Department, Institute of Mother and Child, Warsaw, Poland,*
[2]*Department of Dermatology, Medical University of Warsaw, Warsaw, Poland.*

Simplex epidermolysis bullosa (SEB) is characterized by blister formation within basal or suprabasal layers of epidermis. Twelve clinically distinct subtypes of SEB have been distinguished. The localized SEB, Dowling-Meara SEB and other generalized SEB subtypes caused by mutations in KRT5 and KRT14 are most often. Keratins 5 and 14, encoded by them, form intermediate filaments in basal keratinocytes. According to the consensus on SEB diagnosis and classification, this three subtypes are inherited in an autosomal dominant manner. The aim of present study was to investigate the spectrum of mutations in Polish SEB patients. The 34 probands (10 localized SEB; 2 Dowling-Meara SEB; 5 other generalized SEB, 17 undefined) diagnosed on the basis of clinical symptoms or immunofluorescence mapping were included. Coding regions of KRT5 and KRT14 were analyzed by direct sequencing. We found 9 distinct variants in KRT5 and 7 in KRT14, including overall 7 novel changes. In 17/34 cases full genotype was established; in remaining patients molecular analysis has not been completed yet or no mutations were identified. The most frequent mutation found in 3 distinct families was p.Glu170Lys in KRT5, including siblings with mild SEB, where it was in trans with p.Val143Ala. Both parents of these patients seem to be unaffected carriers. Only few patients with compound heterozygosity in KRT5 have been reported previously, however, to our knowledge, none of them involved p.Val143Ala. Our preliminary results broaden the knowledge about SEB epidemiology and pathogenesis. The results have also practical impact on preparing the Polish molecular diagnostics scheme.

Limb-girdle muscular dystrophys with expressed defeats of a myocardium

T. Adyan*, E. Dadali, A. Polyakov;*
Medical Genetics Research Center, Moscow, Russian Federation.

Severe lesions of the myocardium at limb-girdle muscular dystrophy (LGMD) are the serious problem, sharply reducing quality and life expectancy of patients. In most cases a myocardium is involved in the pathological process to a greater extent than the skeletal muscles, which causes the characteristic clinical picture, in which the main symptoms are different types of arrhyth-

mias and malfunctions of cardionector. It is shown that the most severe disorders of the heart are observed at the following three genetic variants of LGMD: LGMD 1B, LGMD 1D and X-linked form of Emery-Dreifuss muscular dystrophy, caused by mutations in genes LAMIN, DES, EMD, respectively. Early diagnostics of the given forms will allow to prevent heavy complications at patients and to increase duration of their life. By means of direct automatic sequencing we analyzed coding sequences and adjacent introns of the three above mentioned genes among a sample of 12 patients (6 men, 6 women), were under our supervision. At 4 from them the vertical type of inheritance of disease in a family was observed, the others were isolated. As a result, we obtained the following data: for 7 patients were identified mutations in the LAMIN gene (58,33%), for 4 in the EMD gene (33,33%) and for 1 in the DES gene (8,33%). Revealed some features of the clinical picture for patients with mutations in the genes analyzed.
The data obtained may be the basis for the algorithm of molecular genetic diagnosis of LGMD with severe cardiac conduction system.

A novel missense mutation (p.Arg309His) in the nuclear localization signal sequence of spastin protein causes a complicated form of Hereditary Spastic Paraplegia

A. Magariello[1]*, C. Tortorella*[2]*, A. Patitucci*[1]*, R. Tortelli*[2]*, M. Liguori*[1]*, R. Mazzei*[1]*, F. L. Conforti*[1]*, L. Citrigno*[1]*, C. Ungaro*[1]*, I. L. Simone*[2]*, M. Muglia*[1]*;*
[1]Institute of Neurological Sciences -CNR-, Piano Lago di Mangone (CS), Italy, [2]Institute of Neurology, Department of Neurological and Psychiatric Sciences, University of Bari, Bari, Italy.

Hereditary spastic paraplegia (HSP) is a clinically and genetically heterogeneous group of neurodegenerative diseases causing slowly progressive spasticity and weakness of the lower extremities. Mutations in the *SPAST* gene are responsible for approximately 40% of autosomal dominant HSP and 6-15% of sporadic cases. Here we report the case of a 53-years old man who was complaining for a progressive gait difficulty in the last 4 years. At the time of the study his neurological examination showed spastic paraparesis with mild spasticity of the legs, slight weakness of the thigh and big toe extensor muscles, hyperreflexia of arms and legs, and left extensor plantar sign. Brain MRI showed diffuse T2-hyperintensities in the posterior periventricular white matter, possibly due to chronic vascular damage, and a mild atrophy of cerebellar vermis and hemispheres. The family history was negative for neurological diseases and consanguinity was excluded. Genomic DNA was extracted from peripheral leucocytes using the salting out method, after receiving informed consent from the patient. Sequencing of all 17 coding exons of the *SPAST* gene revealed a c.926 G>A transition in the exon 6. The change substitutes the arginine 309 with an histidine (p.Arg309His) in the functional nuclear localization signal sequence (NLS) of the spastin protein. This novel mutation was not found in 200 normal chromosomes. Arg309 is conserved among species and the PolyPhen-2 modelling analysis predicts the aminoacid substitution to be “probably damaging”, with a score of 0.991. The change p.Arg309His represents the first *SPAST* mutation identified in the NLS spastin domain.

J12.28

A mutation-site approach helps predicting the phenotypic expression of MYH7 mutations

A. Mazzanti[1]*, C. Medrano*[2,3]*, L. Cazon*[1]*, M. Perez_Barbeito*[1]*, M. Rodriguez_Garcia*[1,4]*, C. Fernandez_Otero*[1]*, I. Lesende_Rodriguez*[1]*, M. Vazquez_Alvarez*[2,3]*, F. Rueda_Nunez*[4]*, D. Garcia*[1]*, R. Barriales_Villa*[1]*, L. Monserrat*[4]*;*
[1]INIBIC - Instituto de investigación biomédica, La Coruña, Spain, [2]Pediatric Cardiology. Hospital General Universitario Gregorio Marañón, Madrid, Spain, [3]MyEstela Study Group, Madrid, Spain, [4]Complejo Hospitalario Universitario, La Coruña, Spain.

PURPOSE. We describe 3 novel MYH7 mutations (b-myosin heavy chain) associated with Dilated Cardiomyopathy (DCM) and Left-Ventricular-Non-Compaction (LVNC), localized within the region of actomyosin interface.
METHODS. Clinical assessment of 3 children with MYH7 mutations (E525K, M528I, F540L) was performed in dedicated clinics. Genetic study included sequencing of MYH7,MYBPC3,TNNT2,TNNI3,TPM1,ACTC1,LDB3,LMNA and TAZ. Mutations occurred once in >500 samples and were predicted as pathogenic by in-silico analysis. RESULTS. E525K was found in a newborn with DCM/LVNC without familial history of cardiac disease. She underwent a heart transplant (HTx) at 5 months. The M528I variant was detected in a girl with LVNC and mitral regurgitation. The mutation was inherited by the father‘s family. F540L was identified in a 16 year-old boy with DCM/LVNC. His mother and 2 siblings were affected. The mutations lie within the 50k lower sub-domain of the globular myosin head, in a region with surface hydrophobic helical peptides that are part of the binding site actomyosin. Other mutations in the same subunit have been described (G529D, M531R, S532P, M539L, A543T, D545N and A550V): the most prevalent phenotype was DCM/LVNC or DCM. High penetrance and early onset of disease were common (52% of affected were <21 years). The evolution was severe: 3 deaths from heart failure, 4 HTxs, 1 myectomy. CONCLUSIONS. We identified 3 novel mutations in MYH7 related to early-onset DCM and LVNC. This phenotype is shared by other mutations affecting the same sub-domain of MYH7. Such a site-specific approach could help interpreting the pathogenic role of previously undetected mutations.

Mutation analysis of the GRIN2B gene in Alzheimer’s Disease

F. Trecroci, R. Cittadella, E. V. De Marco, M. Liguori, P. Spadafora, G. Di Palma, ***V. Andreoli****;*
Institute of Neurological Sciences-National Research Council, Pianolago di Mangone (CS), Italy.

Various mechanisms may contribute to neurodegeneration in Alzheimer‘s disease (AD), including glutamate-mediated excitotoxicity. This excitotoxic effect appears to be mediated by the N-methyl-D-aspartate receptors (NMDARs). The NMDAR subunit 2B (NR2B) has attracted more attention due to its characteristic distribution and selective reduction in AD brain. The potential involvement of the GRIN2B gene, encoding NR2B, in the risk for AD was evaluated in an independent series of Southern Italy samples. Clinical data and blood sample were collected from 270 selected AD patients, after inform consent. All coding exons and exon-intron junctions were amplified and a mutational screening was done by DHPLC and direct sequencing. Although the six detected variants are in the coding sequence, they are silent polymorphisms: Ala5; Pro122; Ser555; Cys838; Thr888 and His1178. First, we investigated Ser555 in exon 8 and His1178 in exon 13 of the GRIN2B in our patients and 250 healthy-matched controls. No statistically significant differences were found in GRIN2B genotype and allele frequencies (Ser555 P=0.142; His1178 P=0.868) between the AD sample and controls, even when the subjects were stratified by gender, APOE and age of disease onset in AD patients. The results of the Ala5 and Cys838 polymorphisms were omitted (low frequencies detected), while the analysis of the Pro122-Thr888 variants are in progress.Systematic mutation search of the GRIN2B gene in our patients with AD failed to identify any functional changes. However, we will continue with a more comprehensive screening of GRIN2B polymorphisms that might be useful to determine the involvement of this gene in AD.

Identification of *TNFRSF13B* (TACI) mutations in pediatric patients with Cerebellar Hypoplasia and Common Variable Immunodeficiency (CVID).

G. Zanni[1]*, S. Barresi*[1]*, A. Finocchi*[2,3]*, S. Cascioli*[2]*, R. Cusmai*[4]*, V. Moschese*[3]*, R. Carsetti*[2]*, P. Rossi*[3,2]*, E. Bertini*[1]*;*
[1]Dept of Neurosciences, Unit of Molecular Medicine, Bambino Gesù Children‘s Hospital, Rome, Italy, [2]Dept. of Pediatric Immunology, Bambino Gesù Children‘s Hospital, Rome, Italy, [3]University of Tor Vergata, Rome, Italy, [4]Dept of Neurosciences, Unit of Pediatric Neurology, Bambino Gesù Children‘s Hospital, Rome, Italy.

Common variable immunodeficiency (CVID) (OMIM#240500) is the most prevalent human primary immunodeficiency, diagnosed on the basis of an impaired ability to produce specific antibodies after vaccination and markedly reduced serum levels of IgG and IgA . *TNFRSF13B*, the gene encoding transmembrane activator and calcium modulator and cyclophilin ligand interactor (TACI) a member of the TNF(Tumor Necrosis Factor) receptor family , is mutated in 5-10% of patients with CVID. C104R together with A181E are the most frequent coding variants accounting for 90% of TACI mutations. The C104R mutation abolishes ligand binding and, consequently TACI signalling which plays a fundamental role in immunoglobulin class switching, production and in B-cell homeostasis regulation. We analyzed by direct sequencing all five coding exons of *TNFRSF13B* in 9 pediatric patients (5 sporadic patients and 4 siblings belonging to two families) presenting with hypogammaglobulinemia, cerebellar hypoplasia, psychomotor delay and mild to bordeline intellectual disability. We identified the recurrent C104R mutation in heterozygous state, in two affected males in one family and in one sporadic patient. In all patients with *TNFRSF13B* mutations, we also analyzed by RT-PCR, TACI expression on peripheral lymphocytes, which was not impaired. Recent evidence suggests that tumor necrosis factor receptor superfamily members (TNFRSF) are expressed in an overlapping regulated pattern during neuronal development, participating in the regulation of neuronal expansion, differentiation and development. The association between TACI mutations and cerebellar hypoplasia has not been described before and could provide interesting clues for investigating the non-immunological role of *TNFRSF13B* in brain and cerebellar development.

J12.31

Are synaptophysin (SYP) mutations causing a syndromic form of X-linked intellectual disability?

A. K. Philips[1], *K. Avela*[2], *S. Haas*[3], *H. Hu*[3], *M. Somer*[2], *V. Kalscheuer*[3], *I. Järvelä*[1];
[1]Department Of Medical Genetics, Helsinki, Finland, [2]Department Of Medical Genetics,Family Federation of Finland, Helsinki, Finland, [3]Max Planck Institute for Molecular Genetics, Berlin, Germany.

Background

To date, about 100 genes have been identified to underlie XLID (http://xlmr.interfree.it/home.htm).

Sequencing of the coding region of X-chromosome has revealed four mutations (T92fs*45, N59_K60>K*, D277fs*59 and G217R) in the synaptophysin gene (*SYP*) at Xp11.23-p11.22 encoding an integral membrane protein of small synaptic vesicles (Tarpey et al. 2009) in families with ID.

Subjects and Methods

Exome sequencing using AgilentSureSelectHumanX-chromosome kit and single-read76nt NGS on the Illumina GAII sequencer was applied to find the causative gene in the index patient belonging to a large Finnish family with a total of nine male patients with ID in three generations. DNA of six patients and their mothers were available for the study.

Results

A novel missense mutation c.879G>A (p.Gly293Ser) in exon 6 of *SYP* was identified that perfectly co-segregates with the disease in the family. The mutations were not found in 440 Finnish anonymous blood donors respectively. In detailed clinical investigation of the three affected patients (III/5, IV/1 and IV/2) similar dysmorphic features were identified including hyperplastic supra-orbital ridges, straight eyebrows, deep set eyes, and short philtrum. The carrier mothers were normal.

Conclusions

We anticipate that mutations in the *SYP* gene cause a previously undescribed syndrome of with X-linked intellectual disability.

Analysis of the *GJB2* coding region in Tuvinian deaf patients (the Tuva Republic, Southern Siberia)

M. S. Bady-Khoo[1,2], *N. A. Barashkov*[3,4], *I. V. Morozov*[5], *E. V. Duvak*[2], ***O. L. Posukh***[1,6];
[1]Institute of Cytology and Genetics, Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russian Federation, [2]Republican Hospital #3, Kyzyl, Republic of Tuva, Russian Federation, [3]Yakut Scientific Centre of Complex Medical Problems, Siberian Branch of the Russian Academy of Medical Sciences, Yakutsk, Russian Federation, [4]M.K. Ammosov North-Eastern Federal University, Yakutsk, Russian Federation, [5]Institute of Chemical Biology and Fundamental Medicine, Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russian Federation, [6]Novosibirsk State University, Novosibirsk, Russian Federation.

Mutations in the *GJB2* gene, encoding the gap-junction protein connexin 26 (Cx26), are the most common cause of non-syndromic deafness. To investigate the molecular basis of non-syndromic deafness in the Tuva Republic (Southern Siberia, Russia), we analysed nucleotide sequences of the *GJB2* gene entire coding region in 90 deaf patients of Tuvinian ethnicity. The Tuvinians are the indigenous population of the Tuva Republic located northwest of Mongolia and directly east of the Altai Republic. Most of the Tuvinians are descended from ancient Turkic-speaking Central Asian tribes and Mongolian-speaking groups assimilated by them. Mutations p.W172C (c.516G>C), p.L79fs (c.235delC), p.V37I (c.109G>A), p.H100fs (c.299_300delAT) in homozygous or compound heterozygous state or as a single allele were found in 24 out of 90 patients (26.7%). Besides, 18.9% of studied Tuvinian chromosomes were carrying polymorphisms p.V27I (c.79G>A), p.E114G (c.341A>G), and p.F192L (c.571T>C). Interestingly, we observed high prevalence of the p.W172C mutation (79.4% out of all mutant chromosomes): 7 patients were homozygous and 13 patients -**heterozygous for** p.W172C. The p.W172C was first reported in the Altaians (the Altai Republic) (Posukh et al., 2005) and then in one Mongolian deaf patient (Tekin et al., 2010). The p.W172C change is located in the second extracellular domain of Cx26 protein. Based on evolutionarily conservation of c.516G in the *GJB2* sequence in many species and the PolyPhen analysis, p.W172C (c.516G>C) was considered to be probably pathogenic. The study was supported by RFBR grant #11-04-01221-à and by grant of the Chairman of the Tuva Republic Government for young scientists.

A Novel Mutation of Ceruloplasmin Gene in a Patient with Atypical Pattern of Neuroimaging

P. Tarantino[1], *M. Salsone*[2], *L. Passamonti*[3], *F. Rocca*[3], *M. Gagliardi*[1,4], *F. Cavalcanti*[1], *M. Caracciolo*[1], *A. Gambardella*[1], *A. Quattrone*[2,3], *G. Annesi*[1];
[1]Institute of Neurological Sciences, National Research Council, Mangone (Cosenza), Italy, [2]Institute of Neurology, Department of Medical Sciences, University of Magna Graecia, Catanzaro, Italy, [3]Neuroimaging Research Unit, National Research Council, Catanzaro, Italy, [4]University of Magna Graecia, Catanzaro, Italy.

Hereditary aceruloplasminemia (HA) is a rare autosomal recessive disease characterized by anemia, iron overload, diabetes and progressive neurodegeneration, caused by homozygous mutation of the ceruloplasmin (CP) an necessary enzyme for the normal transportation of iron by plasma transferring. Recently, some authors have demonstrated that all their patients with HA showed on T2* scans, a pattern of brain iron deposition characterized by involvement of globus pallidus, putamen, caudate, thalamus, dentates and substantia nigra. Here, we report a case of patient affected by HA with an atypical pattern of neuroimaging. The patient was a 47-years-old man who presented progressive psychiatric symptoms, neurological symptoms and type I diabetes. A patient's cousin with a biochemical diagnosis of aceruloplasminemia was asymptomatic. Laboratory findings showed mild anemia, low serum iron concentration and high ferritin concentration value. CP was undetectable. Liver function test were normal. Genetics screening for hemochromatosis, HFE and CP genes was performed and demonstrated in CP gene a novel mutation (IVS6+1G/A) into a splice donor site on the intron 6. The same mutation was found in the asymptomatic cousin, confirming the biochemical diagnosis of HA. The T2*-MRI scans, showed the brain iron deposition as a marked hypointensity in all the typical cerebral structures. No abnormalities were found in the globus pallidus as typically occurs in a patients with HA. In conclusion, this is the first evidence of a patient affected by HA with the brain iron deposition which does not involve the globus pallidus.

Sacsin-related ataxia caused by the novel missense mutation Arg272His in a patient from Southern-Italy

F. Cavalcanti[1], *A. Nicoletti*[2], *G. Annesi*[1], *P. Tarantino*[1], *M. Gagliardi*[1,3], *G. Mostile*[2], *V. Dibilio*[2], *A. Quattrone*[4,5], *A. Gambardella*[1], *M. Zappia*[2];
[1]Institute of Neurological Sciences, National Research Council, Cosenza, Italy, [2]Department of Neurosciences, University of Catania, Catania, Italy, [3]University of Magna Graecia, Catanzaro, Italy, [4]Institute of Neurology, Department of Medical Sciences, University of Magna Graecia, Catanzaro, Italy, [5]Neuroimaging Research Unit, National Research Council, Catanzaro, Italy.

Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS) is an early-onset cerebellar ataxia with spasticity, amyotrophy, nystagmus, dysarthria, and peripheral neuropathy. SACS is the only gene known to be associated with the ARSACS phenotype. The gene was initially reported to be encoded by a single gigantic exon. Recently eight additional exons were identified upstream of the giant exon. The SACS protein product, sacsin, is believed to integrate the ubiquitin-proteasome system and Hsp70 chaperone machimery. Recent studies indicates a role for sacsin in regulation of mitochondrial dynamics. To date, more than 70 different mutations, predominantly located in the giant exon, have been identified worldwide; of these only seven, exclusively located in the giant exon, were identified in Italian patients. The authors identified a novel homozygous variation c.815G>A, which results in the missense mutation p.Arg272His (R272H) in a patient from Southern-Italy. This mutation was present in heterozygosis in both unaffected parents as in one unaffected sibling and in several unaffected relatives. The phenotype of our patient closely resembled the classic phenotype. R272H missense mutation falls in the seventh coding exon of the SACS gene, hence not in the carboxyterminal giant coding exon which contains most reported sacsin mutations. R272H represents the first described Italian mutation located upstream of the giant exon of the SACS gene. The residue is completely conserved in evolution. The missense mutation R272H was not detected among 200 control chromosomes. Although it is also in a well-conserved region of the protein, no functional domain is defined for this region.

Lack of the VPS35 Asp620Asn mutation in southern Italian patients with familial Parkinson's disease

G. Annesi[1], *M. Gagliardi*[2,3], *P. Tarantino*[1], *F. Cavalcanti*[1], *M. Caracciolo*[1], *A. Bagalà*[1], *A. Gambardella*[1], *T. Mirante*[1], *A. Quattrone*[4];
[1]Instit Neurol.Sciences National Research Council, Mangone (Cosenza), Italy, [2]Instit. Neurol.Sciences National Research Council, Mangone (Cosenza), Italy, [3]University Magna Graecia,, Catanzaro, Italy, [4]3Institute of Neurology, University Magna Graecia, Catanzaro, Italy Neuroimaging Research Unit, Institute of Neurological Sciences, National Research Council, Germaneto, Catanzaro, Italy.

Parkinson's disease (PD) is a common neurodegenerative disorder, affecting 2% of those over the age of 75 years. Although generally considered a sporadic disease, Mendelians forms of the disease are described (SNCA and LRRK2 for causing autosomal dominant PD and 3 genes causing autosomal recessive, juvenile PINK1, Parkin, DJ1). Recently using an exome sequencing based approach, 2 indipendent groups have identified a missense mutation in vacuolar protein sorting 35 homolog (VPS35 c.1858G>A; p.Asp620Asn) as the probable cause of late onset PD in a number of kindreds. To estimate the frequency of the Asp620Asn mutation in VPS35 in familial PD, we screened for this variant in a southern Italy PD cohort. Our population included 114 patients with familial PD, having at least 1 relative among their first degree, second degree, in third degree family members with a formal diagnosis of PD (major PD genes had been analyzed and positive cases (9 LRRK2) were not excluded. This variant was not detected in any of the 150 analyzed familial PD cases, thus indicating that this mutation is rare among familial PD cases in the southern Italy.

The diagnosis and the clinical features of a rare disease; Alpha-mannosidosis

B. G. Nur, *E. Mıhcı;*
Akdeniz University School of Medicine, Department of Pediatric Genetics, Antalya, Turkey.

Alpha-mannosidosis is a rare autosomal recessive lysosomal storage disease of glycoprotein catabolism caused by a deficiency of lysosomal **alpha-**mannosidase activity. The incidence is approximately 1 of 500,000 live births. Characteristic clinical features include mental retardation, coarse facial features, ataxia, hearing loss, dysostosis multiplex, and immunodeficiency. Three clinical subtypes include a mild form recognized after age ten years with absence of skeletal abnormalities, myopathy, and slow progression (type 1); a moderate form recognized before age ten years with presence of skeletal abnormalities, myopathy, and slow progression (type 2); and a severe form manifested as prenatal loss or early death from progressive central nervous system involvement (type 3). Assay of acid alpha-mannosidase enzyme activity in leukocytes or other nucleated cells is the confirmatory diagnostic test. We presented a 8-year-old girl with psychomotor development delay. She was an adapted child. She attended a special education. On her physical examination was consisted with **alpha-**mannosidosis. The urine tests for mucopolysaccharides showed small amount of dermatan sulfate. The alpha-mannosidase enzyme activity was 1.6 umol/g/h (normal range: 100-800 umol/g/h), 3.2 umol/l/h (normal range: 20-100 umol/g/h) in white cells and plasma, respectively. Although **alpha-**mannosidosis is a rare disorder, it is important to consider the **alpha-**mannosidosis in the differential diagnosis of young patients with neurodevelopmental disabilities. We could not forget the importance of the screening for oligosaccharides in children with neurodevelopmental delay with mild phenotypic signs and symptoms. Early diagnosis allows more effective medical management and genetic counseling.

J13.02

Inflammatory cytokine gene expression profile in patients with coronary artery disease

J. Tavakkoly-Bazzaz[1], *M. M. Amoli*[2], *M. Khojasteh-Fard*[1], *P. Amiri*[2]*;*
[1]*Department of Medical Genetics, School of Medicine, Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran,* [2]*Endocrinology and Metabolism Research Center (EMRC), Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran.*

Objective. Both adaptive and innate immune systems are involved in coronary artery disease (CAD). The aim of this study was to evaluate cytokine expression profiles in un-stimulated peripheral blood lymphocytes (PBMCs) of patients with coronary artery disease.

Methods. Expression profiles of IL-4, IL-6, IL-10, IL-17, IL-23, INF-γ, TNF-α and TGF-β1 were determined in individuals with and without CAD using Real-time PCR.

Results. IL-4, and IL-10 gene expression were decreased in un-stimulated PBMCs of patients with CAD, while IFN-γ gene expression as a prototype of Th1 immune response and IL-6, were increased in patients with CAD compared to individuals without CAD. However, the differences were not significant. Nevertheless, a significant decrease in IL-23 gene expression in un-stimulated PBMCs of patients with CAD compared to those without CAD was found ($p<0.001$, 95% CI: 0.29-0.80).

Conclusion. Our data reinforce the potential role of the IL-23-IL-17 axis as a critical regulatory system that bridges the innate and adaptive arms of the immune system in the complex mechanisms associated with the development of atherosclerosis. Since IL-23 is main cytokine in Th17 pathway, future studies focusing on the role of Th17 immune response in atherosclerosis will be important to clarify the regulatory mechanisms involved in pathogenesis of CAD.

A Case of Persistent Neonatal Hypoglycemia

A. Manea[1], *M. Boia*[1], *D. Iacob*[1], *D. Nicoara*[2], *R. Iacob*[3]*;*
[1]*University of Medicine and Pharmacy Timisoara, Timisoara, Romania,* [2]*Clinical Emergency of Children Hospital, Timisoara, Timisoara, Romania,* [3]*County Emergency Hospital Arad - Departmentt of Pediatric Surgery, Arad, Romania.*

Introduction: Hyperinsulinism is the most common cause of persistent hypoglycaemia in early infancy. Hyperinsulinemic infants are usually macrosomic, reflecting the anabolic effects of insulin during pregnancy; also, in most cases there is no history of maternal diabetes. Common symptoms of hypoglycaemia are non-specific and include increasing demands for feeding, hypotonia, irritability, jitteriness, and frank seizures.

Case report: Two days old female newborn from a mother with no history of diabetes was admitted to our clinic presenting with macrosomia and severe hypoglycaemia for further management. Glucose level upon arrival was extremely low, 0.72 mg/dL (0.04 mmoL/L) and despite vigorous therapy the severe hypoglycaemia persisted throughout the first two months of life. Further investigations revealed inappropriately elevated insulin levels at the time of documented hypoglycaemia, as well as lack of acidosis or ketonuria. The presence of organomegaly, structural abnormality, and tumours was assessed by abdominal echography and CT scan

Conclusions: Blood glucose levels should be closely monitored in infants with hyperinsulinism even if the baby does not present with jitteriness, frank seizures or other signs of hypoglycaemia. An increase in glucose level of at least 40 mg/dL proves that glucose mobilization has been inhibited by insulin and that the mechanisms of glycogenolysis are intact.

Does inherited thrombophilia influence the course of Wilson disease?

A. Gusina, *S. Dubovik, S. Miasnikov, N. Gusina;*
National Research and Applied Medicine Centre "Mother and Child", Minsk, Belarus.

Wilson disease (WD) is an autosomal recessive disorder of copper balance leading to hepatic damage and neurological disturbance. Clinical manifestations include hepatic disease ranging from acute liver failure to chronic liver conditions more frequently. Mechanisms that influence the course and clinical presentation of WD are not well understood. Here we describe two young (25 and 20 years old) female patients whose WD manifested as acute liver failure first. Patient 1 was pregnant woman developed signs of preeclampsia and acute liver failure at 30 weeks gestation. Patient 2 had thromboembolic complications after the liver transplantation performed for acute liver failure. Inherited thrombophilia testing was performed in both patients before the diagnosis of WD was made and both were heterozygous for Leiden mutation. Later WD was confirmed and they were found to be compound heterozygotes for p.H1069Q and unknown mutation of ATP7B gene. The incidence of WD is 1 per 11000 and the frequency of heterozygous Leiden mutation is 2,9% in Belarus. The probability of random coincidence of these conditions is $2{,}6x10^{-6}$. We conclude that more studies are necessary to investigate the influence of inherited thrombophilia on course of WD. Inherited thrombophilia testing can be useful for patients with acute liver failure.

Preliminary Results of Early Diagnostics of Lysosomal Storage Diseases by Tandem Mass-Specrometry

A. Nagimtayeva, *G. Abildinova, M. Bayanova, B. Kamaliyeva, A. Kostina;*
National Research Center for Maternal and Child Health, Astana, Kazakhstan.

To measure the enzyme activity of dried blood spots by tandem mass spectrometry had used standard operation protocols (SOP) for the diagnosis of lysosomal storage diseases. Had examined the enzyme concentration β-glucocerebrosidase (ABG), galactocerebrosidase (GALC), α-galactosidase (GLA), α-iduronidase (IDUA) from 46th of newborns in dry blood spots by tandem mass spectrometry.

The substrate molecule had subjected to degradation products under the action of enzymes in extracts of dry blood spot. The appearance of products is directly proportional to enzyme activity.

The results of research had showed that the concentration of metabolites did not differ from the control of standard indicators. The values of enzyme activity were in the range of 95 percent and are consistent with low, medium and high levels of standards.

A novel IDUA gene mutation in an Iranian family affected by mucopolysaccharidosis type I

H. Aryan[1], A. Tajik[1], M. Sanati[2];
[1]Fazeli-Sanati genetic laboratory, Tehran, Islamic Republic of Iran, [2]National institute for genetic engineering and biotechnology, Tehran, Islamic Republic of Iran.

Mucopolysaccharidosis type I (MPS I) arises from a deficiency in the α-L-iduronidase (IDUA) enzyme. MPS-I is an autosomal recessive disease. Although the clinical spectrum in MPS I patients is continuous, it was possible to recognize 3 phenotypes reflecting the severity of symptoms, viz., the Hurler, Scheie and Hurler/Scheie syndromes. In this study, One Iranian MPS I family was investigated. The proband was a three years old girl who had severe symptoms of MPS-I including gibbus deformity of the lower spine, progressive skeletal dysplasia and linear growth ceases. After clinical investigation, DNA extracted from proband was sequenced for whole IDUA gene. In sequencing results 1 novel mutation was identified. It was a 32bp homozygote deletion located in IVS 5 and c.590-607 (exon6) deletion codon: 197-202. For more investigation and confirmation of the mentioned deletion we examined parents. Result approved heterozygote deletion for parents.
Key words: mucopolysaccharidosis type I, α-L-iduronidase, novel mutation.

Molecular Study of Multiple Endocrine Neoplasia type 2 in Iranian Patients

S. Dadgar[1], M. Dehghan Manshadi[1], O. Aryani[1], M. Houshmand[1,2];
[1]Special Medical Center, Dep. of Medical Genetics, Tehran -Iran, Tehran, Islamic Republic of Iran, [2]National Institute of Genetic Engineering & Biotechnology, Pazhohesh Blv. 17th Km Tehran-Karaj Highway, Tehran, Iran, Tehran, Islamic Republic of Iran.

Multiple endocrine neoplasia type 2 (MEN 2) is classified into three subtypes: MEN 2A, FMTC (familial medullary thyroid carcinoma), and MEN 2B. All three subtypes involve high risk for development of medullary carcinoma of the thyroid (MTC). MTC typically occurs in early childhood in MEN 2B, early adulthood in MEN 2A, and middle age in FMTC.
RET is the only gene known to be associated with MEN type 2. Molecular genetic testing of the RET gene identifies disease-causing mutations in 98% of individuals with MEN 2A, more than 98% of individuals with MEN 2B, and in about 95% of families with FMTC.All MEN 2 subtypes are inherited in an autosomal dominant manner. The probability of a de novo gene mutation is 5% or less in index cases with MEN 2A and 50% in index cases with MEN 2B. Offspring of affected individuals have a 50% chance of inheriting the mutant gene. Approximately 98% of families with MEN 2A have a RET mutation in exon 10 or 11 Prenatal testing is possible.
Testing for known common and rarer mutations is performed in our laboratory. PCR and Sequence analysis of exons 10, 11, 13, 14, 15, and 16 (hot spotes exons) was applied to detect these mutations.
Up to now, we investigated molecularly 7 cases suspected to MEN type 2 syndrome (majority with thyroid papillary carcinoma), each of these heterozygote mutations C 630 R (exon 11) , C634 F(exon11) , G691 S(exon11), L790 F(exon 13) were found in one patient , respectively.

New frameshift mutation in the *SMPD1* gene causesNiemann pick disease type A in a child from southwest Iran: A case report

H. Galehdari;
Genetics, Ahwaz, Islamic Republic of Iran.

Niemann pick disease type A (NPA: OMIM #607608) is a variants of a group of lipid storage disorders that is inherited in an autosomal recessive manner. The *SMPD1* gene encoding the enzyme sphingomyelinase is disrupted by pathogenic mutations, which leads to accumulation of sphingomyelin in different organs.
We report firstly a 2.5 years old boy with NPA in southwest Iran. Initially, the diagnosis resulted on the basis of consultation and clinical symptoms. The suspected individual was subjected to the molecular genetics diagnostics.
A novel mutation was observed at codon 247 in the *SMPD1* gene that might be causative for the formation of the disease.
The present report is the first molecular genetics diagnosis of the NPD type A in south west Iran.
The detected deletion in the *SMPD1* gene is remarkable because of its novelty.

J13.09

Two New Mutations in Iranian Niemman-Pick patients

M. Dehghanmanshadi[1], F. Keshavarzi[1], S. Dadgar[2], A. Arastehkani[3], O. Aryani[4], T. Zaman[5], M. Houshmand[6];
[1]Department of Biology ,Science and Research branch, sanandaj, Islamic Republic of Iran, [2]3Special Medical Center, Dep. of Medical Genetics, Tehran, Islamic Republic of Iran, [3]Department of Biology ,Science and Research branch, Islamic Azad university, sanandaj, Islamic Republic of Iran, [4]Special Medical Center, Dep. of Medical Genetics, tehran, Islamic Republic of Iran, [5]tehran university of medical sience, tehran, Islamic Republic of Iran, [6]National Institute for Genetic Engineering and Biotechnology, Dep. Of Medical Genetics, tehran, Islamic Republic of Iran.

Types A and B Niemann-Pick disease both result from the deficient activity of the lysosomal hydrolase, acid sphingomyelinase. Type A Niemann-Pick disease is a severe neurodegenerative disorder of infancy which leads to death by three years of age, whereas Type B disease has a later age at onset, little or no neurologic involvement, and most patients survive into adulthood.
The first symptom in NPD-A is hepatosplenomegaly, usually noted by age three months; over time the liver and spleen become massive. Psychomotor development progresses no further than the 12-month level, after which neurologic deterioration is relentless. Acid sphingomyelinase (ASM) deficiency is inherited in an autosomal recessive manner. SMPD1 is the only gene known to be associated with acid sphingomyelinase deficiency.
The SMPD1 gene is composed of six exons and is located on chromosome 11p15.1-11p15.4.
This study included 20 patients suffering from Niemann-Pick disease. The initial diagnosis was based on clinical and biochemical findings.
For genetic diagnosis ,all exons amplify and sequence to find defective mutations in this gene. The result showed Gly 508 Arg was found in 6 patients . This mutation was reported previously .Val 36 Ala was found in 3 patients And del CT in codon 473 was found in one patients. These mutations were not reported.

Association of the angiotensin converting enzyme (ACE) gene I/D polymorphism with sarcoidosis in Turkish patients

G. Sarı[1], E. Kurt[1], **F. Saydam**[2], I. Değirmenci[2], H. V. Güneş[2];
[1]Eskişehir Osmangazi University Faculty of Medicine, Department of Chest Diseases, Eskişehir, Turkey, [2]Eskişehir Osmangazi University Faculty of Medicine, Department of Medical Biology, Eskişehir, Turkey.

Sarcoidosis is a chronic inflammatory disease of complex pathogenesis and unknown etiology characterized by noncaseating epithelioid granuloma that invades the lung, eye, liver and other organs. Angiotensin converting enzyme (ACE) gene insertion (I)/deletion (D) polymorphism has been investigated for a genetic predisposition to sarcoidosis in different populations, but results have been inconsistent and inconclusive. This study was carried out to detect the frequencies of I/D polymorphism genotypes and allele of ACE gene in Turkish patients with sarcoidosis. Genomic DNA obtained from 154 persons (70 patients with sarcoidosis and 84 healthy controls) was used in the study. DNA was amplified by polymerase chain reaction using allele-specific primers. Amplified products were assessed with UV transilluminator by being exposed to 2% agarose gel electrophoresis. The allele frequencies and genotype distribution of the groups were analyzed with the chi-square test. There were no statistically significant differences between controls and sarcoidosis cases with respect to genotype distribution (x^2=4.202, p=0.122) and allele frequencies (x^2=1.358, p=0.244). Our results suggest that there is no genetic predisposition to sarcoidosis in Turkish population.

ACE genotype distrubution and allel frequencies
in Turkish patients with sarcoidosis and controls.

Groups	N	Male	Female	Genotype II (%)	Genotype DD (%)	Genotype ID (%)	D allele	I allele
Control	84	41	43	18 (21.4)	14 (16.7)	52 (61.9)	0.524	0.476
Sarcoidosis	70	18	52	15 (21.4)	21 (30)	34 (48.6)	0.457	0.543

VEGF gene mRNA expression in un-stimulated PBMCs of patients with coronary artery disease and its association with -2578*C/A polymorphism

M. M. Amoli[1], J. Tavakkoly-Bazzaz[2], P. Amiri[1];
[1]Endocrinology and Metabolism Research Center (EMRC), Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran, [2]Department of Medical Genetics, School of Medicine, Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran.

Objective: Based on previous reports on association between VEGF and pathogenesis of vascular disorders the aim of this study was to verify the expression of VEGF mRNA in unstimulated peripheral blood mononuclear cells (PBMCs) of patients with and without coronary artery disease (CAD) and comparing the expression of VEGF expression in patients carrying va-

rious genotypes for VEGF -2578*C/A polymorphism.
Methods: The study was performed patients who underwent coronary artery angiography and patients with >50% stenosis in vessels considered as case groups (CAD+) and normal vessels group as control (CAD-). VEGF mRNA expression was examined using quantitative real-time PCR and genotyping for VEGF -2578*C/A was performed using ARMS-PCR technique.
Results: VEGF mRNA expression was significantly decreased in CAD+ patients compared to CAD- patients (p=0.01, 95%CI=-4.2- -0.4). Also in patients carrying AA genotype VEGF mRNA expression was increased compared to patients carrying CC and CA genotype.
Conclusion: Increased expression of VEGF in patients without CAD is indicating an important role for VEGF in CAD development. More studies on larger number of samples are required to further confirm the results obtained in our study.

Prevalence of signs of Hurler and mild Hunter syndrome in infants of the first year of life

***N. V. Buchinskaya**, O. V. Kalashnikova, M. M. Kostik, V. G. Chasnyk;*
State Pediatric Medical Academy, Saint-Petersburg, Russian Federation.

Background: The prevalence of mucopolysaccharidosis (MPS) is 1 case in 16,000-30,000 births, and MPS II accounts for 80% of all cases. Clinical presentations depend on the type of enzyme defect. Usually patients with MPS initially have normal development and the signs of pathology are seen later in childhood, which causes late diagnosis and makes lower their quality of life.
Objectives: To evaluate the prevalence of pathologic signs during the first year of life in patients with MPS I and MPS II in order to diagnose MPS early.
Materials and methods: 7 children with MPS I (Hurler) and 5 children with MPS II (mild Hunter) were examined and their history was analyzed.
Results: Only 29% of MPS I and 20% of MPS II cases were diagnosed during the first year of life. During the first/second half of the first year of life MPS I manifested with hydrocephalus (71% / 86%), mental and neurologic retardation (43% / 71%), hearing impairment (29% / 43%), corneal clouding (29% / 43%), hepatomegaly (14% / 14%) while MPS II manifested with hydrocephalus (80% / 80%), umbilical or/and inguinal hernia (40% /
60%). In addition in the second half of the first year coarse facial features (43%) and umbilical hernia (14%) were revealed in MPS I and kyphoscoliosis (40%), coarse facial features (20%), hepatomegaly (20%) in MPS II infants.
Conclusions: The revealed prevalence of clinical signs can help a pediatrician to diagnose MPS I and mild MPS II during the first year of life.

J13.13

Analysis of side effects due to valproic acid in patients with epilepsy respective of SNPs polymorphisms in *CYP2C9, CYP2C19* and *MDR1*

***M. M. Danilova**[1,2], A. S. Glotov[1,2], T. V. Sergeeva[3], V. S. Baranov[1];*
[1]D.O.Ott Research Institute of Obstetrics and Gynecology, Saint-Petersburg, Russian Federation, [2]Saint-Petersburg State University, Saint-Petersburg, Russian Federation, [3]Bekhtereva's Institute of Human Brain, Saint-Petersburg, Russian Federation.

Epilepsy is a chronic disorder caused by brain lesion and characterized by repeated convulsive and/or other seizures. The valproic acid (VPA medication is the basic approach to the therapy of epilepsy. Detoxification of VPA and its major metabolites is known to be carried out by cytochrome P450 enzyme system with special emphasis on CYP2C9 and CYP2C19 as well as on ATP-binding cassette (ABC) transporter, P-glycoprotein-MDR-1. Analysis of VPA treatment efficiency respective of polymorphisms in SNPs in *CYP2C9* (430C>T and 1075A>C), *CYP2C19* (681G>A) and *MDR1* (3435C>T) was a main goal of the present study. PCR-RFLP analysis was carried out in 76 epilepsy patients and in 210 individuals of the control group. The genotype and allele frequencies of the relevant genes were different in the patient compared to the control groups (P>0.05, χ2<5.99). Chronic adverse complications were associated with *CYP2C9* allele (**2* and/or **3*), which correlates with reduced activity of this enzyme (P=0,048 F=0,049). The multivariate logistic regression analysis also supported that carriers of particular SNPs alleles have higher risk of chronic adverse events. Analysis of SNPs polymorphism in cytochrome P450 genes allows more precise control of the necessary dosage of VPA medication, thus making epilepsy treatment more efficient, personalized and less toxic.

J13.14

Chinese Hamster Ovarian (CHO) cell lines expressing mutant ATP7B

***E. Scvortova**[1,2], T. Todorov[3], V. Sacara[2], A. Zibert[3], H. H. J. Schmidt[3];*
[1]University of Academy of Sciences of Moldova, Chisinau, Republic of Moldova, [2]National Center of Reproductive Health and Medical Genetics (NCRHMG), Chisinau, Republic of Moldova, [3]Clinic for Transplantation Medicine, Muenster University Hospital, Muenster, Germany.

Wilson disease (WD) is a rare autosomal recessive disorder of copper (Cu) homeostasis that is caused by mutations of gene *ATP7B.* WD patients mostly present hepatic and/or neurological manifestations, however, severity and age of **onset** are variable. We explored whether Cu resistance of tissue culture cell lines that express specific mutations of *ATP7B* can predict severity and course of disease. Chinese Hamster Ovary cells that lack intrinsic *ATP7B* expression were used for stable expression of *ATP7B* mutants by retroviral vectors. 12 mutations were chosen for analysis from reports of homozygotic patients. To determine Cu resistance MTT assay was established. *ATP7B* protein expression was determined by Western-blot analysis. Cu resistance of the cell lines appeared to be highly specific and could be classified into three groups. The first group showed high copper resistance similar to that of wild-type *ATP7B*. The second group showed low copper resistance similar to native CHO cells, the third group displayed intermediate resistance. Magnitude of *ATP7B* protein expression correlated with level of Cu resistance in most but not all cases. *ATP7B* mutants found in patients having a mild clinical presentations were highly resistant to Cu. In contrast, an early onset and severe disease was found in the group of mutants that showed low Cu resistance. The third group with intermediate Cu resistance was heterogenous with respect to clinical manifestation of disease. Our observations indicate that functional characterization of *ATP7B* mutants can give further insights into the understanding of individual mutations and for prediction of WD.

The mutational spectrum of Phenylketonuria in Egypt : A unique pattern of mutations including four common mutations and five novel mutant PAH alleles.

***L. K. Effat**;*
Division of Human Genetics and Genome Research, giza, Egypt.

Phenylketonuria (PKU) is one of the most common inborn errors caused by deficiency of the hepatic phenylalanine hydroxylase gene (PAH). Extensive studies identifying mutational spectrum of PKU have been published during the last two decades. The frequencies of the different mutations vary in different locations of the world. On the basis of phenotype/genotype correlations, determination of phenylketonuric genotype is crucial for better classification of the clinical phenotype and treatment, including tetrahydrobiopterin therapy. We report here on the mutational spectrum of *PAH* gene in 150 Egyptian families using the following systems: (1) PCR-RFLP analysis for common Mediterranean mutations; (2) single stranded conformational polymorphism; (3) direct sequencing; and, (4) Long range PCR for detection of large deletions. Of the 300 mutant alleles, 288 (96%) were genotyped and a total of 25 distinct mutations were identified including 5 novel mutations. R176X, R243X, Y198fs and IVS10-11G>A were prevalent mutations in our population. The mutational data obtained reflects a unique pattern of mutations in Egyptian patients with PKU which will permit precise carrier detection, prenatal diagnosis and genetic counseling for these families.

Strong association between ABCB1 gene (MDR1) 3435 C>T polymorphism and multiple drug nonresponder patients of chronic hepatitis C

***O. Ozdemir**[1], H. Alagozlu[2], M. Timucin[3];*
[1]Department of Medical Genetics, Faculty of Medicine, Canakkale Onsekiz Mart University, Canakkale, Turkey, [2]Department of Medical Genetics, Faculty of Medicine, Cumhuriyet University, Sivas, Turkey, [3]Department of Gastroenterology, Faculty of Medicine, Cumhuriyet University, Sivas, Turkey.

The curing viral infection of chronic hepatitis C (CHC) is a main strategy to prevent progression of liver disease and cancer. Some CHC patients are failed to respond to common antiviral theray in some populations. In the current study it was aimed to find the possible role of multidrug ressistance gene 1 polymorphism(MDR1) in nonresponder patients with CHC. Peripheral blood samples were used for total genomic DNA isolation. In a total of 55 HCV positive patients [31 male (56.4%), 24 female (53.6%) and mean age-min-max; 56.9±9.66 (39-71)]; 19 responder (34.5%) 21 non-responder(38.2%) and 15 recurrence (27.3%) were included, genotyped for functional MDR1 gene polymorphism. Target gene were genotyped by multiplex PCR-based reverse-hybridization StripAssay method. The current results indicate that codon 3435 C>T polymorphism in exon 26 of MDR1 gene is associated with colchicine resistance in nonresponder CHC patients.

J14.02

Creation of the carriers containing gene encoding site of apolipoprotein B100 and green fluorescent protein (GFP) gene for transfection into eukaryotic cells.

***E. A. Vasileva**, V. A. Zemkov, D. S. Polyakov, N. A. Grudinina, K. V. Solovyov, T. D. Aleynikova, M. M. Shavlovsky;*
Department of molecular genetics, Institute of Experimental Medicine Nord-West Branch of Russian Academy of medical sciences, St.Petersburg State, Russian Federation.

The purpose of this work is creation of new carrier for transfection the genetic information into eukaryotic cells. Apolipoprotein B100 (apoB) provides binding of low-density lipoprotein (LDL) particles to the receptor. Such cells as hepatocytes, fibroblasts and lymphocytes have LDL-receptor. We have created fusion protein consisting GFP and high conservative receptor-binding region named site B (3359-3369) of apoB. Site B is strongly requied for interaction between carrier and cells LDL-receptor, and its entering into the cells. Presence of GFP in the recombinant polypeptide will help to determine the localization of the protein by fluorescence microscopy. We used plasmid pTRC99a-p7 with two unique restriction sites for SalI (after sfGFP) and HindIII (downstream). We have created plasmid with GFP gene, sequence encoding site of apoB, five histidine codons for chromatography purification of recombinant and stop codon. The resulting plasmid was successfully sequenced. As a result we synthesized protein, which peaks of excitation and emission were equal to the GFP peaks. It had high affinity to nickel agarose. This fusion protein is basis of new construction for transfection the genetic information into eukaryotic cells. It contains GFP and site B of apoB. Amino-acid sequence of siteB could be used as an alternative way of delivery of different therapeutic substances into eukaryotic cells. Studies on cell cultures are expected.

Complexity of rehabilitation treatment in a case with limb-girdle muscular dystrophy

***S. Mihalcea**[1], M. Cevei[2], D. Stoicanescu[3];*
[1]Medical Rehabilitation Clinical Hospital, Baile Felix, Romania, [2]University of Oradea, Faculty of Medicine and Pharmacy, Oradea, Romania, [3]University of Medicine and Pharmacy „Victor Babes", Timisoara, Romania.

Limb-girdle muscular dystrophy comprises a heterogeneous group of disorders, with progressive evolution, affecting especially proximal limb musculature. Here we report the case of a 39-year-old man with autosomal recessive limb-girdle muscular dystrophy, with negative family history, diagnosed 7 years ago. The clinical examination revealed major motor deficit, severe muscle hypotrophy in the scapulohumeral girdle and arms, impossibility to perform active movements of the scapulohumeral joint, regarding passive movements abduction and flexion limited to 90 degrees. Walking and standing were impossible, requiring wheelchair, person-assisted transfers from clinostatism to sitting position. He can maintain a sitting position without hand support, but otherwise requires constant help of another person. Assessment with functional ambulation classification showed that the patient needed firm continuous support from one person, who helps carrying weight and with balance. Particularity of the case is represented by the rapid evolution, with impaired self-care capacity and occurrence of osteoporosis due to immobilization. In 2010 he fell when transferring from wheelchair to bed, with the fracture of left body of tibia, right humeral head, resulting into the complex regional pain syndrome. Rehabilitation program objectives were maintaining mobility, transfers re-education, gain maximum independence. Methods were medication and physical-kinetic treatment for basic disorder and complications, with hydrokinetotherapy, massage, electrotherapy, laser. The patient should have done daily kinetic program, but plaster immobilization forced him to interrupt exercises, with repercussions on the achieved performances. Early diagnosis and improvements in management of patients with this disorder by a multidisciplinary team will improve their prognosis and quality of life.

J14.04

Intrathecal Enzyme Replacement Therapy for Neurological Impairment in Mucopolysaccharidosis 1(4 Iranian cases)

***F. Hadipour**, Y. Shafeghati, P. Sarkhail, Z. Hadipour;*
Medical genetics Department,Sarem Cell Research Center & Hospital, Tehran, Islamic Republic of Iran.

MPS1 is an autosomal recessive disorder caused by deficient activity of the lysosomal enzyme alpha-L iduronidase, which leads to accumulation of heparan sulfate and dermatan sulfate, resulting in a progressive multisystem disease with respiratory, skeletal, and neurologic manifestations. Treatment for MPS1 consists of supportive care, and enzyme - replacement therapy with Laronidase. Bone marrow and hematopoietic stem cell transplantation is the treatment of choice for patients suffering from MPS1 with no or minimal central nervous system manifestation.

Case Report: We report 4 Iranian cases of MPS type 1, 3boys who are 60 months-old, 34 months-old, & 30months -old; and 1 girl who is 41 months-old .They have phenotype of MPS1, coarse facial features, prominent forehead, corneal cloudy, sleep disturbance, hepatosplenomegaly, inguinal hernia, joint stiffness, and dysostosis multiplex congenital. They diagnosed MPS1 on the basis of clinical findings, an elevated urinary glycosaminoglycan level and low alpha- L- iduronidase activity in leukocytes. For 3 of the cases mutation analysis revealed homozygous mutation in the IDUA gene, and for one of them reveals novel mutation . They have been started injection of aldurozyme intravenously every week from 26 months - old, 18 months-old, 12 months-old, and 19months-old. To prevent neurological impairment before bone marrow transplantation, they receive intrathecal enzyme replacement of aldurozyme monthly from 29 months-old, 21months-old, 21months-old, and 31 months-old. They tolerate intrathecal ERT with no adverse events. One of them when he was 50 months - old, he received bone marrow transplantation, but others are now receiving aldurozyme intravenously and intrathecally.

The Spinal Muscular Atrophy Therapeutics: Progress and Promise

***A. Ben Itto**;*
LGPM, Casablanca, Morocco.

Spinal muscular atrophy (SMA) is an inherited neuromuscular disorder that causes degeneration of α-motor neurons. Frequently, muscle weakness is very severe causing affected infants to die before reaching two years of age, but mild forms of the disease can be characterized by relatively static muscle weakness for many years. SMA is caused by recessive mutations of the SMN1 gene, but all patients retain at least one copy of SMN2, a similar gene capable of producing low levels of full-length SMN protein. No treatments currently exist for SMA patients, but the identification of therapeutic targets as Hydroxyurea ,Quinazoline derivatives, Salbutamol, Small molecules , Antisense oligonucleotides, aminoglycosides and proteasome inhibition , Riluzole and Ceftriaxone, Olesoxime and Embryonic stem (ES) cells also the development of suitable animal models for preclinical testing have resulted in increased drug development efforts in the past ten years. Here, we review the current status of many of these programs, including those designed to activate SMN2 gene expression, modulate splicing of SMN2 preRNAs, stabilize SMN protein, replace SMN1, provide neuroprotective support, and transplant neural cells. The knowledge of SMA pathogenesis and the development of clinical candidates have increased considerably since the discovery of the disease-causing gene. Drug development in SMA has been characterized by robust collaborative efforts between academic, government, pharmaceutical, and non-profit organizations. As the promise of a treatment for this devastating disease continues to grow, we are hopeful that progression over the next 15 years will be even more rapid than the last.

The effect of age and strain on screening, proliferation, and differentiation of chicken bone marrow mesenchymal stem cells

***F. Piryaei**[1], F. Piryaei[2], M. Ramezani[3];*
[1]Department of Biology, Payame Noor University of Tehran, Tehran, Iran, Tehran, Islamic Republic of Iran, [2]National Institute of Genetics Engineering and Biotechnology, Tehran, Islamic Republic of Iran, [3]Dept. of Biology, Faculty of Science, Islamic Azad University, Ashtian Branch, Ashtian, Iran, Tehran, Islamic Republic of Iran.

Background: Noticing the practical significance of stem cells, this study was conducted to culture and screen bone marrow mesenchymal stem cells derived from Raf and Hilline chicken strains and investigate the effect of age and race on the morphology and differentiation of the generated cells.

Materials and Methods: In this fundamental study, bone marrow cells from 3 to 25 day-old Raf and Hiline chicken strains were cultured in low glucose DMEM, 10% BFS. Then third passage bone marrow cells of the two strains were compared in terms of morphology, differentiation to bone, cartilage, and adiposity. Data were analyzed through SPSS software.

Results: In culturing Raf chicken derived bone marrow cells, in contrast to Hiline chicken strain, colonization took place and they almost had a better fibroblastic morphology. The results indicated higher yields of differentiation to bone, cartilage, and adipose tissues in Raf chicken derived bone marrow cells than Hiline chicken. These differences were statistically significant. Also, 15 days was the most suitable age for screening the mesenchymal stem cells of chicken.

Conclusion: Screening and proliferation of mesenchymal stem cells from 15-day old Raf chicken bone marrow cells are good resources for differentiation and purification of chicken bone marrow mesenchymal stem cells.

Treatment with bisphosphonates in osteogenesis imperfecta

S. Bucerzan[1], *C. Al-Khzouz*[2], *M. Crisan*[3], *C. Denes*[3], *P. Grigorescu-Sido*[2];
[1]*First Pediatric Clinic - UMF ,Iuliu Hatieganu, Cluj-Napoca, Romania,* [2]*First Pediatric Clinic - UMF „Iuliu Hatieganu", Cluj-Napoca, Romania,* [3]*First Pediatric Clinic, Cluj-Napoca, Romania.*

Introduction. Osteogenesis imperfecta, a genetic disease of bone formation, with autosomal recessive trait, is characterized by bone fragility and reduced bone mass due to mutations in genes coding for type I collagen. Different severity of clinical signs is due to imperfect genotype-phenotype correlation. Because the treatment with bisphosphonates (antiresorptive agents that inhibit osteoclast function and stimulates osteoblastic bone formation) was recently introduced, the authors have proposed to evaluate the effects of pamidronate in patients with osteogenesis imperfecta.

Patients and method. The study group consisted of 11 patients (3 girls and 8 boys), aged between 4 ys 1 mo - 18 ys 3 mo, who were registered in the Centre of Genetic Disease of the First Pediatric Clinic Cluj with osteogenesis imperfecta. The method consisted in: clinical and bio-humoral assessment regarding the parameters of bone mineralization, radiological examinations, osteodensitometry; assessing occupational score.

Results. Treatment with bisphosphonates (commercial preparations Aredia) was administered in 2 - 14 cycles, at a dose of 0.5 - 1 mg/kg/day IV infusion, 3 consecutive days at 4 months interval. The drug was well tolerated, the only side effect being fever recorded in the first cycle of treatment in 4 patients. Bio-humoral parameters of phospho-calcic metabolism remained within normal limits, except for reduced alkaline phosphatase values in a girl who associated hipophosphatasia tarda. Bone pain has resolved, fractures have not occurred (except in one patient), occupational score and Z score were improved.

Conclusions. Under bisphosphonates treatment the clinical symptoms, occupational score and Z score were improved.

J14.08

A cell model system to monitor the translocation of Ataxin-3 in SCA3

Z. Wang, *T. Schmidt;*
Human Genetics Institute, Tuebingen, Germany.

Spinocerebellar ataxia type 3 (SCA3), also known as Machado-Joseph disease (MJD), is an autosomal dominantly inherited neurodegenerative disorder caused by the expansion of a CAG repeat in the MJD1 gene encoding a expanded polyglutamine repeat in the Ataxin-3 protein. Ataxin-3, the affected protein in SCA3, is mostly a cytoplasmatic protein, however, it distributes to different subcellular regions i.e the cytoplasma and the nucleus in different cell types. The characteristic hallmark of this disease is the formation of Neuronal intranuclear inclusions (NII) including expanded and misfolded causative protein. Whether NII are toxic or protective, their presence indicated that expanded ataxin-3 plays a role in the nucleus. In addition, transcriptional regulation of ataxin-3 occurs in the nucleus and nuclear localization of ataxin-3 indeed aggravate the symptoms in SCA3 animal model. Therefore, if ataxin-3 localizes in the nucleus, this is a negative event. Prevention of ataxin-3 nuclear translocation maybe ameliorate this disease progression. To gain insight into how to inhibit the translocation of Ataxin-3, we will undertake a small molecular library screen to explore which small molecules influence the location of this protein in a SCA3 cell model, analyze the mechanisms regulating Ataxin-3 transport and attempt to develop a therapeutic strategy for this disease. For this, a high-throughput screening method is established in this project.

Cloning and transient expression of cytoprotective factor, Nrf2, in mesenchymal stem cells using the adenoviral expression system through Gateway technology

M. Mohammadzadeh, ***M. Habibi Roudkenar***;
Transfusion Research Center, High Institute for Research and Education in Transfusion Medicine, Tehran, Islamic Republic of Iran.

Background and Objectives: Nuclear factor erythroid-2 related factor 2 (NRF2) is one of the potent cytoprotective factor. The goal of this study was cloning and transient over expression of the human Nrf2 gene in MSCs using the adenoviral expression system based on gateway technology.

Material and Methods: In order to induce expression of Nrf2, MSCs were exposed to UV for 1 hour. Full length cDNA of Nrf2 was isolated and cloned into pENTR TOPO/D vector by TOPO cloning reaction. To construct the expression clone, a LR recombination reaction was carried out between the entry clone and destination vector, pAd/CMV/V5-DEST. The Recombinant virus was produced in appropriate mammalian cell line. MSCs were infected by the recombinant virus expressing Nrf2.

Results: The results showed that human recombinant Nrf2 was successfully cloned and the accuracy of the gene and its frame in the vector were confirmed by DNA sequencing. Expression of Nrf2 in MSCs was confirmed by RT-PCR and western blot analysis. The results indicated that the expression of Nrf2 is transient.

Conclusions: The adenoviral expression system through Gateway technology was successfully used to clone and over-express cytoprotective factor, Nrf2, in MSCs.

Italian National External Quality Assessment in molecular genetic testing - VII round (2010-2011)

F. Censi, *M. Marra, F. Tosto, G. Floridia, V. Falbo, D. Taruscio;*
Centro Nazionale Malattie Rare - Istituto Superiore di Sanità, Roma, Italy.

The Italian External Quality Assessment for molecular genetic testing, coordinated by the Istituto Superiore di Sanità, started in 2001; it cover four pathologies: Cystic Fibrosis (CF), Beta Thalassemia (BT), Fragile X-Syndrome (FX) and Familial Adenomatous Polyposis Coli (APC). A web utility dedicated to this activity has been developed and, since 2010, participation is open both to public and private Italian laboratories.

In 2010 the number of participants was 53; 43, 17, 15 and 5 laboratories participated for CF, BT, FX and APC schemes respectively.

In each scheme four DNA samples were validated and sent to participants together with clinical and technical information. Laboratories were asked to use their routine procedures and protocols to analyse samples. A panel of assessors reviewed the final returns to assess the quality of genotyping, interpretation and reporting.

In 2010 assessors reviewed 320 genetic testing analyses. Genotyping results showed complete and correct data in 98.5%, 95.9%, 100%, 100% of CF, BT, FX, APC samples analyzed respectively; satisfactory interpretation of data was recorded only in 9.9%, 32%, 20%, 40% of CF, BT, FX, APC reports respectively; lack of information/inaccuracy in reports was detected in all schemes.This work will show in detail all 2010 results comparing, when possible, our data with those of other European schemes.

J15.03

The Italian External Quality Assessment in classical cytogenetics: results of the 2010/2011 round

G. Floridia, *F. Censi, F. Tosto, M. Marra, V. Falbo, D. Taruscio;*
Centro Nazionale Malattie Rare, Istituto Superiore di Sanità, Roma, Italy.

The Italian External Quality Assessment in classical cytogenetics, coordinated by the Istituto Superiore di Sanità, started in 2001 and covers prenatal, postnatal and oncological diagnosis. The scheme is retrospective and each part of the scheme stands alone; a web-utility dedicated to the CEQ has been developed.

Since 2010 the EQA has been recognised as istitutional activity; laboratories pay a fee for each scheme as published in an official document issued by the Italian government (GU n.199-28th August 2009). Participation is open either to public and private laboratories.

Assessment takes into account technical, analytical and interpretative performance; an assessment system with scores was developed. Assessors are selected in collaboration with the Italian Society of Human Genetics and, at the end of the round, participants receive a report with marks and comments to improve the analysis.

The total number of laboratories participating in 2010-VII round was 69, 17 of them were private (i.e. 40%); in particular 55, 60 and 22 laboratories participated in the prenatal, postnatal and oncological scheme respectively. A banding quality not adequate for the analysis was observed in about 6% and 10% of 108 prenatal and 120 postnatal cases respectively; an analytical error was identified in one case, out of 44, in oncological diagnosis. An use of the nomenclature ISCN not appropriate was detected in about 15%, 13% and 75% of reports in prenatal, postnatal and oncological diagnosis respectively. Not completeness and/or inadequacy of information in reports was the most frequent analytical inaccuracy recorded in all schemes.

Priority setting in genetic testing: a pilot discrete choice experiment

F. Severin[1], *J. Schmidtke*[2], *A. Mühlbacher*[3], *W. Rogowski*[1];
[1]Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Germany, [2]Hannover Medical School, Institute for Human Genetics, Hanover, Germany, [3]Hochschule Neubrandenburg, University of Applied Science, Neubrandenburg, Germany.

Given the increasing number of genetic tests available for clinical practice, decisions have to be made on how to allocate limited health care resources to them. Many criteria have been proposed to guide the process of priority setting. However, their relative importance is still unclear. This paper explores the feasibility of discrete choice experiments to identify and weight various criteria in a form that allows prioritisation through a rank ordering of different testing options. Therefore a pilot discrete choice experiment was carried out, using face-to-face interviews, among 22 genetic professionals. Respondents chose between two generic scenarios (dual choice options) that described testing options, represented by medical and non-medical attributes. Choice data was used to rank order a set of seven testing options on the basis these attributes and their relative weights. A series of follow up questions were asked to learn about participants' understanding of the choice format and potential improvements in the discrete choice instrument. The criteria "Prevalence", "Severity", "Clinical Utility" and "Alternatives available" were significant, all including "Infrastructure available" and "Urgency" had positive signs. A preliminary rank order of tests could be established. Findings from this pilot demonstrate the discrete choice methodology to be a feasible approach to use stated preference techniques in priority setting of genetic tests. We believe that the DCE framework is an important step towards the development of a rational approach to priority setting that meets the needs of decision makers.

EPL1.2

First Trimester Screening, it's not a routine test An education module for General Practitioners to help women to make an informed choice

K. K. Barlow-Stewart[1,2], *K. Dunlop*[2];
[1]University of Sydney, Sydney, Australia, [2]Centre for Genetics Education, Sydney, Australia.

In NSW, Australia, health care professionals should inform all pregnant women about first trimester screening (FTS) and give appropriate risk information to enable an informed choice. This requirement usually applies to general practitioners (GPs), with increased risk results usually referred to genetic counsellors (GCs) or obstetricians. Challenges for GPs include addressing patients' different perceptions and interpretations of risk; presenting the pros and cons of screening; the possible implications of an increased risk result; the potential for coercion in guiding decision making; and the inconsistencies in the availability of FTS and genetic counselling services. To support GPs, and at the request of providers of professional development, an education module, First Trimester Screening- it's not a routine test, was developed to be used in group educational settings or stand alone. Content included a slide presentation of information and three video case studies of GP consultations that addressed issues anecdotally reported to commonly occur. Process evaluation consisted of piloting the module in GP education sessions (1 hr 52 GPs) and GCs (5). The module was rated highly relevant, useful and reflected questions that arise in GP practice (96%) and comments included prompting future more thorough discussion of FTS, having discuss over more than one session, adopting ideas from the way the GP in the videos phrased her comments and be more confident. 13% of GPs requested a further video case discussing increased risk results be included. The next process evaluation results following incorporation of recommendations will be presented.

EPL1.3

What do pregnant women and their partner know about Down Syndrome when they decide to undergo prenatal diagnosis?

C. Ingvoldstad[1], *P. Lindgren*[2], *G. Annerén*[3], *E. Ternby*[2], *O. Axelsson*[4];
[1]Department of Public Health and Caring Sciences, Uppsala University, Uppsala, Sweden, [2]Department of women´s and children´s health, Uppsala University, Uppsala, Sweden, [3]Department of genetics and pathology, Uppsala University, Uppsala, Sweden, [4]Department of women`s and children´s health, Uppsala University, Uppsala, Sweden.

Information to expecting parents about prenatal diagnosis (PND) for chromosomal aberrations focus on the risk of bearing children with chromosomal abnormalities, i.e. Down syndrome (DS), and the risks associated with amniocentesis and chorionic villus sampling. Routinely, no information is given about the symptoms of DS and the consequences for the child and the family. This study examined what prospective parents know about medical, cognitive and social aspects of DS. A questionnaire was answered by 208 parents taking a CUB test (combined ultrasound and biochemistry) at Uppsala university hospital during 2011.

Only 25% of the parents had received information about DS and more than 60% would like more information. The reason for taking a CUB test was, for 70% of the parents to get a warranty of a healthy child. Half of the parents had not taken a position on what to do if the CUB test showed an increased risk of DS. Almost all knew that DS is caused by a chromosomal abnormality. Still there was a vast lack of knowledge about medical and cognitive complications in children with DS, as well as social consequences for the children and the families.

This study shows that a high proportion of parents who undergo a CUB test have little knowledge of DS and might consider invasive PND procedures, and perhaps also pregnancy termination, without knowing what Downs syndrome implies. Improved information to expecting parents about medical, cognitive and social consequences of DS, could help the parents to make informed decisions regarding PND.

EPL1.4

How do women make decisions about genetic carrier screening for fragile X syndrome? A qualitative study

A. G. Ames[1,2], *A. D. Archibald*[1], *R. Duncan*[1], *J. Emery*[3], *S. A. Metcalfe*[1,2];
[1]Murdoch Childrens Research Institute, Melbourne, Australia, [2]University of Melbourne, Parkville, Australia, [3]The University of Western Australia, Crawley, Australia.

Background:

As population-based genetic carrier screening becomes more common there is increasing need to evaluate decision-making, ensuring participants make free and informed choices. Carrier screening for fragile X syndrome (FXS), the leading cause of inherited intellectual disability, provides individuals with information about their health and risk of having children with FXS. It is important individuals participating understand the personal and familial implications of such screening. This study aimed to explore perceptions and decision-making styles of non-pregnant women from the general population offered FXS carrier screening in Australia.

Methods: Purposive sampling was used to select equal proportions of participants who declined and accepted screening. 37 qualitative, semi-structured telephone interviews were conducted after women accepted or declined screening, but prior to receiving test results (if tested). Interviews were transcribed with data coded into themes.

Results: A range of decision-making styles emerged from the data, including: relying on initial gut reaction, being influenced by previous experiences and in-depth deliberation. Most participants felt they made an informed decision, although there was substantial variation in perceptions of an informed decision and a 'good decision'. Preliminary analysis suggests differences in how informed decisions are defined in the literature and perceived women considering screening.

Implications: This research provides valuable insight into women's decision-making processes and how they view an 'informed decision'. These data will be instrumental in informing the development of tools for evaluation of informed decision-making in genetic screening programs and in determining how best to support women through the testing process in the future.

EPL1.5

Development and validation of a short family history screening tool for chronic disease prevention in primary care

F. M. Walter[1,2], *T. A. Prevost*[1,3], ***L. Birt***[1], *N. Grehan*[1], *K. Restarick*[1], *H. C. Morris*[1], *P. Rose*[4], *S. Downing*[5], *S. Sutton*[1], *J. D. Emery*[2,1];
[1]University of Cambridge, Cambridge, United Kingdom, [2]University of Western Australia, Perth, Australia, [3]King's College London, London, United Kingdom, [4]Oxford University, Oxford, United Kingdom, [5]Addenbrooke's Hospital, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom.

Introduction: Family history (FH) is an important risk factor for many common diseases, yet no simple, validated tools exist in primary care for accurate FH management. We aimed to develop and validate a short FH screening tool for systematic FH assessment in primary care. Diabetes (DM), ischaemic heart disease (HD), breast (BC) and colon cancer (CC) were selected as marker conditions as they fulfil screening criteria, and effective interventions and lifestyle strategies exist for their primary and secondary prevention.

Methods: Participants were identified via randomised electronic searches in 10 Eastern England general practices. During a practice-based consultation participants completed a FH Questionnaire (FHQ), then had a 3-generational ‚gold standard' pedigree taken. In stage 1 the FHQ comprised 12 items; in stage 2 the shorter FHQ was validated against the same 'gold standard'

pedigree, and the psychological impact of FH screening was examined using questionnaires containing validated measures at baseline and 4 weeks.
Results: 1,147 participants were recruited (stage 1: 618; stage 2: 529). Among stage 1 participants, 32% were at increased risk of one or more marker conditions (DM 18%, HD 13%, BC 5%, CC 2%). Determination of the sensitivity, specificity, and predictive values of each item allowed the refinement of the FHQ to 6 items for identification of any of the four conditions (sensitivity 91%, specificity 61%). Results of stage 2 validation of the FHQ-6 will be presented, with psychological findings indicating that FH knowledge, including awareness of being at increased risk, does not increase anxiety.

EPL1.6

Measuring patient benefits from interventions in clinical genetics and genetic counselling services: Are we finally able to do this?

M. McAllister[1], *A. M. Wood*[2], *G. Dunn*[2], *K. Payne*[2], *L. Davies*[2], *D. Donnai*[3], *R. MacLeod*[2], *C. Todd*[2];
[1]*Cardiff University, Cardiff, United Kingdom,* [2]*University of Manchester, Manchester, United Kingdom,* [3]*St Mary's Hospital, Manchester, United Kingdom.*

An enduring challenge in evaluating interventions in clinical genetics and genetic counselling is how best to measure patient benefit. Patient Reported Outcome Measures (PROMs) offer a possible solution. PROMs are self-completion questionnaires used in research to evaluate patient benefits from new interventions e.g. in randomised controlled trials, and for service evaluation in routine clinical practice. PROMs differ from satisfaction questionnaires because they measure change over time in outcomes valued by patients, rather than simply reporting satisfaction with service received. Current UK health policy encourages use of PROMs data. But in clinical genetics, there is no consensus about the best PROMs to use. A research programme involving ~450 patients and 130 clinicians tackled the issue of PROMs use in clinical genetics (Manchester 2003-2011). Mixed methods were used to identify patient benefits: (a) a systematic review of validated outcome measures used (b) a Delphi survey to identify consensus amongst clinicians and patients about appropriate outcome domains and (c) qualitative interviews and focus groups. The next stage involved validating the Genetic Counselling Outcome Scale (GCOS-24), a new PROM developed from the qualitative data, and the existing Perceived Personal Control (PPC) scale. Both PROMs were proven to (i) have high internal consistency (PPC: Cronbachs α=0.83, GCOS-24: α=0.87) (ii) have concurrent validity with health locus of control, satisfaction with life, depression, and authenticity and (iii) capture statistically significant patient benefit following clinic attendance (PPC: Cohens d=0.4, GCOS-24: d=0.7). These properties suggest that both GCOS-24 and PPC are appropriate validated PROMs to evaluate clinical genetics services.

EPL2.1

Breast cancer risk communication by health care providers' in 4 European countries

C. Julian-Reynier[1,2,3], *A. Bouhnik*[1,2], *G. Evans*[4], *H. Harris*[5], *C. van Asperen*[6], *A. Tibben*[7,8], *I. Nippert*[9];
[1]*INSERM, UMR912 „Health Economy, Social Sciences & Medical Information Processing" (SESSTIM), Marseilles, France,* [2]*Aix-Marseille Université, UMR-S912, Marseille, France,* [3]*Institut Paoli-Calmettes, Marseille, France,* [4]*Medical Genetics Research Group, Regional Genetics Service and National Molecular Genetics Reference Laboratory, Central Manchester Foundation Trust, St Mary's Hospital, Manchester, United Kingdom,* [5]*GenEd Coordinating Centre, University of Manchester, Manchester, United Kingdom,* [6]*Center for Human and Clinical Genetics, Department of Clinical Genetics, Leiden University Medical Center (LUMC), Leiden, Netherlands,* [7]*Centre of Human and Clinical Genetics, Leiden University Medical Centre (LUMC), Leiden, Netherlands,* [8]*Department of Clinical Genetics, Erasmus MC, Rotterdam, Netherlands,* [9]*Women's Health Research, Münster Medical School, Münster, Germany.*

Cancer genetic clinics are focused on communication of familial/genetic risks but other factors intervene in breast cancer (BC). Our objective was to investigate the options chosen by European Breast Surgeons (BS) and General Practitioners (GP) to present BC risk factors according to the « state of the art » of a better risk communication.
Questionnaires were sent to 3999 GPs and 3293 BS in 4 countries (UK, France, the Netherlands, Germany). Assessment of family risks and communication about risk factors including alcohol, obesity, oral contraception, hormonal replacement therapy (HRT), physical exercise, early pregnancy, breast-feeding were investigated as well as the formats preferred to present risks (numbered, verbal, framing …).
The overall answer rates were 30% and 37% for GPs and BS, respectively. Risk family history and HRT were the most frequently risk factors explained by GP's and BS. Countries and providers differed significantly ($p<0.001$) for the kind of factors discussed particularly for those other than family history. Event frequency was the most frequently used presentation (47% GPs; 52% BS), particularly in UK. Absolute risks were more frequently presented than relative risks. Only 11% of GPs' and 17% of BS would present risk communication including absolute and relative risks with both negative and positive framing and no verbal presentation. Preferences and declared behaviours will be presented according to specialty and country after multivariate adjustment on personal characteristics.
In order to optimise cancer risk communication in medicine, initial and vocational training could be reinforced by published guidelines issued from multidisciplinary task forces.

EPL2.2

International variation in physicians' attitudes towards prophylactic mastectomy - comparison between the UK, France, Germany, and the Netherlands

M. den Heijer[1], *C. J. van Asperen*[2], *H. Harris*[3], *I. Nippert*[4], *C. Julian-Reynier*[5], *G. Evans*[6], *A. Tibben*[2];
[1]*Department of Clinical Genetics, Erasmus MC, Rotterdam, Netherlands,* [2]*Department of Clinical Genetics, Leiden University Medical Centre, Leiden, Netherlands,* [3]*GenEd Coordinating Centre, University of Manchester, Manchester, United Kingdom,* [4]*Women's Health Research, Munster Medical School, Munster, Germany,* [5]*U912, INSERM, IRD, Institut Paoli-Calmettes, Aix-Marseille Universite, Marseille, France,* [6]*Medical Genetics Research Group and Regional Genetics Services, St. Mary's Hospital, Manchester, United Kingdom.*

Introduction

Prophylactic mastectomy (PM) has proven to be the most effective method to reduce the risk of breast cancer in high-risk women. The present study aimed to present and compare the attitudes towards PM among physicians in France, Germany, the Netherlands and the UK.

Methods

An international sample of 1196 general practitioners (GP) and 927 breast surgeons (BS) were surveyed using a mailed questionnaire.

Results

Both GP's as well as BS's opinions towards PM significantly differed from one country to another. Only 30% of the French and 27% of the German GPs were of opinion that PM should be an option for an unaffected female BRCA1/2 mutation carrier, as compared to 85% and 92% of the GPs in the Netherlands and UK, respectively. Similarly, 78% of the French and 66% of the German BS reported a positive attitude towards PM, as compared to 100% and 97% of the BS in the Netherlands and UK, respectively.
In the whole sample of GPs, a positive attitude towards PM was associated with country of residence, being female, and having more knowledge of breast/ovarian cancer genetics, while among BS there was a positive association with country of residence and having more knowledge of breast/ovarian cancer genetics as well, and, in addition, with a higher number of newly diagnosed breast cancer patients last year.

Conclusion

These results demonstrated the international variations in the attitude towards PM among physicians. This might reflect that different policies are adopted to prevent breast cancer in women at-risk.

EPL2.3

"Life at risk": Negotiating identities on healthy carriers of a genetic alteration predisposing to cancer.

E. Sumalla[1], *V. Castejon*[1], *C. Ochoa*[2], *Y. Valverde*[1], *A. Solanes*[3], *G. Capella*[1], ***I. Blanco***[1,4];
[1]*Genetic Counseling Unit. Hereditary Cancer Program., L'Hospitalet, Spain,* [2]*Psycho-Oncology Unit, L'Hospitalet, Spain,* [3]*Genetic Counseling Unit. Hereditary Cancer Program., Badalona, Spain,* [4]*Genetic Counseling Unit, Hereditary Cancer Program, Badalona, Spain.*

Cancer survivorship often involves identity reconstruction and integration of the experience into one's self-concept, and may even lead to radical transformations in one's identity. The increasing availability of genetic testing enables other family members who have not yet developed cancer to determine if they have inherited the risk; those with a mutation are known as previvors. Once a previvor is identified, they are faced with complicated and often difficult decisions and this new situation may have important psychological and social impacts. To date, little is known about the formation of previvor identities and the extent to which genetic diagnosis is central to one's identity. The main objective of this study was to conduct a qualitative investigation based on a phenomenological framework in order to understand the lived experience of cancer previvors and to examine the centrality of the genetic diagnosis and the associated life changes. Eighteen previvors were studied using a qualitative semi-structured interview. All interviews were subjected to interpretative phenomenological analysis. We have identified at least four different basic strategies of identity negotiation in these previvor individuals showing that adjustment to a pre-symptomatic genetic diagnosis is an active psychosocial process of negotiating identity strategies resulting in both positive and negative life changes. Genetic diagnosis centrality was fairly low in our studied population. According with our results, adoption of a specific previvor identity may impact well-being and health behavior changes and warrant further research.

EPL2.4

Women's experiences of familial ovarian cancer screening: A qualitative study

K. J. Lifford[1], *A. Clements*[2], *L. Fraser*[3], *D. Lancastle*[4], *K. Brain*[1];
[1]*Institute of Primary Care and Public Health, School of Medicine, Cardiff University, Cardiff, United Kingdom,* [2]*Department of Primary Health Care Sciences, University of Oxford, Oxford, United Kingdom,* [3]*Gynaecological Oncology, University College London Institute for Women's Health, London, United Kingdom,* [4]*Department of Humanities and Social Sciences, University of Glamorgan, Pontypridd, United Kingdom.*

Until recently, the main risk management options for women at increased risk of familial ovarian cancer have been risk-reducing surgery to remove the ovaries or ovarian cancer screening (OCS) as part of a research study. The psychological evaluation of familial OCS (PsyFOCS) was conducted to examine the psychological impact of taking part in OCS on women who are at increased genetic risk. The aims of the qualitative component of PsyFOCS were to understand 1) women's experiences of OCS and 2) the catalysts for surgery to remove the ovaries and reactions to subsequent withdrawal from OCS. Semi-structured interviews were conducted with 48 women who were or had been taking part in OCS. Women were chosen on a number of demographic and clinical criteria to endeavour to capture a range of OCS experiences. Interview topics included: family history, cancer risk, the screening experience, risk management decisions and information provision. Results suggested that OCS provides reassurance for women and they feel privileged to take part in OCS. A number of catalysts, including OCS test results, and secondary considerations were found to prompt surgery. The emotional impact of discontinuing OCS following surgery varied between relief, acceptance and loss. In conclusion, OCS appears to be an acceptable risk management strategy for women at increased risk of ovarian cancer. However, OCS results may prompt women to reconsider their risk management options. These findings highlight the benefit women feel they receive from OCS as well as the importance of the timing of decision-making about risk management options.

EPL2.5

What counts as successful in genetic counselling for presymptomatic testing in late onset disorders? The consultands' perspective.

L. Guimarães[1], *J. Sequeiros*[2,1], *H. Skirton*[3], ***M. Paneque Herrera***[2,1];
[1]*ICBAS-Universidade do Porto, Porto, Portugal,* [2]*CGPP-IBMC, Porto, Portugal,* [3]*School of Nursing and Midwifery, University of Plymouth, Plymouth, United Kingdom.*

Genetic counselling must be offered in the context of presymptomatic testing (PST) for severe late-onset diseases; however, what is effective genetic counselling is not well-defined, and measurement tools that allow a systematic evaluation of genetic practice are still not available. The aims of this qualitative study were to (1) recognize relevant aspects across the whole process of genetic counselling in PST for late onset neurodegenerative disorders that might indicate effective practice from the consultand's perspective; and (2) analyse aspects of current protocols of counselling that might be relevant for a successful practice. We interviewed 24 consultands undergoing PST for late-onset neurological disorders (Huntington disease, spinocerebellar ataxias and familial amyloid neuropathy ATTRV30M) in the three major counselling services for these diseases in Portugal. Main themes emerging from the analysis of content were (1) consultand's general assessment of the PST process in genetic services; (2) appropriateness and adaptation of the protocol to the consultand's personal expectations and needs; and (3) consultand's experience of the decision-making process and the role of engagement and counselling skills of the counsellor. Participants provided also a set of recommendations and constructive criticisms relating to the length of the protocol, the time gap between consultations and the way results were delivered. These issues and the construction of the relationship between counsellor and counselee should be further investigated and used for the improvement of current protocols.

EPL2.6

Impact of predictive genetic testing for Huntington's disease (HD), Familial Cardiomyopathy (FCM) and Hereditary Breast and Ovarian Cancer (HBOC) in young people

R. M. MacLeod[1], *A. Beach*[2], *S. Henriques*[2], *J. Knopp*[2], *K. Nelson*[2], *L. Kerzin-Storrar*[1];
[1]*Genetic Medicine, Manchester Academic Health Science Centre, Central Manchester University Hospitals NHS Foundation Trust, Manchester, United Kingdom,* [2]*University of Manchester, Manchester, United Kingdom.*

Introduction

Whilst debate has focused on testing of minors for late onset genetic disorders, less is known about the impact on young people (<25years) who have had predictive testing often many years before the likely onset of symptoms.

Method

36/61 individuals who had a predictive test for HBOC, HD or FCM, age 15-25, in our Centre, at least 3 months previously, agreed to participate. Telephone interviews with the 36 participants (10 HD, 16 HBOC and 10 FCM) were audiotaped, transcribed and analysed using Interpretative Phenomenological Analysis.

Results

None of the participants expressed regret at having the test at a young age. Participants saw the value of pre test counselling not in facilitating a decision, but rather as a source of information and support. Several reflected it had been difficult to emotionally rehearse the potential outcomes prior to testing and thought this was related to their youth. Differences emerged amongst the three groups in parent/family involvement in the decision to be tested. Parents in HBOC and FCM families were a strong influence in favour of testing, whereas in HD the decision was more autonomous and sometimes went against the opinions of parents/grandparents. Participants from all three groups proposed more tailoring of predictive test counselling to the needs of young people.

Conclusion

Some individuals will benefit from knowing their genetic status in young adulthood. The challenge for professionals is adapting the counselling process to the needs of the young person, with possible emphasis on post test support.

EPL3.1

The impact of NIPD on clinical practice: what do prenatal care providers need to know?

M. Bishop, *J. Haydon, D. Latham, J. Tennant, P. Farndon;*
NHS National Genetics Education and Development Centre, Birmingham, United Kingdom.

New genetic technologies impact on the practice of a wide range of health professionals who may be called upon to offer these tests to their patient groups. One such development is non-invasive prenatal diagnoses (NIPD) which has the capacity to transform prenatal diagnosis. To understand how health professionals in the UK see NIPD impacting on clinical care, interviews and focus groups with professionals from fetal medicine (n=7), clinical genetics (n=12) and midwifery (n=46) were conducted, audio taped and transcribed. Thematic analysis was employed to elicit common views regarding the integration of NIPD into clinical practice and the education needs of the workforce who will deliver this service. All three groups recognised that NIPD will impact on the service they provide, however they believed this new technology should be viewed as supplementing current roles as opposed to changing practice. As such, the identified educational needs focused primarily on the procedural issues associated with NIPD, such as the laboratory process and appreciating the implications of test results. Participants stated that any educational package developed needed to reflect the service model for delivering NIPD to ensure education was relevant to the health professional's role. These findings have informed the development of a national competence framework outlining the clinical activities and underpinning knowledge required by health professionals who offer NIPD to women. This framework forms the basis of an online educational package which has been developed by the National Genetics Education and Development Centre to support the implementation of NIPD into clinical practice.

EPL3.2

Non-invasive prenatal diagnosis for fetal sex determination - benefits and disadvantages from the service users' perspective

C. Lewis[1], *M. Hill*[2], *H. Skirton*[3], *L. Chitty*[4,2];
[1]*Genetic Alliance UK, London, United Kingdom,* [2]*Great Ormond Street Hospital for Children NHS Trust, London, United Kingdom,* [3]*Faculty of Health, University of Plymouth, Plymouth, United Kingdom,* [4]*Clinical and Molecular Genetics, UCL Institute of Child Health,, London, United Kingdom.*

Prenatal fetal sex determination is clinically indicated for women who are at risk of having a child with a serious genetic disorder affecting a particular sex. Ultrasound has been the traditional method used, but early fetal sex determination using non-invasive prenatal diagnosis (NIPD) can now be performed using cell free fetal DNA in maternal plasma. The study aim was to assess the views and experiences of service users who had used NIPD for fetal sex determination. A qualitative approach using semi-structured interviews was used. Forty four participants (38 women and 6 partners of participating women) were recruited. Participants' views and experiences of NIPD were overwhelmingly positive. Concerning benefits over traditional methods, three themes emerged: (1) technical aspects of technology; (2) timing; and (3) enhanced decision-making. Practical advantages of NIPD included avoiding miscarriage, and there were a number of psychological advantages associated with timing such as perceived control, early re-engagement with pregnancy, normalisation and peace of mind. NIPD facilitated a stepwise approach to decision-making whereby women divided time into manageable 'chunks' and focused on the immediate future. This is likely to have been a coping mechanism. A number of disadvantages were discussed including concerns about social sexing and increased bonding at a time in pregnancy when miscarriage risk is high. However, participants felt these were minor in comparison to the advantages. Until definitive genetic diagnosis using NIPD is available, NIPD for fetal sex determination is perceived as a good interim measure with a number of notable advantages over traditional methods.

EPL3.3

Using discrete choice experiments to explore stakeholder preferences for non-invasive prenatal diagnosis compared to current invasive testing

M. Hill[1,2], *F. Forya*[2], *J. Fisher*[3], *S. Morris*[4,5], *L. Chitty*[1,2];

[1]Clinical and Molecular Genetics, Institute of Child Health and Great Ormond Street Hospital for Children NHS Trust, London, United Kingdom, [2]Fetal Medicine Unit, University College London Hospitals NHS Foundation Trust, London, United Kingdom, [3]Antenatal Results and Choices, London, United Kingdom, [4]UCLH/UCL Comprehensive Biomedical Research Centre, London, United Kingdom, [5]Research Department of Epidemiology and Public Health, University College London, London, United Kingdom.

Non-invasive prenatal diagnosis (NIPD) using cell-free fetal DNA has the potential to bring many positive improvements for prenatal diagnosis. There are, however, many challenges ahead for successful implementation and it is critical that stakeholder preferences and opinions are considered. Discrete choice experiments (DCE) have been widely utilised in healthcare research to examine stakeholder preferences. Participants choose between a series of healthcare options and in doing so reveal their preferences and trade-offs in a way that reflects the complex nature of real-life decisions. Here we describe the use of DCE's to compare patient and health professional preferences for key attributes of NIPD relative to invasive testing for Down syndrome and for single gene disorders such as sickle cell anaemia and beta-thalassemia. Participants include; 1. pregnant women and partners attending maternity services for routine procedures; 2. members of relevant patient support groups; and 3. health professionals involved in prenatal care. Women (n=335) and health professional's (n=181) were found to have differing preferences when considering diagnostic tests for Down syndrome. The key attribute for women's decisions regarding testing was no risk of miscarriage, while for health professional's accuracy and timing were most important. Studies exploring preferences for diagnostic tests for single gene disorders are ongoing. Our results are important for the implementation of NIPD. In particular, women's strong preference for tests with no risk of miscarriage indicates that test safety has the potential to outweigh other factors in decision making and highlights the need for effective pre-test counselling and informed consent processes.

EPL3.4

Ethical issues in the use of pronuclear and maternal spindle transfer to prevent mitochondrial disorders

T. Clancy;

Genetic Medicine, St Mary's Hospital, Manchester, United Kingdom.

Mutations in mitochondrial DNA are passed from mother to child and can cause diseases such as Leber hereditary optic neuropathy, MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes) and maternally-inherited Leigh syndrome. However, assessing the risk of a mother passing on mitochondrial mutations and whether, and how severely, a child will be affected is complex. Prenatal diagnosis (PND) and preimplantation genetic diagnosis (PGD) are possible but predicting the outcome for a child who inherits the mutation is difficult. The new techniques of pronuclear transfer (PNT) and maternal spindle transfer (MST) may enable women to avoid transmitting mitochondrial disease to their children. PNT and MST are currently permitted in research in the UK; the Human Fertilisation and Embryology Authority is undertaking a consultation on whether it would be acceptable to use these techniques in treatment. Both PNT and MST involve the creation of embryos containing nuclear DNA from a man and a woman, plus mitochondrial DNA from another woman. There are therefore some ethical considerations additional to those raised by PND and PGD. These include that the child would have a genetic connection to three people, and that PNT and MST alter the germline of the child i.e. the alteration would in turn be passed on to future generations. An explanation of the techniques and a review of the ethical issues will be presented to help professionals providing clinical services and those involved in psychosocial and other research to engage with the debate about using PNT and MST in treatment.

EPL3.5

The impact of carrier results generated by newborn screening on the family

F. Ulph[1], *T. Cullinan*[2], *N. Qureshi*[3], *J. Kai*[3];

[1]University of Manchester, Manchester, United Kingdom, [2]East Staffordshire Clinical Commissioning Group, Burton upon Trent, United Kingdom, [3]University of Nottingham, Nottingham, United Kingdom.

Newborn screening for sickle cell disorders and cystic fibrosis identifies carriers in addition to children with the diseases. Carrier results must be conveyed to parents, yet there is a lack of evidence to inform best practice. This study examined the impact on families of newborn screening carrier results, and subsequent familial communication through semi-structured interviews with 67 purposively sampled family members with experience of receiving carrier results communicated by a range of different methods. Data were analysed thematically by constant comparison, and validated via member checking. Parents valued carrier results and sought to share this information with their extended families and to inform their children in the future. Parental anxiety or distress was attributed to how information was communicated during the screening process rather than the result itself; appeared more common in those with less prior awareness of the disease or possibility of a carrier result, resulting in concerns their child had a serious problem, particularly while awaiting results, before seeing a professional, or when left in an "information vacuum"; or could be triggered by family communication and responses to carrier results. However, family communication and support provided great benefits to some respondents. Practice suggestions developed from respondent suggestions included: timely access to an informed health professional, improvement of community awareness and information, greater support after communication of results in considering and accessing cascade testing, and negotiating further communication within their families.

EPL3.6

Divergent views on newborn and infant genetic screening: perspectives of parents of healthy children and relatives of children with genetic conditions causing developmental delay

S. A. Metcalfe[1], *A. D. Archibald*[2,3], *A. Atkinson*[1], *C. Hickerton*[2], *S. Lawton*[1], *B. McClaren*[2], *S. Wong*[1];

[1]Murdoch Childrens Research Institute and Dept Paediatrics, University of Melbourne, Parkville, Vic, Australia, [2]Murdoch Childrens Research Institute, Parkville, Vic, Australia, [3]Genetic Health Services Victoria, Parkville, Vic, Australia.

Debate exists about introducing genetic conditions for which there are no curative treatments into newborn screening, although this information can be valuable for future reproductive decision-making and early interventions may improve quality of life. One important consideration for policy makers is the views of consumers about acceptability of such programs. We conducted semi-structured in-depth interviews with 14 parents of 26 healthy children (10wks- 13yrs), as well as 15 parents of children with Duchenne muscular dystrophy (DMD) and 10 relatives of individuals with spinal muscular atrophy types 2 and 3 (SMA2/3). Interviews were digitally-recorded, transcribed and thematic analysis performed, with independent coding by at least 2 researchers.

Almost all participants supported screening for such conditions provided it is voluntary. However, parents of healthy children generally thought that newborn screening should be offered, perceiving this as a convenient time, while parents of children with DMD or SMA2/3 were overall much more supportive of screening at a later stage (~1 year old), as they valued having a period of 'normality'. They perceived that receiving a diagnosis from newborn screening would have impacted negatively on the relationship with their child. Those favouring infant screening suggested it could be targeted to children whose parents are concerned about their child's development, while parents of healthy children often worried that targeted screening might reduce equity of access. These divergent views probably reflect the contrasting experiences participants had with regard to their children's development. These findings highlight the ethical complexities of offering screening for conditions causing developmental delay.

EPL4.1
Evaluation of the efficacy of two models of delivering information about treatment-focused genetic testing among young women newly diagnosed with breast cancer

B. Rahman[1,2], *B. Meiser*[1,2], *K. Watts*[1,2], *M. Gleeson*[3,2], *C. Saunders*[4], *G. Mitchell*[5], *K. Barlow-Stewart*[6], *J. Kirk*[7], *K. Tucker*[2];
[1]*Psychosocial Research Group, Sydney, Australia,* [2]*Department of Medical Oncology, Prince of Wales Hospital, Sydney, Australia,* [3]*Hunter Genetics, NSW, Australia,* [4]*Department of Surgery, University of Western Australia, WA, Australia,* [5]*Peter MacCallum Cancer Centre, VIC, Australia,* [6]*Centre for Genetics Education, Sydney, Australia,* [7]*Westmead Institute for Cancer Research, Sydney, Australia.*

Background: Increasingly, women newly diagnosed with breast cancer with a relevant cancer family history or other high risk features are being offered genetic testing to guide their treatment (Treatment-Focused Genetic Testing 'TFGT'). In this randomised controlled trial, we evaluate two ways of offering information about genetic testing to young women at diagnosis.
Methods: Women (<50 years) at diagnosis before definitive breast cancer surgery, with either suggestive cancer family history or other high risk features, are invited to participate by their surgeon. After completion of a baseline questionnaire, participants are randomised to receive information about TFGT either: a) in educational materials (Intervention) or, b) at a genetics service (Control). Free rapid genetic testing is offered; results are disclosed at a genetics service. Self-report questionnaires assess demographic information, decisional uncertainty about TFGT, surgical and psychosocial outcomes. The second questionnaire is administered after the intervention; the third and fourth questionnaires are completed 2 weeks after results disclosure, and at 12 months, respectively.
Results: Preliminary results for change in decisional conflict are reported for 62 women who completed the first and second questionnaires, all of whom opted for TFGT. Decisional conflict (DC) decreased following receipt of information about TFGT, with no difference in mean change between the two groups (Intervention N=33, M = -13.8, SD = 20.7; Control N=29, M = -17.6, SD = 25.8), t60 = 0.642, p = .523.
Conclusions: These early data suggest that both modes of delivering information about genetic testing to women at breast cancer diagnosis are equally effective.

EPL4.2
Psychological outcomes of familial ovarian cancer screening: No evidence of long-term harm

K. E. Brain[1], *K. J. Lifford*[1], *L. Fraser*[2], *A. N. Rosenthal*[2,3], *M. T. Rogers*[4], *D. Lancastle*[5], *C. Phelps*[6], *E. K. Watson*[7], *A. Clements*[8], *R. Iredale*[4], *I. Jacobs*[9], *U. Menon*[2];
[1]*Institute of Primary Care and Public Health, School of Medicine, Cardiff University, Cardiff, United Kingdom,* [2]*Gynaecological Oncology, University College London Institute for Women's Health, London, United Kingdom,* [3]*Barts Cancer Institute, Barts and the London School of Medicine and Dentistry, Queen Mary University London, London, United Kingdom,* [4]*School of Medicine, Cardiff University, Cardiff, United Kingdom,* [5]*Department of Humanities and Social Sciences, University of Glamorgan, Pontypridd, United Kingdom,* [6]*School of Psychology & Counselling, Swansea Metropolitan University, Swansea, United Kingdom,* [7]*School of Health and Social Care, Oxford Brookes University, Oxford, United Kingdom,* [8]*Department of Primary Health Care Sciences, University of Oxford, Oxford, United Kingdom,* [9]*Faculty of Medical and Health Sciences, University of Manchester, Manchester, United Kingdom.*

Background: Ovarian cancer screening for women at increased genetic risk in a large UK study involved 4-monthly CA125 tests and annual ultrasound, with further tests prompted by an abnormal result. The longer-term psychological and behavioural effects of frequent ovarian cancer screening are unknown. *Methods:* Prior to their first routine 4-monthly CA125 test, 1999 (62%) of N=3224 women completed baseline psychological measures. One week follow-up questionnaires were completed by 1384 participants (86%): 1217 (89%) women who received a normal screening result and 167 (69%) women with abnormal results. Of these, 141 (86%) completed a further questionnaire one week after being returned to routine 4-monthly screening (primary end-point). A total 912 (78%) women completed nine month follow-up questionnaires. Measures included cancer distress, general anxiety/depression, reassurance, and rate of withdrawal from screening. *Results:* Compared to women with normal results, women with abnormal results reported moderate cancer distress (F=27.47, $p \leq .001, \eta^2=0.02$) and were significantly more likely to withdraw from screening for surgery ($\chi^2_{(1)}=18.92$, p<.001) after their abnormal result. These effects were not apparent after return to routine screening or at longer-term follow-up. No differences were found in general anxiety or depression. Regardless of screening result, women reported high overall reassurance gained from screening (p=0.15). *Conclusions:* Women participating in frequent ovarian screening who are recalled for an abnormal result may experience transient negative effects, which can prompt reconsideration of risk management options. Health professionals and policy makers may be reassured that familial ovarian screening does not cause sustained psychological harm.

EPL4.3
Are illness perceptions a useful predictor of emotional distress over time in individuals undergoing cancer genetic risk assessment?

C. Phelps[1], *P. Bennett*[2], *A. Murray*[3], *K. Brain*[4];
[1]*Swansea Metropolitan University, Swansea, United Kingdom,* [2]*Swansea University, Swansea, United Kingdom,* [3]*Cancer Genetics Service for Wales, Cardiff, United Kingdom,* [4]*Institute of Medical Genetics, Cardiff University, Cardiff, United Kingdom.*

Background: It is well recognised that objective risk status rarely predicts psychological responses to risk information. The predictive utility of Leventhal's self-regulation model in explaining psychological responses to undergoing cancer genetic risk assessment was explored.
Methods: Questionnaire data from 331 individuals undergoing cancer genetic risk assessment was analysed to explore associations between baseline psychological variables (taken upon referral) and psychological distress and emotional outcomes one month later whilst waiting for risk assessment results (Time 2) and following the provision of risk information (Time 3).
Findings: Illness perception variables (measured by the Illness Perceptions Questionnaire-Revised) explained 20.3% of the variance in cancer-specific distress at Time 2 and 11.8% of the variance at Time 3, with strong beliefs about the consequences of being at risk of cancer uniquely contributing to psychological distress. The same variables explained 7% of the variance in positive affect at Time 2 with beliefs about greater consequences of being at risk (p=<0.01) and stronger beliefs in screening/surgery being able to control their chances of getting cancer (p=<0.01) making a unique contribution. Following risk provision, those at high risk reported significantly greater understanding of their risk than those at average risk (p=<0.01).
Discussion: Understanding cognitive representations of being at risk may have some use in explaining psychological responses to cancer genetic risk assessment. Specifically, these findings suggest that those receiving a high risk result have a greater understanding of its implications: this may reflect differences in the mechanisms by which individuals at different levels of risk are informed.

EPL4.4
The underestimated impact of prophylactic mastectomy

J. P. Gopie[1], *R. Timman*[2], *M. T. Hilhorst*[2], *M. A. M. Mureau*[2], *A. Tibben*[1,2];
[1]*Leiden University Medical Center, Leiden, Netherlands,* [2]*Erasmus University Medical Center, Rotterdam, Netherlands.*

Purpose The decision for bilateral prophylactic mastectomy with immediate breast reconstruction (BPM) in BRCA1/2 mutation carriers is a radical decision. The impact on cancer distress, general mental and physical health, and satisfaction with body image, sexuality and the partner relationship was investigated.
Methods Fifty women opting for BPM completed psychological questionnaires at baseline, 6 and 21 months after surgery. With repeated measures ANOVA the quality of life in time was explored with a prospective design.
Results Cancer distress significantly decreased after BPM. Physical health and satisfaction with body image diminished shortly after BPM, but increased on the long-term. General mental health improved on the short-term, but decreased thereafter. Satisfaction with sexuality tended to decrease up to 21 months. In the end, 30% was not satisfied with the aesthetic result of their breasts and 30% indicated they had less frequent sex with their partner than they used too.
Conclusion Although cancer distress significantly declined, the psychosocial impact of BPM including immediate breast reconstruction should not be underestimated. Particularly, the intimate relationship can be adversely affected. Adaption to the new body image and the impact on femininity and identity may take a long time. Psychological consults should be provided preoperatively as well as postoperatively to catch the patients and partners in need of psychological counseling.

EPL4.5
The impact of risk-reducing hysterectomy and/or oophorectomy in premenopausal women at high risk of endometrial and ovarian cancer due to Lynch syndrome

R. Moldovan[1,2], *S. Keating*[1,3], *T. Clancy*[1];
[1]*Genetic Medicine, University of Manchester, Manchester, United Kingdom,* [2]*Department of Clinical Psychology and Psychotherapy, Babes-Bolyai University, Cluj-Napoca, Romania,* [3]*Genetic Health Service, Auckland, New Zealand.*

Lynch syndrome is an inherited predisposition to cancer caused by mutations in mismatch repair genes. The lifetime risk of endometrial cancer for women who carry mutations is 40-60%, and the lifetime risk of ovarian cancer is 7-12%. There is no proven efficacy of screening for the early detection and treatment of either cancer. Another option for women is risk-reducing hysterectomy and/or bilateral salpingo-oophorectomy. We used a combined methods study to explore women's experience of such surgery and the impact it had on their cancer worry, general health and menopause-specific quality of life. We sent validated questionnaires to and conducted semi-structured interviews with 15 of the 24 women invited to take part (response rate 62.5%). The results suggest that risk reducing surgery does not lead to significant psychological distress. Women tend not to think or worry much about developing cancer. Women tend to be distressed about the physical and somatic symptoms associated with menopause; their social well-being is somewhat affected, but sexual difficulties are minimal. The 5 major themes identified from the interviews were: motivating factors; taking control; benefits of surgery; physical and emotional costs of surgery; and, experiences of HRT and the menopause. Recommendations from the study include that professionals discuss the menopause, its side effects and HRT in detail prior to surgery.

EPL4.6

The use of an electronic genealogy database in cancer genetic counseling in Iceland

V. Stefansdottir[1], *O. T. Johannsson*[2], *H. Skirton*[3], *L. Tryggvadottir*[4], *H. Tulinius*[5], *C. Chapman*[6], *J. J. Jonsson*[7,8];
[1]Dept. of Genetics and Molecular Medicine, Landspitali, Reykjavik, Iceland, [2]Dept. of Medical Oncology, Landspitali - The National University Hospital, Reykjavik, Iceland, [3]Faculty of Health, Education and Society, Plymouth Univ., Plymouth, United Kingdom, [4]Icelandic Cancer Registry, Reykjavik, Iceland, [5]The Genetical Committee of the University of Iceland, Reykjavik, Iceland, [6]West Midlands Regional Genetics Unit, Birmingham Women Hospital NHS Trust, Birmingham, United Kingdom, [7]Landspitali - The National University Hospital, Reykjavik, Iceland, [8]Department of Medicine, University of Iceland, Reykjavik, Iceland.

Background: Pedigrees are key tools in cancer genetic counseling where accurate and comprehensive information is needed for risk assessment. Counselees often have imcomplete information. We have adopted the use of an electronic population-based genealogy database to generate a full 3 generation pedigrees.

Materials and methods: From January 2007 to January 2012, over 600 counselees have been seen in the cancer genetic counseling clinic, for 3 or 4 visits each. During the intake the counselee signs a consent for tracing her family through the database of the Genetical Committee of the University of Iceland (GCU) and the Icelandic Cancer Registry. The GCU holds accurate information on at least all Icelanders born after 1840. As cancer diagnosis recording is mandatory, the Cancer Registry provides very accurate information.

Families with pedigrees in the clinic are 265. Pedigrees made during intake, include10-25 individuals and the electronic pedigrees 40 - 2000 individuals, most commonly 3-500. Families with the BRCA2 founder mutation are 42 and BRCA1 families 5. Tested individuals are 541 resulting in over 107 BRCA2 and 14 BRCA1 carriers.

Conclusion: In our experience this method adds considerable information. No disapprovement on the behalf of the families have been noticed. This is especially inportant in the light of the policy of many cancer registries to only release individual information based on informed consent. We argue, in part based on our experience, that persumed consent should suffice. Such policy would be consistent with other sharing of individual´s genetic pedigrees, between health care facilities.

EPL5.1

Self- and Other-Oriented Reassurance in Telegenetic Counselling

S. Sarangi[1], *O. Zayts*[2];
[1]Cardiff University, Cardiff, United Kingdom, [2]The University of Hong Kong, Hong Kong, China.

This paper focuses on telephone-mediated genetic counselling in Hong Kong where nurses contact mothers whose newborns have been diagnosed with a mild hereditary disorder (G6PD deficiency, commonly known as favism). Since this condition is preventable through avoidance of certain food and medication, it becomes imperative that when mothers are given the 'affected' status of their child, reassurance of the manageability of the condition ensues.

Our data is drawn from 50 transcripts of audio-recorded telephone counselling encounters as part of a funded study. We use thematic discourse analysis (Roberts and Sarangi, 2005) to demonstrate that the 'affected' status of the child is always delivered first, which is immediately and briefly mitigated before explanations about causes and consequences of the condition are offered. The delivery of 'good news' in the form of reassurance follows a particular structural pattern: typically advice is offered about life-style practices that the mothers must adhere to as a way of avoiding the inherent risks associated with the condition. We argue that this 'positive' framing of advice allows nurses not only to reassure mothers that they are able to manage their child's condition, but also to become self-reassured that there is manifest uptake of the advice by the mothers (e.g. via confirmation check questions; recycling of information). We examine how the nurses orient themselves to the mothers' existing knowledge of the condition vis-à-vis identifiable reassurance trajectories. In conclusion, we discuss the ways in which the reassurance trajectories are a specific feature of the telephone mode of counselling.

EPL5.2

Profile of genetic counsellor and genetic nurse practice in Europe

H. Skirton[1], *C. Cordier*[2], *D. Lambert*[3], *U. Hosterey-Ugander*[4], *M. Voelckel*[5];
[1]Faculty of Health, Education and Society, Taunton, United Kingdom, [2]University Hospital of Strasbourg, Strasbourg, France, [3]Our Lady's Children's Hospital, Crumlin, Ireland, [4]Sahlgrenska University Hospital, Gothenburg, Sweden, [5]La Timone Hospital, Marseille, France.

The opportunities for genetic nurses and genetic counsellors to work professionally in Europe have varied according to the country of practice, the health service structure and educational opportunities. The European Society of Human Genetics is supporting development in these two professions through the promotion of a new European registration system. To inform the design of a European Master level curriculum and registration process, we undertook an online survey of 216 practitioners working in 19 European countries to ascertain current areas of practice, legal regulation, collaborative working and clinical responsibilities. Of the respondents, 82.7% were genetic counsellors and 9.9% were genetic nurses. It was a legal requirement to work with a medical colleague for 40.8%, while another 32.1% always did so, however many of the remaining respondents were unsure about the legal obligation in this regard. The majority of respondents stated that they alone or with a medical colleague took responsibility for making the first contact with the family (87.9%) drawing the pedigree (85.2%), explaining a genetic test to the patient (79.5%) and providing psychological support through the testing process. Over 81% managed some cases without the input of a medical doctor. These findings indicate that genetic nurses and counsellors in Europe are working autonomously and are making a substantial contribution to the care of patients. However, with a specific registration system operating in only four countries (United Kingdom, Netherlands, France, Israel), a unified European registration system is required to ensure comparable standards of education and competent practice operate across countries.

EPL5.3

Rational and reasonable: requests for genetic testing of children

I. Holme, *G. Crawford, A. Fenwick, A. Lucassen;*
Southampton University, Southampton, United Kingdom.

Professional guidelines state that predictive genetic testing of children for adult onset conditions should generally be delayed unless the result would affect medical management of the child or until the child can make a decision about testing for themselves. Based on 50 semi-structured interviews with UK genetic service professionals and families who have spoken with genetic services about childhood predictive genetic testing, this paper will explore the reasons given by HCP and parents for testing against the guidelines. These include parental anxiety about the unknown status of their child; the parent's right to know and decide what and when to tell their children; and the need to maintain a positive relationship with parents. In examining these accounts we explore how the 'reasonable parent' is constructed to argue for or against testing outside of the guidance. The paper concludes by exploring the implications for genetic service current practices.

EPL5.4

Assessing the effects of genetic counseling for people with serious mental illness: findings of the first randomized controlled trial

J. Austin[1], *C. Hippman*[1], *A. Inglis*[1], *A. Ringrose*[1], *J. Cheek*[2], *W. Honer*[1];
[1]University of British Columbia, Vancouver, BC, Canada, [2]Vancouver Island Health Authority, Victoria, BC, Canada.

Serious mental illnesses (schizophrenia, bipolar and schizoaffective disorder) cumulatively affect ≥3% of the population. They are complex disorders (typically arising as a result of the combined effects of genetic and environmental factors) for which no genetic testing is clinically available. Previous work shows that people with serious mental illness want genetic counseling but that few have had it, and no studies had examined its effects in this population. We conducted the first randomized controlled trial to test the effects of genetic counseling among people with serious mental illness. We hypothesized that as compared to a control intervention or a waitlist group, genetic counseling would: decrease internalized stigma, increase perceived control and knowledge about mental illness, and facilitate more accurate risk perception when measured 4 weeks later. Between 2008 and 2011, psychiatric diagnosis (and therefore eligibility) was confirmed by Structured Clinical Interview for 120 individuals (44=male, 66=female, mean age=42) with serious mental illness, who were then randomized to one of three groups, each of n=40: genetic counseling, a control intervention (involving an educational booklet about the causes of mental illness), or a waitlist group. Before, immediately after, and one month after the interventions, participants completed validated measures of internalized stigma and perceived control, and a purpose designed measure of knowledge and risk perception. The waitlist group completed the same measures at baseline, and one month later. Those randomized to the waitlist or control interventions were offered genetic counseling at the end of the study period. Results will be presented.

EPL5.5

Assessing wellbeing in women caring for children with Duchenne or Becker muscular dystrophy

H. L. Peay[1,2], *K. Kinnett*[1,3], *B. Meiser*[4], *A. Tibben*[2];
[1]*Parent Project Muscular Dystrophy, Richmond, VA, United States,* [2]*Leiden University Medical Center, Leiden, Netherlands,* [3]*Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States,* [4]*Prince of Wales Clinical School, University of New South Wales, Sydney, Australia.*

Background: Caring for children with progressive disorders places significant demands on mothers. This study assesses perceived needs, motivations, and wellbeing of mothers of offspring with Duchenne or Becker muscular dystrophy (DBMD). We examine the effects of mothers' carrier status, self-concept, worry, caregiver burden, perceived control, and coping efficacy on adaptation.

Methods: Mothers were recruited through advocacy organizations, a DBMD registry, and from clinic populations to complete one online survey each year for five years. This abstract includes data from the first 124 participants in the first survey. We anticipate reaching the target sample (over 200) by May 2012.

Results: Preliminary results are reported for 124 respondents. 55.6% of affected children were ambulatory. Mothers endorsed highest needs for ways to deal with uncertainty about their child's future (60% med/high); specific ways to cope with being a mother of a child with DBMD (57% med/high); specific ways to manage fears (55% med/high); and better ways to get needed support (55% med/high). The predictor variables dispositional optimism (r=.427, p<.001), self concept (r=-.384, p<.001), coping efficacy (r=.531, p<.001), perceived control (r=.286, p<.001), perceived burden (-.273, p<.001), and self-efficacy (r=.309, p<.001) were significantly correlated with mothers' adaptation. Backwards elimination regression was used to assess the ability of the variables to predict adaptation. The preliminary model showed that dispositional optimism (β=.191, p=.041) and coping efficacy (β=.424, p<.001) explained 30.7% of the variance in adaptation (F=26.11, p<.001).

Conclusions: These early data suggest that interventions targeting coping efficacy may improve the adaptation of mothers of individuals with DBMD.

EPL5.6

Interventions and Outcomes for Inherited Retinal Dystrophy: A Qualitative Examination

R. Combs[1], *G. Hall*[2], *M. McAllister*[3], *K. Payne*[1], *S. Downes*[4], *J. Lowndes*[4], *A. Moore*[5], *S. Devery*[5], *G. Wright*[5], *S. Ramsden*[2], *G. Black*[1];
[1]*University of Manchester, Manchester, United Kingdom,* [2]*Central Manchester University Hospitals NHS Foundation Trust, Manchester, United Kingdom,* [3]*Cardiff University, Cardiff, United Kingdom,* [4]*Oxford Eye Hospital, Oxford, United Kingdom,* [5]*Moorfields Eye Hospital, London, United Kingdom.*

The needs and outcomes of Inherited Retinal Dystrophy patients are not fully understood. Furthermore, there is a disparity between the way genetic ophthalmology services are delivered in the UK. This research used thematic qualitative analysis to identify and describe the needs and outcomes desired by a set of UK patients and their families (n=20). Extensive prior qualitative research has identified five outcome domains in clinical genetics: Behavioural Control, Cognitive Control, Decisional Control, Emotional Regulation and Hope, referred to as Empowerment. Yet, the relevance of these five domains to inherited eye disease is unknown. The data were analysed through the Empowerment theoretical framework to determine what attributes, if any, differentiate retinal dystrophy patients from other clinical genetics patients. The research found that patients' desired outcomes relate to medical, psychosocial and practical categories of need, most of which line up closely to the Empowerment domains. However, three themes discovered in the data do not have a corresponding Empowerment outcome measure: Information about benefits, Adaptations and Mobility. Thus, a new outcome domain, Independence, defined as "The ability to participate fully in social, family, economic, educational and/or public life", is proposed to reflect the desired practical outcomes. Independence is a logical outcome for coping with a potentially disabling condition. It may not apply to genetic conditions that are non-disabling, which could account for its absence in previous studies. This data will be used to design and evaluate an optimal care model for genetic retinal services.

Providing written information as an aid in Genetic Counseling - dispensable or helpful?

C. Walter[1,2], *H. Berth*[3], *F. Kreuz*[3], *K. Schenck-Kaiser*[4], *H. Schindelhauer-Deutscher*[1];
[1]*Association Psychosocial Aspects of Human Genetics, Homburg/Saar, Germany,* [2]*Institute of Human Genetics, Freiburg, Germany,* [3]*Association Psychosocial Aspects of Human Genetics, Dresden, Germany,* [4]*Association Psychosocial Aspects of Human Genetics, Freiburg, Germany.*

Providing written information as an aid in Genetic Counseling - dispensable or helpful?

Written information can complement and aid genetic counseling . This information allows patients to re-read the information presented during counseling thus strenghtening and deepening it. An appendix with additional addresses and consultation possibillities helps to increase the options for becoming fully informed. This can be of great importance, in particular when the genetic counseling entails difficult decisions , .

Since 1996 the Association for Psychosocial Aspects of Human Genetics (VPAH eV) has been publishing the brochure „Bad news after prenatal diagnosis - A companion brochure for women and couples who consider termination of pregnancy". The brochure enjoys ever-increasing demand, and theVPAH has now published the 13th updated edition. In addition, the brochure has also been available online for several years.

The poster shows the positive reception history that the booklet has seen since its inception, and which has reached a preliminary high with the enactment of the Gene Diagnostics Law in Germany. In addition, the poster shows the recipients of the brochure by professional category, as well as the regional distribution of purchasers in Germany.

Finally, an outlook is given on further patient brochures that the VPAH e.V. publishes orissues or plans to publish. These (will) treat the use of predictive tests in the context of HNPCC, breast cancer or neurological diseases.

EPL6.2

Communicating familial breast cancer risks: risk presentation formats and women's preferences

L. Henneman[1,2], *C. J. Van Asperen*[3], *J. C. Oosterwijk*[4], *F. H. Menko*[1], *L. Claassen*[1,2], *C. F. Ockhuysen-Vermey*[1,2], *D. R. M. Timmermans*[1,2];
[1]*VU University Medical Center, Amsterdam, Netherlands,* [2]*EMGO Institute for Health and Care Research, Amsterdam, Netherlands,* [3]*Leiden University Medical Center, Leiden, Netherlands,* [4]*University Medical Center, Groningen University, Groningen, Netherlands.*

Background: Besides the effectiveness of risk communication formats, it is also important to consider patient preferences to improve patient-centred care. This study assessed women's preferences and satisfaction with different risk presentation formats.

Methods: 279 unaffected women with a breast cancer family history were allocated to receive one of five additional risk consultations after standard genetic counseling, in which breast cancer risks were presented as: 1) percentages (X%); 2) frequencies (X out of 100); 3) frequencies and graphical format (10x10 human icons); 4) lifetime risk and age-related risk in numerical format; 5) lifetime risk and age-related in both numerical and graphical format. Preferences and satisfaction were assessed 2-weeks follow-up.

Results: Both numbers and words (37%) and numbers only (26%) were preferred most. Of the numerical formats, 55% preferred percentages. Women who had received graphical displays favored graphical displays more than other women (p<.001). This preference was lower for women who were lower educated compared to those higher educated (5%vs.41%). The majority (73%) preferred to hear both lifetime risk and 10 year age-related risk. This preference was not affected by experience with the format. However, women >40 years preferred the age-related format (without lifetime risk) more than younger women (20%vs.2%). There was no difference in satisfaction between groups.

Conclusions: Lifetime cancer risk information in addition to age-related risk in a numerical format (percentages) was most

preferred. The results suggest that in counseling, women's preference for a risk communication format may be influence by previous experiences and women's age and education.

EPL6.3

The Signal-Trial: Evaluation of a Checklist to Improve Communication about Psychosocial Problems in Cancer Genetics

W. Eijzenga[1]*, N. K. A. Aaronson*[1]*, D. E. E. Hahn*[1]*, I. Kluijt*[1]*, G. N. Sidharta*[1]*, M. G. E. M. Ausems*[2]*, E. M. A. Bleiker*[1]*;*

[1]*The Netherlands Cancer Institute, Amsterdam, Netherlands,* [2]*University Medical Center Utrecht, Utrecht, Netherlands.*

Introduction

Approximately 20% of individuals undergoing oncogenetic counseling with/without DNA-testing experience clinically relevant levels of distress. Within the counseling session, information provided is mostly biomedical and provider-driven. The use of a checklist, completed by counselees prior to the counseling session, might facilitate discussion of psychosocial issues. The aim of this trial is to evaluate the use of a checklist as an aid in 1) facilitating communication, 2) increasing counselors' awareness, and 3) improving the management of psychosocial problems.

Methods

In total, 260 individuals undergoing oncogenetic counseling at the family cancer clinics of the NKI-AVL (Amsterdam) or the UMCU (Utrecht) will be randomised to either a group whereby the results of the checklist, completed prior to the counselling session, are shared with the genetic counselor (intervention), or a group where the results of the checklist are not used within the counseling (control). The counseling sessions are audiotaped for purposes of content analysis.

Results

Preliminary data on the first 98 participants indicate that counselees experience problems in the following psychosocial domains: living with cancer (95% of the counselees), genetics (67%), children (51%), family and social issues (30%), emotions (24%), and practical problems (14%). Whether these issues are more frequently addressed in the intervention group as compared to the control group will be evaluated when the study matures.

Discussion

If proven effective, the use of a oncogenetics-specific psychosocial problem checklist can be recommended as an aid in facilitating communication, increasing counselors' awareness, and improving the management of psychosocial problems within cancer genetics.

Disclosure of information within french families with BRCA mutation

C. Rambaud[1]*, A. Birot*[1]*, A. Damette*[2]*, C. Populaire*[2]*, A. Cueff*[3]*,* ***F. Coron***[1]*, C. Loustalot*[4]*, C. Cassini*[1]*, P. Fumoleau*[3]*, J. Sautière*[5]*, X. Pivot*[6]*, F. Debomy*[1]*, S. Gauthier*[1]*, M. Collonge-Rame*[2]*, L. Faivre*[1]*;*

[1]*Centre de génétique, Hopital d'Enfants, Dijon, France,* [2]*Service d'oncogénétique, Besançon, France,* [3]*Service d'oncologie, Centre G.F. Leclerc, Dijon, France,* [4]*Service d'oncogénétique, Centre G.F. Leclerc, Dijon, France,* [5]*Service de gynécologie, Besançon, France,* [6]*Service d'oncologie, Hôpital Minjoz, Besançon, France.*

Disclosure of genetic information to first-degree relatives in families with a genetic predisposition was studied in two French regions. Data for 64 women were collected (24 index cases, 40 relatives with the BRCA mutation).
Concerning disclosure to children over 18, 98% of these had been informed (100% of daughters and 96% of sons) and 46% underwent genetic screening.
For siblings, all of sisters and 98% of brothers had been informed and 44% underwent genetic screening.
85% of parents had been informed; 59% of mothers and 44% of fathers had undergone genetic screening.
Concerning age of the communicant, incomplete information to first-degree relatives was observed in 14% of those above 60 years of age, 11% in the 50/60 age group, 5.5% in the 40-50 years, and 0% in those between 30 and 40 years.
Complete information of the relatives was also more observed when the communicant was index case (96% versus 92,5% for relatives), and was symptomatic (97% versus 85% for asymptomatic women)
The reasons for non-disclosure of the information to relatives included family dispute (33%), wish not to worry others (50%), or no particular reason (17%).
This study showed that disclosure of the information is well done for children and siblings, whatever the sex, and less constant for parents. Disclosure of the information was better in young and/or symptomatic women. The reasons for not providing the information were not related to poor understanding or difficulties reiterating the information to members of the family.

EPL6.5

The impact on self and family of receiving genetic test results following participation in the Australian Ovarian Cancer Study (AOCS)

N. Hallowell[1]*, K. Alsop*[2]*, M. Gleeson*[3]*, D. Bowtell*[2]*, G. Mitchell*[2]*, .. The Australian Ovarian Cancer Study Group*[4]*;*

[1]*PHG Foundation, Cambridge, United Kingdom,* [2]*Peter MacCallum Cancer Centre, Melbourne, Australia,* [3]*Hunter Genetics, Newcastle NSW, Australia,* [4]*Westmead Institute for Cancer Research, University of Sydney and Millennium Institute, and Departments of Gynaecological Oncology, Westmead Hospital, NSW, Queensland Institute for Medical Research,, Australia.*

The generation of clinically significant genetic data during research studies raises a number of ethical issues about the disclosure of this information to research participants and their family. Little is known about individuals' experiences of receiving research results . This qualitative interview study investigated research participants' (n=10) or their nominated next of kin's (n=15) experiences of receiving notification that (genetically) significant information is available following the proband's participation in the Australian Ovarian Cancer Study (AOCS). This paper describes the emotional impact of receiving a notification letter, interviewees' views about the personal/familial relevance of receiving this type of feedback and their subsequent/intended disclosure practices. In general, interviewees had a mixed response to receiving feedback. AOCS participants' tended to be more positive, acknowledging that genetic information may be useful (primarily) for their kin. Next of kin, in contrast, described themselves as distressed at receiving feedback, particularly those who were unaware of their mother's participation in AOCS and who were not expecting to be contacted about her results. All interviewees described the different implications of receiving genetic information for self and others. Both AOCS participants and next of kin expressed an intention to disseminate the information to relatives following confirmation of the result in an accredited laboratory. We discuss the practical and ethical issues raised by the adoption of different strategies to avoid causing distress in next of kin, for example, seeking next of kin's consent to feedback at the outset versus only disclosing research findings to the participant.

EPL6.6

Enhancing family communication about genetics: ethical and professional challenges

C. Gaff[1,2]*, J. Hodgson*[3,4]*;*

[1]*Department of Medicine, The University of Melbourne, Melbourne, Australia,* [2]*Victorian Comprehensive Cancer Centre, Melbourne, Australia,* [3]*Murdoch Childrens Research Institute, Melbourne, Australia,* [4]*Department of Paediatrics, The University of Melbourne, Melbourne, Australia.*

Genetic counsellors describe a sense of responsibility towards the at-risk family members of a person newly diagnosed with a genetic condition, wishing to ensure that they are appropriately informed about their status and options. While a small number of probands directly state their intention not to inform their relatives, many who do intend to communicate this information appear to be unsuccessful for a wide range of reasons. Some evidence suggests that successful communication of genetic information may be enhanced by follow up support from a genetic counsellor. Nonetheless, when we began to develop a genetic counselling intervention to optimise the number of informed family members for evaluation in a funded randomised control trial, we were faced with a number of ethical and professional challenges. We will share those challenges, drawing on the Reciprocal-Engagement model of genetic counselling and concepts of autonomy, to describe a framework for their resolution. While the resulting intervention aims to facilitate decision-making and is theoretically grounded in genetic counselling, little is known of practice in this area. Strategies used in practice by genetic counsellors when addressing difficulties in family communication with clients were identified while training genetic counsellors to deliver the intervention. These strategies will be compared and contrasted with the intervention.

Intentions to receive individual results from whole-genome sequencing among participants in the ClinSeqTM study

B. B. Biesecker[1]*, F. M. Facio*[1]*, H. Eidem*[1]*, T. Fisher*[1]*, S. Brooks*[1]*, A. Linn*[1]*, K. A. Kaphingst*[2]*, L. G. Biesecker*[1]*;*

[1]*National Human Genome Research Institute, Bethesda, MD, United States,* [2]*Washington University, St. Louis, MO, United States.*

The volume of data generated for a single individual and the wide range of findings from whole genome sequencing raise critical questions about the return of results and their potential value for end-users. We conducted a mixed-methods study of 311 participants in the ClinSeqTM study to assess attitudes toward learning results, perceived opinions of valued others, and how these variables predict intentions to receive results within four categories of findings ranging from medically actionable to variants of unknown significance. 294 participants indicated a preference to learn their genome sequencing results and six were unsure. Most often participants cited disease prevention as their reason, including intention to change their lifestyle behaviors. A third expressed a general desire to know, reflecting those who generally valued information and others who sought to understand the personal implications of findings. Participants had positive attitudes, strong perceived social norms and strong intentions to learn results overall, although there were significant mean differences among categories of findings. Attitudes and social norms for medically actionable and carrier results were most highly rated. Strong intentions were motivated by confidence to use the information to prevent future disease and belief in the value of information. It behooves investigators to facilitate participants' desire to learn a range of information from genomic sequencing, while promoting realistic expectations for its clinical utility and perceived personal utility.

EPL7.2

Introducing high-throughput seqencing in the clinical setting - but what will patients think ?

***A. Soulier**, S. Leonard, S. Julia, A. Cambon-Thomsen;*
UMR 1027, Inserm, Université de Toulouse - Université Paul Sabatier -Toulouse III, Epidémiologie et analyses en santé publique : risques, maladies chroniques et handicaps, Toulouse, France.

Developments in genetics, in particular the advent of high-throughput sequencing technologies, are expected to have a profound impact on health and healthcare, yet much remains to be learned about how people - present or potential recipients of such care- perceive and frame these expectations. What do laypeople anticipate ? How are expected changes understood and portrayed ? Are these expectations grounded in their previous experiences of clinical care or do they reflect principles and values attached to medicine ? In order to explore these questions we carried out a series of 8 focus groups (a total of 64 participants) in three categories : laypeople, research participants and members of patient organisations. This work was done in the context of the European Techgene project, which aimed to develop high-throughput tests for clinical use. The results of these focus groups gave insights into the types of results that people are willing to receive ; the desire for a new kind of physician patient relationship and the differences between the clinician's and the layperson 's perspectives on the distinction between clinic and research. This research provided an opportunity to confront ethical theories about these new technologies with empirical data to test ethical reasoning in context and to allow it to be grounded in the values and concerns of service users. Such empirical ethical analysis is crucial for the development of guidance that is applicable to the experiences and expectations of those who will use these emerging genetic technologies.

EPL7.3

Rapid genetic testing for BRCA1/2 genes: How could oncogenetic counseling deal with an urgent choice?

***E. Razzaboni**[1], L. Cortesi[1], G. Tazzioli[2], M. Pignatti[3], A. Baccarani[3], A. Andreotti[2], E. De Matteis[1], V. Medici[1], M. Federico[1];*
[1]Department of Oncology, Haematology and Respiratory Disease, Modena, Italy, [2]Department of General Surgery and Surgical Specialities, Modena, Italy, [3]Department of Plastic and Reconstructive Surgery, Modena, Italy.

The life-time risk to developing breast cancer in BRCA1/2 mutation carriers is 43% and 46%, respectively, and ten years risk of developing a contralateral breast cancer is 25%. Risk reducing bilateral mastectomy (RRBM) can reduce breast cancer risk in BRCA1/2 mutation carriers up to 95%. Rapid genetic testing is now available for newly diagnosed breast cancer before having surgical treatment. To guarantee autonomous and informed decision we elaborated a new model of oncogenetic counseling focused mostly on psychological aspects and surgical counseling. Since 2008, at the Modena Centre for Hereditary Breast and Ovarian Cancer (Italy) has been performed a rapid genetic testing for women with hereditary profile at the time of breast cancer diagnosis. The entire oncogenetic counselling path is completed within three weeks. So BRCA1/2 carriers have the opportunity to choose for RRBM. About 71 mutational analyses were performed and 25 (35%) patients were mutated. Among the 25 patients with a positive result, 13 (52%) had a RRBM at the surgery time for the breast cancer. A psychological follow-up was performed in all patients undergone RRBM. After 12 months from the intervention, patients showed an overall good emotional adjustment and satisfaction with their decision whereas only in a minor case sexual and psychological problems arose. Our study shows that a rapid genetic testing in patients with a hereditary profile significantly improved the choice of RRBM and that is it fundamental to guarantee both multidisciplinary counseling and psychological follow-up to these women.

EPL7.4

The impact of diagnostic developments in prenatal diagnosis; a psychological challenge

***S. Riedijk**, G. Oudesluijs, J. Hunfeld, S. le Sage, R. Galjaard, A. Tibben;*
Erasmus Medical Center, Rotterdam, Netherlands.

The introduction of new techniques for screening of genetic anomalies such as whole genome microarray analysis (WGA) into the clinic of prenatal diagnosis ensues a number of psychological challenges for pregnant couples. WGA generates more information about the current and future health of the unborn child than conventional karyotyping (CK), the gold standard for genetic chromosome analysis in prenatal diagnosis. One the one hand couples need to determine the extent of information they wish to receive about the (future) health of their unborn child. On the other, professionals may withhold or disclose information in the interest of the (health/future autonomy of the) unborn child. Our experience thus far is that WGA generates more probabilistic results (e.g. increased risk of learning disabilities) than CK. Probabilistic information is more difficult to grasp than information about actual presence of an anomaly. Moreover, probabilities represent an uncertainty that impedes decision-making. A best possible decision about the course of a desired pregnancy needs to reflect consistency with personal values and considerations in order to be processed adequately emotionally. Thus, the broadening of knowledge about the current and future health of the unborn child implies that pregnant couples will have to anticipate a variety of outcomes, determine the extent of information they wish to receive, interpret the meaning of probabilistic results and assimilate the results with personal values and considerations into their decision about the course of their desired pregnancy. Health care professionals must attend each of these themes in the pre- and post test counselling.

EPL7.5

Close parental relatedness identified by SNP microarray - challenges for genetic counselling

***R. Forbes**[1], T. Burgess[2], D. Amor[1,3,4], Z. Stark[1];*
[1]Victorian Clinical Genetics Service, Royal Children's Hospital, Melbourne, Victoria, Australia, [2]Victorian Clinical Genetics Service Pathology, Cytogenetics,Royal Children's Hospital, Melbourne, Victoria, Australia, [3]Murdoch Children's Research Institute, Royal Children's Hospital, Melbourne, Australia, [4]University of Melbourne, Department of Paediatrics, Melbourne, Victoria, Australia.

Introduction

Molecular karyotyping by microarray is recommended as 'first tier' testing in evaluation of individuals with intellectual disability, developmental delay, multiple congenital abnormalities, and autism spectrum disorders. SNP microarrays extend diagnostic scope beyond detection of submicroscopic pathogenic copy number changes by also revealing uniparental disomy, chimerism, chromosomal mosaicism and long continuous stretches of homozygosity (LCSH) creating the potential to determine previously undisclosed incestuous relationships, posing legal and ethical challenges for genetic services.

Methods & Results

SNP microarray was performed on 11000 consecutive samples. LCSH was detected in 1156 samples (10.5%). Close parental relatedness (greater than 6.25% LCSH) was detected in 322 samples (3%), with 4 samples showing homozygosity levels >20%, consistent with a first-degree relationship between parents. Two known cases of first-degree unions were detected with homozygosity levels of 17.3% and 19%.

Discussion

Identification of close parental relatedness poses unique ethical and legal challenges for genetic services. Can we reliably differentiate between extensive LCSH arising from incestuous relationships and consanguineous unions over several generations? How these findings should be reported to avoid inappropriate or insensitive disclosure whilst fulfilling legal and ethical obligations, protect the child's right to privacy, whilst ensuring medically relevant information is available is complex. We will present the approach our service has developed to deal with results indicating close parental relatedness. Next generation microarrays are likely to combine both the CGH and SNP platforms. These issues will arise with greater frequency, necessitating the development of specific guidelines.

EPL7.6

Criteria for responsible introduction of genome-based-technologies and information into public health care

***H. C. Howard**[1], E. Swinnen[2], K. Douw[3], H. Vondeling[3], J. Cassiman[2], A. Cambon-Thomsen[4], P. Borry[2];*
[1]University of Basel, Basel, Switzerland, [2]KULeuven, Leuven, Belgium, [3]University of Twente, Enschede, Netherlands, [4]INSERM, Université de Toulouse 3 Paul Sabatier, Toulouse, France.

With the incredible advances in genome sequencing over the last decade, there has been a shift towards studying more common complex disorders. The integration of this information into the health care setting has proved to be much more problematic than for monogenic disorders. Furthermore, with the 1000$ genome just around the corner, there is a strong push for the uptake of additional genomic testing. Although laudable, these advances also bring with them a slew of ethical and social issues that challenge the normative frameworks used in clinical genetics until now. With this in mind and considering a previous report from the Dutch Health Council, we outline herein five principles that should be considered in order to introduce genome-based-technologies and information (GBTI) into public health.

1) Their introduction should be based on a solid scientific foundation.
2) GBTI introduced into the health care system and financed by public funds should be focused on significant health problems.
3) The advantages of introducing and offering GBTI should outweigh the disadvantages.
4) The autonomy of patients, and individuals in general, must be respected.
5) The offer of GBTI funded from public sources should be justified in the context of the overall healthcare budget.

Parents & Children in Families with Huntington's Disease

L. B. Van der Meer[1], *A. Blom*[2];
[1]Leiden University Medical Center, Leiden, Netherlands, [2]Academic Medical Center, Amsterdam, Netherlands.

In families with Huntington's Disease (HD), family dynamics are often unfavorable for the healthy psychological development of children. In a recent study, we found that persons who grew up with a parent with HD had been exposed to more adverse experiences in childhood than the general population. This may have life-long negative consequences; we found that adults with a parent with HD have poorer mental health and more fear of intimacy and abandonment than the general population.

Recently, in the Netherlands, a meeting with professionals (psychologists, social workers) was held, to explore the nature and extent of problems that professionals encounter in their work with HD families. It was agreed that HD families present with specific difficulties concerning parents and children. Adequate support can not always be given, because couples may not be open for support with child rearing, and because existing support is not tailored to the needs of HD families.

Professionals working in Clinical Genetics, where persons apply for predictive testing and receive counseling on reproductive options, may have an opportunity to address parenting issues in an early stage, before neurological diagnosis of HD and before problems with parent-child interactions occur.

In this workshop, we will exchange experiences with parent-child issues in HD families, and with existing forms of support. Hopefully, we can cooperate in a search for more adequate, specialized programs for prevention and intervention, so that children who are growing up in HD families now and in the future have optimal chances of becoming stable adults.

EW2

Methodological guidelines for empirical validation of genetic counselling interventions

J. C. Rocha;
UnIPSa, ISCS-N, Gandra, Portugal.

Actual constraints and better awareness of critical factors underlying psychosocial based interventions had increased needs, and doubts, about genetic counselling efficacy and effectiveness. Further from the ethical foundations of genetic counseling importance and simple experience-based evidences, there is still a huge gap on empirical validation of genetic counseling interventions and still low number on meta-analytical results are conclusive. We had advocated on several contexts the need for substantial evidences about efficacy and efficiency of genetic counseling interventions and about better understanding of interview skills and programs structure specific impacts. Based on this point of view, it is proposed a model for future research on genetic counseling clinical research based on known guidelines adapted to this context.

Aspects related to frequent difficulties on randomized controlled trials as: 1. Manualization of interventions respecting broad literature reviews and clinical opinions; 2. Sampling aspects envisaging minimum bias; 3. Aspects concerned with proper control groups; 4. Sophistication of methodological design; 5. Problems with outcome measures; 6. Statistical aspects to quantify counselling effects; 7. Concerns will long term effects, acceptability and robustness of interventions, are addressed on this workshop and specific research contingencies are reflected.

Guidelines are operationalized and explained on two levels of discussion: past relevant research examples and based on ongoing or future participant's projects. Participants will be invited to share their clinical research dilemmas in order to enable solutions for future research.

EP01.01

The challenge of diagnosis and counseling for intermediate alleles in Huntington's disease: a clinical example

A. Van Tongerloo[1]*, P. Santens*[2]*, K. Claes*[1]*, A. De Paepe*[1]*;*
[1]*Dept.of Medical Genetics, University Hospital Gent, 9000 Gent, Belgium,* [2]*Dept.of Neurology, University Hospital Gent, 9000 Gent, Belgium.*

In presymptomatic testing for Huntington's disease (HD), counselees expect to receive a clear cut result about their carrier status. However, we are increasingly confronted with counseling dilemmas related to the presence of intermediate (IA) or reduced penetrance (RP)alleles, of which the individual clinical outcome is more difficult to predict than for full penetrance alleles. Moreover, these alleles can expand into full penetrance alleles upon transmission , which has specific disease risk implications for the offspring.

We present a family in which the index patient, a 45-year old man, was clinically diagnosed with HD and shown to carry a HD allele with 43 CAG repeats. Remarkably, he was the youngest in a sibship of nine, with no other affected individuals in the family. His father, who died at age 78, reportedly showed aggressive behavior throughout his life but the diagnosis of HD had never been suspected in him. His mother died at age 77 without signs of HD.

Subsequently, six siblings requested presymptomatic testing: three showed a normal molecular test result, although, in two of them, the pre-test neurologic evaluation was inconclusive regarding the possibility of early signs of HD; three other sibs had an IA of 34 CAG. The clinical history of the father suggested that, most likely, he also a carried the 34 CAG allele and that expansion occurred in the index patient.

This case illustrates the unusual segregation and counseling issues that may arise in families segregating an intermediate HD allele.

EP01.02

Psychological effects of presymptomatic DNA testing for Huntington's Disease. An Italian research.

S. Serpentini[1]*, L. Dal Sasso*[1]*, E. Pasquin*[1]*, G. Dubsky de Wittenau*[2]*, F. Cesca*[2]*, S. Radovic*[3]*, M. Balestrieri*[4]*, F. Curcio*[2,5]*, G. Damante*[1,2]*, R. Lonigro*[2,6]*;*
[1]*Istituto di Genetica, A.O.U., Udine, Italy,* [2]*Dipartimento di Scienze Mediche e Biologiche, Università, Udine, Italy,* [3]*Dipartimento di Scienze Agrarie, Università, Udine, Italy,* [4]*Clinica Psichiatrica, A.O.U., Udine, Italy,* [5]*Dipartimento di Medicina di Laboratorio, A.O.U., Udine, Italy,* [6]*Lab. Neurogenetica, SOC Pat. Clinica, Dip. di Med. di Laboratorio, A.O.U., Udine, Italy.*

Aim: The aim of the present study is to investigate the psychological well-being of presymptomatic Huntington's disease (HD) gene carriers and non-carriers 6-12 months after the genetic testing.

Methods: From May 2009 to October 2011 we evaluated 18 presymthomatic subjects resulted carriers of HD gene and 18 noncarriers. The instrument used is the Psychological General Well-being Index (PWBGI).

Results: Both the 18 subjects resulted carriers (N:18, M:5, F:13; mean age: 47,35, range age: 26-75) and the 18 subjects noncarriers (N:18, M:7, F:11; mean age: 45,93, range age: 26-69) don't show any significant difference from normative data, but the carriers mean scores are lower than the normative scores; moreover the Global Index Score indicate a moderate level of distress (71,37). The Student T-test comparison between carriers and non-carriers shows statistically significant differences in Vitality scale (11,78 versus 14,56; p<.01) and in the Global Index Score (71,37 versus 82,33; p<.05).

Conclusions: The results of the present study indicate that the presymptomatic HD gene carriers in comparison with noncarriers 6-12 months after genetic testing present a significant lower vitality and a significant worse level of the global index of well-being. The research, despite the limited sample, highlights a psychological critical situation in presymptomatic HD gene carriers and suggests the importance of specific psychosocial interventions. Further studies are needed in order to explore in a longitudinal perspective how the communication of HD gene carrier condition impacts on the psychological well-being and the quality of life of the individuals involved in genetic counseling process.

EP01.03

Genetic conditions: a challenge for couple/ family therapy

A. Leonardo[1,2]*;*
[1]*Hospital Santa Maria, Lisboa, Portugal,* [2]*POIESIS - Portuguese Association of Couple and Family Psychoanalytic Psychotherapy, Lisbon, Portugal.*

As a psychologist working and learning with genetics patients in a central hospital, I have become aware of the extreme importance of the family therapy in addition to the individual. During my clinical practice, I have realized that genetic conditions can put family dynamics at risk.

For instance, the termination of pregnancy after prenatal diagnosis. As Klass (1988) pointed out, this experience can have an effect of estrangement between the couple.We know by experience that women often complain about their partners who seem to have no grief feelings. Peppers and Knaps (1980) called out our attention to the tremendous differences between women and men mourning processes and named it *Incongruent Grief.* If we take this knowledge to our practice we will be able to help the couple to recognize these differences in a good instead of a scary way.

What about the cons of a diagnosis/predictive testing kept in secret? We will discuss a case of a woman who decided not to confess her diagnosis of Familial Amyloidotic Polyneuropathy to her husband, and how that decision put the couple bonds at risk. We will compare this case with another woman who asked for family support the diagnosis of CADASIL. Accepting that the secret was a bigger risk, than the disclosure, for her family' bonds, she decided to share the diagnosis with her partner and son.

We will discuss the pros of couple/family therapy in addition to the individual. Examples will illustrate the impact of genetic conditions over the family dynamics.

EP2 Communicating Genetic information

EP02.01

The Process of parental disclosure in Duchenne Muscular dystrophy (DMD)

P. Dasani*;*
Cardiff University, Cardiff, United Kingdom.

The communication process between parents and their affected children regarding a genetic condition and its prognosis is rarely explored. The aim of this study was to investigate this complex communication process about the diagnosis and prognosis of Duchenne muscular dystrophy. To explore this the researcher conducted 1) 6 interviews with parents of affected individuals and 2) 4 interviews with Health professionals involved in the care of the affected boys. This data was transcribed and coded for thematic analysis. We identified the appropriate method of communication, the role of family culture, key issues raised by such communication needs and appropriate source. The most appropriate method of communication was indicated as a 'drip feed' approach using language suited to the child's development. The family culture towards communication played an enormous part is how comfortable they felt discussing difficult issues. The key issues raised during this process were mutual protection, a tension between autonomy and protection and parental responsibility.

EP02.02

Genetic counselor's report to patients in clinical genetics: A survey to establish a quality management

F. R. Kreuz[1]*, b. Leube*[2]*, M. Meins*[3]*, G. Schmidt*[4]*, D. Wand*[5]*, U. Beudt*[6]*, B. Prager*[7]*, B. Prager*[7]*, D. Schäfer*[8]*;*
[1]*Gemeinschaftspraxis für Humangenetik, Dresden, Germany,* [2]*Institut für Humangenetik, Düsseldorf, Germany,* [3]*Wagner Stibbe Laboratoriumsmedizin und Pathologie, Göttingen, Germany,* [4]*Kinderarztpraxis Frankfurt-Schwanheim, Frankfurt/M., Germany,* [5]*Institut für Humangenetik, Halle/S., Germany,* [6]*Gemeinschaftspraxis, Frankfurt/M., Germany,* [7]*Überörtliche Berufsausübungsgemeinschaft, Dresden, Germany,* [8]*Institut für Humangenetik, Frankfurt/M., Germany.*

Genetic counseling is defined as a communication process dealing with genetic diseases, (recurrence) risks, diagnostic possibilities, and choices in individual and family life. An important part is the report for counselees. It is supposed to enable them to reflect on the counseling session, receive help in decision making, and inform their physicians and family members adequately.

In order to get an overview on the current practice and with regard to future quality management of genetic counseling we asked genetic institutions in Germany to send us anonymously and via internet such reports concerning six common diagnostic conditions of genetic counseling, one typical letter for each condition. Between 17 and 40 institutions responded - 40 to the issue "recurrent abortion", 37 to the issue "hereditary cancer", 32 to the issue "prenatal trisomy 21", and 17 to the issues "fragile X syndrome", "infertility pairs", and "unknown syndrome", respectively.

Reflecting the gathered reports with special regard to already existing guidelines we developed a catalogue of criteria, which adequate reports should fulfill. We classified the criteria in general, formal and technical criteria, criteria of content and counseling specific criteria. Additionally, we established a check list for writing a "successful" genetic report, well structured according to topics like general requests, necessary information, anamnesis, medical reports, results of investigations, contents of the counseling, conclusion.

Both, the check list and the catalogue of criteria, could be useful tools for writing adequate for-client reports. Moreover, they might be helpful in establishing a reasonable quality management of genetic counseling.

EP02.03

Using conversation analysis to improve genetic counseling: An example regarding counseling of fellow healthcare personnel

G. Overbeck[1], *B. R. Diness*[2];
[1]Department of Scandinavian Studies and Linguistics, University of Copenhagen, Denmark, Copenhagen, Denmark, [2]Department of Clinical Genetics, Rigshospitalet, Copenhagen, Denmark.

Background and aim: Conversation Analysis (CA) is a qualitative method where recurring speech-patterns are noted and broken patterns identified. For instance if the patient change turn-design from minimal responses to long responses, and thereby change the semi-preallocated turn-taking system. The analysis of the transcription is data-driven, and therefore inductive. CA of recorded consultation might improve provider awareness of mechanisms of communication.

Method: In 4 of 10 recorded counseling sessions the patient had a profession or an education within the health sciences. In one of these sessions excerpts were transcribed and sequentially analyzed. The CA examines how the genetic counselor and the patient linguistically cast the patient"s identity.

Result: Analysis showed that there was an ongoing negotiation of the patient's identity as patient and health care professional respectively. The role of the patient expected by the counselor may therefore be less evident to the patient. This observation was then communicated to the counselor along with suggestions of how to deal with such negotiations.

Discussion: This analysis illustrates, that CA might be a useful tool to analyze the interaction in genetic counseling, because of the data-driven approach. Concurrent interviews with the counselees might be a good supplement to the CA. Genetic counseling is best when provided form a multidisciplinary team. Inclusion of professionals with knowledge of CA might further increase the capacity of the team.

EP02.04

Communication in paediatric clinical genetics: a case study illustrating a useful analytic technique

J. Paul[1,2,3], *J. Hodgson*[1,2], *L. Stirling*[3], *S. Metcalfe*[1,2];
[1]Genetics Education and Health Research, Murdoch Childrens Research Institute, Parkville, Australia, [2]Department of Paediatrics, The University of Melbourne, Parkville, Australia, [3]School of Languages and Linguistics, The University of Melbourne, Parkville, Australia.

Various techniques have been employed to explore interactions in genetic consultations ranging from quantitative methods which have assessed over one hundred consultations, to in-depth qualitative analyses of single transcripts. Overwhelmingly research has demonstrated that dialogue is dominated by the clinician, with content being mostly educational or scientific in rather than psychosocial.

This presentation will illustrate how an interactional sociolinguistic framework, in particular, one making use of Mishler's 'voices' in medical consultations, can enable researchers and clinicians to gain a greater understanding of the apparent medical dominance illustrated in these studies (Mishler, 1984).

Mishler describes two different 'voices' present during medical interactions. Talk relating to the knowledge and experience of the client is described as the 'voice of the lifeworld'. The 'voice of medicine' refers to the technical, scientific talk of the medical world. Mishler argues that the typical or 'unremarkable interview' is dominated by the voice of medicine, while the voice of the lifeworld remains mostly suppressed. Barry et al. support Mishler's theory that allowing more space for the lifeworld can result in more efficient medical consultations (Barry et al. 2001).

In analysing two contrasting paediatric clinical genetic consultations we track the voice of medicine and the voice of the lifeworld through the lens of interactional sociolinguistics. It will be demonstrated how clinicians can effectively engage with the voice of the lifeworld, while preserving other essential elements of the consultation.

We believe that this framework could be useful for both researchers and clinicians to enhance a client-centred model of care.

EP02.05

'I realised it was coming, it was just a question of time': living with the knowledge of increased familial risk

L. Birt[1], *J. Emery*[2,1], *K. Restarick*[1], *N. Grehan*[1], *F. Walter*[1,2];
[1]University of Cambridge, Cambridge, United Kingdom, [2]University of Western Australia, Perth, Australia.

Introduction

The use of family health screening tools is increasing in primary care settings. However, little is known about the psychosocial/behavioural impact of familial risk assessment for common chronic diseases . This qualitative study explored people's response to receiving information about their risk of developing one of four marker conditions: diabetes, heart disease, breast and colon cancer. These conditions fulfil screening criteria, and effective interventions and lifestyle strategies exist for their primary and secondary prevention.

Methods

Thirty participants (aged 24-50, 22 females), recently informed of their personal risk, were recruited via the FAST study, set in 10 East of England general practices. Purposeful sampling led to a cohort of population (N=12) and increased (N=18) risk participants. Data were collected using semi-structured interviews, transcribed verbatim and interpreted using framework analysis.

Results

Receiving information about increased personal risk did not appear to cause psychological distress. Participants used mental models of health to assess salience of risk to themselves and kin. Four personalising processes were identified: 1) actively making lifestyle changes and seeking further health advice; 2) acknowledging risk but not enacting lifestyle changes or seeking further screening;3) not presently perceiving personal risk as high but acknowledging possible changes in the future; 4) being at population risk was generally perceived as a validation of current lifestyle.

Discussion

Participants were influenced by their knowledge of marker condition risk, but reported that being at higher risk did not always lead to preventive behaviours.

Furthermore, being at population risk could lead to fewer preventive behaviours.

EP02.06

Non-syndromic neurossensorial prelingual deafness: the importance of genetic counseling in demystifying parents' beliefs about the cause of their children's deafness

F. Rodrigues[1], *M. Paneque*[2], *C. Reis*[1], *M. Venâncio*[1], *J. Sequeiros*[2], *J. Saraiva*[1];
[1]Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal, [2]Instituto de Biologia Molecular e Celular, Universidade do Porto, Porto, Portugal.

Introduction: Recent advances in molecular genetics have allowed the determination of the genetic cause of some childhood non-syndromic hearing loss. Nevertheless, only a small proportion of families are referred to a clinical genetics service for proper genetic counseling. In Portugal, there are no published studies about the prior beliefs of parents about the causes of hereditary hearing loss of their children and their genetic knowledge after the genetic counseling offered by professionals with specific training. The aim of this study was to assess beliefs about possible causes of non-syndromic neurossensorial prelingual deafness in order to improve the quality of communication.

Methods: Forty-four parents (24 mothers, 20 fathers) of twenty-four children with the diagnosis of non-syndromic neurossensorial prelingual deafness due to mutations in the connexin 26 gene (*GJB2*) answered a questionnaire about genetic knowledge before and after the genetic counseling.

Results: Before counseling 15.9% of the parents knew the cause of deafness, while at a post-counseling setting this percentage was significantly higher. No differences were found between the answers of mothers and fathers before and after genetic counseling. Parents' level of education was a significant factor in pre-test knowledge. After genetic counseling 95.5% of the parents stated that the clinical genetics consultation had met their expectations; 70.5% remembered the inherited pattern, 93.2% recalled the recurrence risk of deafness.

Conclusion: It is important genetic counselors to take into account parents' beliefs and assess their genetic knowledge, in order to increase the knowledge and demystifying parents' beliefs.

EP02.07
Young adults‘ attitudes towards newborn screening and carrier identification

***M. Noke**, F. Ulph;*
University of Manchester, Manchester, United Kingdom.

Research examining parents’ experiences of receiving carrier result information from newborn screening suggests that anxiety and distress are caused by unpreparedness for results and how these results are communicated, rather than the results per se. Questions have been raised about how feasible it is to convey newborn screening information adequately during pregnancy, a time when parents often experience information overload. To understand how these newborn screening processes can be improved for future generations and to investigate the feasibility of providing newborn screening prior to pregnancy, young adults’ understanding of and attitudes towards newborn screening were investigated. Thirty-four young adults, with no experience of screening, took part in one of seven focus groups. Thematic analysis suggested that respondents recognised the benefits of carrier knowledge on altering future reproductive decisions, and despite concern regarding the stigmatisation of carriers, typically expressed a desire to have access to personal carrier status. After viewing key information from Cystic Fibrosis and Sickle Cell Disease websites, adults became preoccupied by the personal threat of being a Cystic Fibrosis carrier, yet did not acknowledge the risk of being a Sickle Cell Disease carrier, despite re-evaluating its perceived severity. Some adults were unable to accurately interpret inheritance diagrams. Young adults were not interested in receiving screening information prior to pregnancy; rationales varied from worry associated with screening information (avoidance) to the inability to conceptualise its relevance (denial). Incremental impartation of information aimed at increasing adult’s interest in screening to enable them to appreciate the personal relevance is suggested.

EP3 Reproductive Decision making

EP03.01
Impact of genetic counselling on reproductive planning of couples in families with myotonic dystrophy type 1

***R. Nunes**[1], M. Paneque[2], J. Sequeiros[2,3], A. Fortuna[4];*
[1]Hospital Center of Porto, Porto, Portugal, [2]Center for Predictive and Preventive Genetics, Institute for Molecular and Cell Biology, Porto, Portugal, [3]ICBAS, University do Porto, Porto, Portugal, [4]Center of Medical Genetics Dr. Jacinto Magalhães, National Institute of Health Dr. Ricardo Jorge, Porto, Portugal.

Myotonic dystrophy type 1 (DM1) is a neuromuscular, multisystem, progressive disease, with autosomal dominant inheritance. Genetic counselling is a delicate process in this disease, as reproductive decisions are difficult due to the variable clinic presentation and the phenomenon of anticipation of age-at-onset. We planned (1) to assess the impact of genetic counselling in families with DM1, their reproductive choices and the factors that influenced it, (2) to consider the results of prenatal diagnosis, and (3) to assess the influence of psychosocial elements in their reproductive planning. A retrospective study of 10 years used a questionnaire aimed at couples with a family history of DM1, followed by genetic counselling for reproductive planning. The main reproductive choice was not to have children (55.6%), followed by pregnancy and prenatal diagnosis (33.3%). In 60% of those couples who had prenatal diagnosis, the foetus was a carrier and the option was for termination of pregnancy. The main factors that have influenced reproductive decisions were (1) the risk of having an affected child, and (2) the existence of other children prior to genetic counselling; (3) the psychosocial impact of the disease also contributed to the reproductive choices. Genetic counselling has a strong impact on reproductive choices in families with DM1. A multidisciplinary team should always be involved in the counselling process, to meet the expectations and the needs of counselees and their families, and to provide the support they need at all stages of their decision-making process about reproductive options.

EP03.02
As the old cock crows, the young cock learns. An intergenerational approach in the perspective of family planning in case of a gene mutation carrier

***T. Brouwer**;*
Department of Medical Genetics, Utrecht, Netherlands.

A BRCA gene mutation carrier has an increased risk of 60-80 % to develop breast cancer and 5-60% to develop ovarian cancer. Its diagnosis may lead to an increased psychosocial disturbance. Female gene mutation carriers are faced with the choice to decide for screening or risk-reducing surgery. Since BRCA carriers may develop breast cancer at an age before reproduction, and the fact that they have 50% probability to pass the gene defect to offspring, this may influence their decisions as how to fulfill the wish to start or complete their family. There is a range of options in the context of reproductive choices: to have children regardless the risk, to remain childless, or adoption, or sperm- or egg donation, or to consider assisted reproduction techniques such as PND or PGD. The moral struggle and concerns that these couples have to face can be driven by various factors: their own desires, desires of the partner, the responsibility to future offspring, prevailing values with respect to the hereditary disorder in the family of origin, opinions in their wider social network and in society in general.
To prevent an unnecessary burden for the prospective parents, it is desirable that themes regarding reproduction are scheduled in the pre- and posttest counseling. In a situation where the decision-making process of reproduction stagnates, it can be beneficial to analyze the underlying reasons from the perspective of an intergenerational approach. This will be illustrated on the basis of several case reports.

EP4 Living with genetic disease

EP04.01
Psychological impact of diagnosis of thrombophilia on women with childbearing potential

***R. Mihaescu**[1], A. Stoian[2], C. Gug[1], S. Negru[1], C. Serban[1];*
[1]University of Medicine and Pharmacy, Timisoara, Romania, Timisoara, Romania, [2]Oncomed, Timisoara, Romania.

Background: Thrombophilia is a inappropriate tendency to thrombus formation. In recent years numerous studies were conducted in the field of thrombophilia, in an attempt to prevent the consequences of thrombotic disease.However, there are few studies to evaluate impact of diagnosis on quality of life for patients with childbearing potential.
Methods: Between 02.2010-01.2012 in Oncomed Timisoara we evaluated 94 patients with thrombophilia, all women. A questionnaire was given to every women, to asses quality of life.
Results: Only 70 patiens accepted to answer the questionnaire. 70% were hopeful about the future, hope generated by the fact that they found the source of miscarriage, but they were frustrated 85% of the patients, stressed about being unable to conceive. Only 27% of them were mentally exausted by the number of attemps to become pregnant and all of them were decided to try again. All patients answered that they where able to get organized and take care of daily activities; still, 25% had difficulties to resolve conflicts and 40% were not able to provide emotional support for others. All patients were able to mantain a normal sexual life. 90% of them experienced sudden mood changes, 75% felt overly sensitive to others comments, but only 37% felt at least once lost.
Conclusion: The answers showed that despite the depression associated with the miscarriages, all of them were still hoping to become mothers. This result shows that a close collaboration between hematologist and psychologist is the key to a good quality of life for these patients.

EP04.02
Quality of life and subjective health complaints in acute intermittent porphyria

***J. Andersen**[1,2], S. Sandberg[1,2], K. Nordin[2,3];*
[1]The Norwegian Porphyria Centre, Bergen, Norway, [2]University of Bergen, Bergen, Norway, [3]Uppsala University, Uppsala, Sweden.

Acute intermittent porphyria (AIP) is a metabolic disease inherited in an autosomal dominant way with reduced penetrance and variable expressivity. Symptoms presents as attacks of abdominal pain, vomiting, muscle aches, muscle weakness, and in extreme cases, respiratory paralysis. Triggering factors can be medications; hormones, alcohol, physical and psychological stress, hunger and fast. There exists little formal information about the subjective experiences of persons suffering from this condition, but previous research indicates that AIP can cause serious life style consequences and reduce quality of life in those affected.
The aim of this study was to describe self-reported quality of life and subjective health complaints in persons with latent, manifest and active AIP respectively, and to investigate the relationship between quality of life and disease related variables, demographic variables and coping strategies.
A written postal survey was distributed to all persons registered with AIP older than 18 years in Norway. Response rate was 55% (n= 140). The instruments WHOQOL-Bref, SHC, IES and MHLC were used, in addition to demo-

graphic data and information on disease severity in the family.
Quality of life in AIP patients was significantly reduced in regards to physical challenges. An overall trend in the material was that disease activity increased subjective health complaints and decreased quality of life. Results indicate that manifest and active AIP has an important impact on the lives of those afflicted.

EP04.03
Features of hospital adolescent with hereditary disease

A. Y. Bozhanov, *E. V. Zaklyazminskaya;*
Petrovsky Russian Research centre of Surgery RAMS, Moscow, Russian Federation.

We recently began offering specialized psychological help to patients with hereditary diseases. One of the first patients in this project is D - a twelve years old boy with primary oxsalosis. D is waiting for the kidneys and liver transplantation and has been carried daily hemodialysis for almost year and a half. Also he has a tracheostomy which significantly reduced his ability to talk. He spent in a hospital two years. D has two younger healthy siblings. His parents are both alive and also haven't any genetic disorders.
Metods used:
- observation
- conversation
- Dembo-Rubinshtein's method for self-esteem studying
- Drawning of nonexistent animal (projective method for studying attitudes and emotional states)

Also D's mother was asked to make a test APE (analysis of family education).
D looks below his age. He doesn't eager to communicate either with other people. D's defensive strategy has been withdrawal from situation through games and movies. He refuses to work with psychologist because he "tired of talking".
D's self-esteem is lowered, but level of claims is high. He praised his skills and intellect at low rate and self-confidence at high at the same time.
D has increased anxiety and high level of verbal aggression, which has been effectively suppressed.
His mother is placing increased responsibilities on D, especially in social sphere.
To help D to effectively cope his situation it is necessary to lower demands which are applied to him and help him to express his aggression and grief.

EP5 Psychosocial issues in cancer genetics

EP05.01
Sharing genetic cancer information with relatives: development and validation of an instrument to assess counselees' knowledge, motivation and self perceived competence.

E. de Geus[1], *C. M. Aalfs*[2], *F. H. Menko*[3], *R. H. Sijmons*[4], *E. M. Smets*[1,2]*;*
[1]*Academic Medical Center, department of Medical Psychology, Amsterdam, Netherlands,*
[2]*Academic Medical Center, department of Clinical Genetics, Amsterdam, Netherlands,*
[3]*VU University Medical Center, department of Clinical Genetics, Amsterdam, Netherlands,*
[4]*University Medical Center Groningen, department of Genetics, Groningen, Netherlands.*

Introduction
Despite the use of genetic services, counselees do not always share genetic cancer information with their at-risk relatives. Reasons for not informing relatives may be categorized as a lack of: 1) knowledge, 2) motivation and/or 3) self perceived competence. The aim of this cross-sectional study was to develop and assess the psychometric properties of an instrument that measures counselees' knowledge, motivation and self perceived competence.
Methods
Consecutive counselees who visited the department of Genetics with questions regarding the possibility of hereditary breast and/or ovarian cancer or colon cancer (including Lynch and FAP/MAP) were asked to complete a home-sent questionnaire after receiving a summary letter from the department of Genetics. This letter included information from the last counselling session. Knowledge, motivation and self perceived competence were assessed with a study-specific questionnaire. Analyses will address the acceptability of the instrument, its dimensionality (i.e. whether knowledge, motivation and self perceived competence items constitute separate scales), the reliability of separate scales and the instruments validity.
Results
Overall, 214 of 343 questionnaires were included in the analyses (response rate 62%); 108 breast and/ovarian cancer and 106 colon cancer. We will report on the instruments' acceptability and its properties to reliably and validly assess counselee characteristics that might hamper sharing genetic information with relatives. Such instrument will allow the evaluation of interventions aimed at enhancing counselees' ability to be a competent, motivated and confident informant of their at-risk relatives, which in turn may lead to more relatives taking up genetic services.

EP05.02
Impact of genetic counselling in women with a family history of breast cancer

L. Godino, *M. Bianconi, E. Razzaboni, D. Turchetti;*
Medical Genetics, Bologna, Italy.

A semi-structured telephone interview was designed to assess the impact of genetic counselling in a series of asymptomatic women with a family history of breast cancer (BC). To date, 58 women who underwent genetic counselling for BC between 2003 and 2011 have been interviewed, and the data of 42 were available for a preliminary analysis. Age ranged from 24-71 years. The majority of women considered the information received during counselling as clear (quite clear: 31.0%; very clear: 33.3%; extremely clear: 21.4%) and helpful (quite helpful: 33.3%; very helpful: 33.3%; extremely helpful: 7.1%). Twenty-five (59.5%) stated that their perceived risk of BC had changed after the counselling: for 20 (80%) it had decreased, for 3 (12%) increased, while 2 did not specify. Twelve (28.6%) declared to have made useful decision for their health after the counselling: most appropriate breast surveillance (75.0%, n=9), healthier lifestyle (8.3%, n=1) or intensification of surveillance for fear (8.3%, n=1). Nevertheless 27 women (64.3%) stated they had not followed the surveillance recommended by the counsellor. The majority of women (88.0%, n=37) had shared the information received with their family: parents (37.8%, n=14), sisters and brothers (32.4%, n=12), daughters (10.8%, n=4) or other relatives (10.8%, n=4). The family reaction was reported as positive (i.e. listening, support) by 29 of these women (78.4%).
These preliminary data suggest that genetic counselling has a significant impact on awareness, risk perception, and communication within the family, but not on surveillance. The reasons for such a low compliance to surveillance will be investigated.

EP05.03
Counselling and clinical implications of an unclassified variant in MLH1 in a family with a history suggestive of Lynch Syndrome.

W. H. Beckett, *D. G. R. Evans;*
Genetic Medicine, St Mary's Hospital and Manchester Academic Health Sciences Centre, Manchester, United Kingdom.

Unclassified variants (UVs or variants of unknown significance) are now a relatively frequent occurrence in genetic tests. Differentiating between a benign polymorphism and a pathogenic mutation can be technically difficult, particularly for missense changes and intronic variants. A number of strategies exist to help this process, but it is not always possible to confirm/exclude pathogenicity because of insufficient data, lack of resources and/or samples from other affected and unaffected individuals within the family. In this case a clinical diagnosis may be tentative and/or predictive testing is unavailable. Genetic professionals face challenges when communicating this information to patients and families. The lack of certainty can cause confusion and/or frustration. We present a case study that highlights some of the counselling implications. A 45 year old woman was referred because of a family history of colon, endometrial and pancreatic cancer. This was suggestive of Lynch syndrome, and the patient was considered to be at 50% risk. She was keen to pursue predictive genetic test to clarify the risk for her and her children. Immunohistochemistry in her cousin's bowel cancer and her mother's endometrial cancer showed loss of MLH1 protein, and molecular testing in the cousin identified a UV in the MLH1 gene. *In-silico* analysis suggested the variant was pathogenic, but no confirmatory tests (e.g. functional studies) were available. Therefore, predictive genetic testing to refine the patient's risk was not possible. She found this frustrating, particularly given the invasive nature of bowel and endometrial screening.

EP05.04
New strategies needed to improve familial colorectal cancer prevention

N. Dekker[1], *R. P. M. G. Hermens*[1], *G. Elwyn*[2], *F. M. Nagengast*[1], *H. de Wilt*[1], *J. H. J. M. van Krieken*[1], *M. J. Ligtenberg*[1], *T. van der Weijden*[3], *W. A. G. van Zelst-Stams*[1], *N. Hoogerbrugge*[1]*;*
[1]*Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands,* [2]*Cardiff University, Cardiff, United Kingdom,* [3]*Maastricht University, Maastricht, Netherlands.*

Background: Currently, only 12-49% of individuals with an increased familial colorectal cancer (CRC) risk are referred for highly effective cancer prevention. This study was performed to improve referral rates for genetic counselling and surveillance colonoscopies for high-risk and moderate-risk families, respectively.

Methods: Eighteen hospitals participated in a clustered RCT. Nine intervention hospitals received a website and brochures about familial CRC risk for patients and clinicians, and education and guideline pocket cards for clinicians. Patients in nine control hospitals received usual care. Data were collected from patients and clinicians using questionnaires and medical records.
Results: Fifty-five percent of patients (n=478/862) and 34% of clinicians (n=47/137) participated. In the intervention group, 110/161 patients (68%) and 7/20 clinicians (35%) visited the website; 34/161 patients (21%) read the brochure. Patients valued clinicians' information as most useful.
Clinicians rated the education and guideline pocket cards as most useful.
In the intervention group, 1/10 high-risk patients (10%) was referred for genetic counselling, versus 5/34 (15%) in the control group (*p*=.705). In the intervention group, relatives of 6/21 (29%) moderate-risk patients had received surveillance colonoscopies, versus 23/43 (53%) in the control group (*p*=.065).

Conclusions: Implementation of tailored digital and printed information did not improve referral rates for genetic counselling or surveillance colonoscopies of individuals at an increased familial CRC risk. Although patients and clinicians appreciated the materials, patients preferred clinicians' advice regarding their familial risk; clinicians preferred more traditional materials. Therefore, new strategies aimed both at patients and clinicians are needed to improve familial colorectal cancer prevention.

EP05.05

Unclassified variants in *BRCA1 and BRCA2*; Assessment of *in silico* analysis and proposal for communication in genetic counseling

S. Moghadasi, *N. Hofland, J. N. Wouts, J. T. Wijnen, M. P. G. Vreeswijk, C. J. van Asperen;*
Leiden University Medical Center, Leiden, Netherlands.

Background: In nearly 15% of *BRCA1/2* tests an unclassified variant (UV) is identified. In the Netherlands the four-group classification system of Bell is in use. In the current practice, class III UVs are communicated with the counselees and class II are not. Aim was to investigate whether UVs in classes II and III showed significant differences in their *in silico* characteristics and would this classification justify differences in counseling protocols regarding communication.
Methods: 88 missense UVs in *BRCA1/2* were analyzed. *In silico* analysis of UVs was performed using SIFT-analysis, Grantham score and AGVGD for the predicted severity of amino acid substitutions.
Results: 60% (n=53) of the UVs were predicted to be tolerated by SIFT-analysis and scored as neutral (C0) by AGVGD. Of the remaining 35 UVs, sixteen were scored as C0, eight were scored C15-C25 (intermediate) and eleven were scored C35-C65 (likely to be deleterious). Class III UVs more frequently show *in silico* parameter outcomes suspicious for a deleterious effect. The observed differences, however, are not absolute. Four UVs classified in class II had similar *in silico* profiles to five UVs in class III.
Conclusion: This study showed that in general *in silico* analysis is consistently applied and is able to discriminate between different classes of UVs. Aditional analyses will be required to classify UVs with more certainty. To reduce psychological distress in UV families we propose that communication of an UV should not primarily depend on its class, but on the possibility to perform additional research in the family.

EP05.06

Breast cancer patients prefer BRCA-testing without prior face-to-face genetic counseling: Preliminary results

A. S. Sie[1], *L. Spruijt*[1], *W. A. van Zelst-Stams*[1], *A. R. Mensenkamp*[1], *M. J. Ligtenberg*[1], *H. G. Brunner*[1], *J. B. Prins*[2], *N. Hoogerbrugge*[1];
[1]*Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands,* [2]*Department of Medical Psychology, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.*

Background: Currently, all breast cancer (BC) patients receive face-to-face genetic counseling prior to *BRCA1/2* mutation testing (DNA-intake). We are evaluating a different format for such an intake: telephone, written and digital information sent to BC patients' homes, and face-to-face contact following *BRCA*-testing (DNA-direct).
Patients/Methods: From August 1st 2011 to February 1st 2012, 160 BC patients referred for *BRCA*-testing could choose between DNA-intake and DNA-direct. Participants received questionnaires on psychological distress and satisfaction, just after inclusion and following face-to-face *BRCA*-result disclosure.
Results: 59% preferred DNA-direct over DNA-intake (p=0.03). Median age at inclusion was 51±11 [23-74] and age at first BC diagnosis 48±10 [23-74]. Indications for *BRCA*-testing included: positive family history (78%), age at BC diagnosis below 40 (25%) or both breast and ovarian cancer (4%). Comparing baseline characteristics, the DNA-direct group showed a lower age of youngest BC-affected relative (p<0.03), higher use of BC-related websites (p<0.01) and more referring physicians having discussed personal consequences of hereditary BC (p<0.01). At baseline the number of cases with psychological distress did not differ. Preliminary analysis of known (incomplete) DNA-results showed *BRCA*-mutations in 11% of DNA-intake and 9% of DNA-direct (n.s.). All detected *BRCA*-mutation carriers fulfilled current *BRCA*-testing criteria. Days between inclusion and result disclosure was 100±30 [22-140] versus 70±25 [23-202] in DNA-intake and DNA-direct, respectively (p<0.001).
Conclusion: More BC patients preferred the DNA-direct procedure, considering it acceptable. Processing time in DNA-direct was reduced by one month. Whether DNA-direct entails more psychological distress in mutation carriers will be evaluated later in the project.

EP05.07

Occurrence of endometrial cancer at young age in a Lynch syndrome family: implications for genetic counseling.

V. Cina[1], *C. Monnerat*[1], *P. Hutter*[2], *S. Unger*[1];
[1]*Service of Medical Genetics, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland,* [2]*Department of Genetic Medicine and Laboratory, University Hospitals of Geneva, Geneva, Switzerland.*

Lynch syndrome is a genetic predisposition to colorectal, endometrial and other types of cancers. This case illustrates that, although endometrial cancer is a well-known component of Lynch syndrome, early referral for genetic counseling based on family history of this tumor is still not systematic. We report a family in which Lynch syndrome was indentified through a patient who developed colorectal cancer at 46 years of age and one year later two sebaceous skin tumors. He was referred for genetic counseling after his dermatologist suspected Muir-Torre syndrome. The family history revealed that his sister died of endometrial cancer at 41, his mother died of a gynecological cancer at 61 and a paternal cousin developed uterine cancer at 50. Immunohistochemistry analysis of the colorectal cancer showed extinction of MSH-6 and MSH-2 proteins. Molecular analysis identified a mutation in the *MSH2* gene. By the time the result was available, his 27 year old niece had been diagnosed with endometrial cancer. Genetic counseling was offered to the family including the patient's 16 year old daughter. They did not follow up on this offer. We contacted the patient a year later and learned that his niece had died of metastatic endometrial cancer. He was very concerned about his daughter's cancer risk. The daughter and her parents received genetic counseling and requested genetic testing. Although rare, endometrial cancer at young age may occur in Lynch syndrome. This case raised questions about when uterine surveillance should begin and at what age predictive genetic testing should be offered.

EP05.08

Consent to tissue testing: Other-orientation and responsibility in cancer genetics

H. E. Shipman, *A. J. Clarke, S. Sarangi;*
Cardiff University, Cardiff, United Kingdom.

Although consent theory fundamentally focuses on the 'autonomous' choices of patients involved in clinical testing, in recent years there have been more novel conceptualisations. Within medical genetics there has been increasing recognition of the uncertainties and shifting responsibilities involved in predictive genetic testing.
In this study we take consent to tumour testing for evidence of mis-match repair defects, indicative of Lynch Syndrome, as an example of the interplay between individual autonomy, population health screening, familial involvement and beneficence. This work is part of a broader PhD study exploring the complexities of consent in the context of novel genetic testing technology. We use data (transcripts of audio-recordings) from 11 semi-structured interviews with clinicians and 13 observations of clinic sessions in the UK and Australia where consent is sought. Adopting discourse analysis, we explore the rhetoric of consent as manifest in these interviews and encounters. We relate our findings to the concept of responsibility (in relation to self, relatives and unrelated others).
We demonstrate how testing is framed as beneficial, altruistic and of minimal burden. Using observational data we demonstrate how clinicians reassure and minimise the risk due to the preliminary nature of the testing,

which enables those attending clinic (or their relatives) to be available to consent. The familial dimensions of testing and consent, in terms of communication and burden, are played down in professional interviews and yet are foregrounded in observations. This analysis provides an alternative frame to explore the dynamics of the consent process within cancer genetics.

EP05.09

A qualitative study of provider and patient experiences with decisions about risk-reducing surgery in women at increased familial risk of ovarian cancer

J. Witt[1], *G. Elwyn*[1], *F. Wood*[1], *M. T. Rogers*[2], *U. Menon*[3], *M. Johnson*[3], *W. Jones*[4], *K. Brain*[1];
[1]*Institute of Primary Care and Public Health, School of Medicine, Cardiff University, Cardiff, United Kingdom,* [2]*School of Medicine, Cardiff University, Cardiff, United Kingdom,* [3]*Gynaecological Oncology, University College London Institute for Women's Health, London, United Kingdom,* [4]*Cancer Genetics Department, Swansea Singleton Hospital, Swansea, United Kingdom.*

Women at increased familial risk of ovarian/breast cancer are offered risk-reducing bilateral salpingo-oophorectomy (RRBSO) to reduce their risk of ovarian cancer. As there is no evidence for effectiveness of ovarian screening, surgery is the only active management option available to these women. However, this decision is complex and depends on patient values and preferences.

We explored the views of healthcare professionals through semi-structured interviews and the views of patients through focus groups to obtain a detailed picture of the process of decision-making about RRBSO.

Eleven interviews with professionals, including genetic counsellors and gynae-oncologists, were conducted. They felt that women's questions mainly related to surgical menopause and hormone replacement therapy (HRT), although a number of other factors, such as body-image and risks of surgery, were also discussed.

Five focus groups with women at increased risk of ovarian/breast cancer were held. In agreement with professionals, women were especially concerned about surgical menopause and HRT. Additionally they felt it was important for them to understand their personal risk and the effects of surgery on that risk. Many women felt that elective surgery was an extreme step and said they needed a catalyst, such as a confirmed genetic mutation, to sway them towards surgery.

Both professionals and women felt that standardised, evidence-based information to facilitate deliberation about RRBSO was currently not available and that this would be helpful to support women's decision making. The results of this study will be used to develop decision support for women considering RRBSO.

EP05.10

Factors which influence participants to follow up genetic test results as a result of taking part in a population based ovarian cancer research study?

M. Young[1], *K. Alsop*[1], *D. Bowtell*[1], *G. Mitchell*[1], *T. Australian Ovarian Cancer Study Group*[2,3], *L. Plunkett*[4], *A. Crook*[5], *M. Gleeson*[6], *N. Hallowell*[1];
[1]*Peter MacCallum Cancer Centre, Melbourne, Victoria, Australia,* [2]*Westmead Institute for Cancer Research, University of Sydney, New South Wales, Australia,* [3]*Departments of Gynaecological Oncology, Westmead Hospital,, Nsw, Australia,* [4]*Department of Paediatrics, the University of Melbourne, Royal Children's Hospital, Melbourne, Victoria, Australia,* [5]*Department of Paediatrics, the University of Melbourne, Royal Children's Hospital,, Melbourne, Victoria, Australia,* [6]*Hunter Genetics, Newcastle, NSW, Australia.*

Background: The Australian Ovarian Cancer Study (AOCS), a population based study, recruited women with invasive ovarian cancer between 2002 and 2006. BRCA1 or BRCA2 mutation testing has been undertaken. Women in whom a mutation has been identified, or their next of kin in the case where the women is deceased, have been told of a mutation in writing and the availability of obtaining mutation results through a family cancer clinic. The AOCS Psychosocial project has interviewed individuals who received these letters.

Aims of AOCS Psychosocial study:

1. explore individuals' understanding of information contained in the letter they received from the researchers
2. determine factors that inform individuals' decisions about whether or not to contact a Familial Cancer clinic and take up genetic testing information

Results: a total of 25 in depth interviews have been undertaken. Factors influencing follow up acted as both barriers and enablers.

Personal
Emotions, experience and readiness
Social
Familial obligations and genetic responsibility
External
Life demands and participation in psychosocial research study

Although AOCS participants were not primarily recruited to a familial cancer study as such, uptake rates were similar to previously reported familial cancer genetics studies. The results from AOCS provide a new insight into some of the barriers which prevent research participants, and their next of kin, accessing clinical genetic services and assist in understanding why there are low numbers of individuals who make contact with a clinical genetics service following participation in a genetic research project.

EP05.11

New Model of Support and Information for Women and Men with a BRCA 1 / 2 gene fault

L. Taylor, *D. Petrie*;
Association of Genetic Support of Australasia (AGSA), Surry Hills, Australia.

Introduction
Individuals with BRCA 1 & 2 gene faults are a unique group. They may not have had cancer and are referred to by one support organization as "previvors" (FORCE).
In 2001, The Association of Genetic Support of Australasia (AGSA) was approached to provide support for BRCA 1 / 2 gene fault carriers describing anxiety around cancer risk, decision making related to risk management and grief due to lack of support.
Aims
Emotional support, accurate information / management options and analysis of participant evaluations ensuring applicability of format.
Method
From 2001 - 2004 invitations were sent to past attendees and individuals selected by Cancer Genetic Counsellors. In 2005, invitations were mailed to all families within NSW with a known BRCA 1 / 2 gene fault.
The program is devised by AGSA and a committee of consumer advocates and genetic counselors. Presentations are determined by evaluations.
Results
In 2001, 15 attended, in 2009, 102 attended; of these 70% were first time visitors. Evaluations reflect larger numbers did not affect access to information and support. Participants attend after diagnosis, to assist with decision making and others come each year. Men and women attend and discussion groups for men have focused on needs of men as partners, fathers, brothers and carriers.
This event is a non clinical approach providing emotional support. Presentations by cancer specialists ensure validity of information. Evaluations completed by 73 % of attendees show a positive response to attending. AGSA seeks funding to run the program nationally.

EP05.12

Teachable moments and missed opportunities in cancer genetic counseling.

V. Castejon[1], *C. Ochoa*[1], *E. Sumalla*[1], *S. Iglesias*[1], *C. Lazaro*[2], *I. Blanco*[1];
[1]*Genetic Counseling Unit, Hereditary Cancer Program, L'Hospitalet, Spain,* [2]*Molecular Diagnostic Unit, Hereditary Cancer Program, L'Hospitalet, Spain.*

The label 'teachable moment' (TM) has been used to describe naturally occurring life transitions or health events thought to motivate individuals to spontaneously adopt risk-reducing health behaviors. Three key constructs underlie whether a cueing event is significant enough to be a TM: the extent to which the event (1) increases perceptions of personal risk and outcome expectancies, (2) prompts strong affective or emotional responses, and (3) redefines self-concept or social role. Teachable moments have been used in preventive care to promote changes in life styles (i.e. smoking cessation) and to improve cancer screening adherence. In cancer genetic counseling, teachable moments could be a form of opportunistic counseling that could take advantages of health concerns and events in patients' lives to increase willingness and commitment to change behavior and to improve adherence to cancer screening and prophylactic measures. To do this effectively, genetic counselors need to recognize and explore the salience of patient concerns and identify opportunities to link them with unhealthy behaviors. The purpose of this study is to review and discuss the concept of TM and to explore the discourse between genetic counselors and patients identifying potential teachable moments for health behavior changes during the cancer genetic counseling process.

EP6 Education and professional development

EP06.01
The Manchester MSc Genetic Counselling Programme: 20 years experience

D. Scotcher, *T. Clancy, R. Macleod, L. Kerzin-Storrar;*
Genetic Medicine, Manchester Academic Health Science Centre, Central Manchester University Hospital NHS Foundation Trust, Manchester, United Kingdom.

We present 20 years experience of running the first master's genetic counselling programme in Europe. The course provides a vocational and academic training for genetic counsellors, and the career and professional outcomes provide evidence of its success. 115 students have graduated from 17 intakes. After graduating, 103 (90%) went on to practice as genetic counsellors (mostly in the UK but also elsewhere in Europe and internationally), and when and where eligible, have become registered or certified genetic counsellors. Graduates have also made a significant contribution to the academic field of genetic counselling through research and education.

The programme's curriculum and experience has helped to inform the establishment of additional masters and other training programmes for genetic counsellors in Europe, as well as the professional competencies required for UK genetic counsellor registration.

Since its inception the programme has prioritised 3 key elements, academic modules, clinical placements and research; however the content has evolved to ensure students are prepared for current and future practice given changes in clinical genetics including referral patterns and professional roles. This reflects a greater emphasis on autonomous practice, and a shift from primarily paediatric and reproductive genetics to encompass adult onset conditions including cancer, neuropsychiatric and cardiac genetics. A recent practical change has been to move from annual to biennial intake of a larger group which has been positive for both staff and students. Advantages have included efficiencies of scale for the teaching team, and for students realistic job prospects within current NHS constraints.

EP06.02
Global engagement with an online genetics education resource: using Google Analytics to evaluate visitor activity and behaviour in countries developing genetics-genomics within nursing practice

M. Kirk[1], *R. Morgan*[2], *E. Tonkin*[1], *K. McDonald*[2], *H. Skirton*[3]*;*
[1]*NHS National Genetics Education & Development Centre, Pontypridd, United Kingdom,* [2]*Genomics Policy Unit, Pontypridd, United Kingdom,* [3]*Plymouth University, Taunton, United Kingdom.*

The rapid increase in gene-disease discoveries offers real promise of clinical applications for people and families affected by genetic conditions but for which health professionals are unprepared because of lack of training. The availability of clinically relevant education resources is critical to enabling nurses and other health professionals to develop the appropriate genetics-genomics knowledge and skills to provide optimum care for individuals and families. Online education resources play an essential role in this but such resources can be personnel-intensive and developed over an extended period. Optimising such resources, particularly in economically challenging times, is essential.

Telling Stories, understanding real life genetics (www.tellingstories.nhs.uk) is a web-based education resource using real life stories to promote understanding of the impact of genetics-genomics in healthcare. Google Analytics provides time series data for analysing web usage to optimise website effectiveness. We present data of visitor activity and behaviour from 123 countries from 2009-2011 and consider how the application of the web analytics:

- informs approaches to enhancing visibility of the website;
- provides an indicator of engagement with genetics-genomics both nationally and globally;
- informs future expansion of the site as a global resource.

Telling Stories is an accessible, broad-reaching resource that is of global relevance for health professionals, attracting over 33,500 visitors between 2009-2011, with a steady increase in numbers of returning visitors. The majority of visitors come from the UK, USA, Netherlands, Canada and Australia. More needs to be done now to enhance its accessibility for people of other languages and cultures.

EP06.03
Flexible online learning in genetics: meeting the needs of the medical specialty trainee

J. Instone, *M. Bishop, R. Newton, P. Farndon;*
NHS National Genetics Education and Development Centre, Birmingham, United Kingdom.

Widespread inclusion of genetics into medical specialty training in the UK is placing demands on genetics specialists to provide education. A review of the Royal College of Physicians' (RCP) specialty curricula showed over 80% of the 27 medical specialties (excluding Clinical Genetics) include genetics training. Training directors for these specialties have expressed concern about how to provide equitable and appropriate training in genetics to their trainees. One approach is to provide e-learning opportunities. The National Genetics Education and Development Centre has collaborated with the cardiology curriculum committee of the RCP to develop a genetics e-learning package for cardiology trainees. This online package covers the genetics learning outcomes within the curriculum using modules based on clinical encounters that cover a range of conditions and contextualise the genetic concepts. Modules can be accessed at any stage during training, allowing trainees to individualise their learning by completing them during relevant clinical rotations. The core genetic concepts are presented separately, allowing learners to access information as needed. The electronic format provides a record of progress and completion for inclusion into the electronic training portfolios. These materials are currently being piloted to inform a wider evaluation strategy which will assess the acceptability of this mode of delivery and the perceived ability of UK trainees to apply the knowledge learnt to their clinical practice. E-learning provides a viable option to deliver genetics education to medical specialty trainees that complements face-to-face teaching and clinic observation while offering flexibility in meeting the individual needs of specific training programmes.

EP06.04
A collaborative evaluation of a dual model of consultative supervision combining individual and team supervision in genetic counselling practice

A. Phillips[1], ***G. Mannion***[2], *J. Birch*[2]*;*
[1]*Alder Hey Children's NHS Foundation Trust, Liverpool, United Kingdom,* [2]*Liverpool Women's NHS Foundation Trust, Liverpool, United Kingdom.*

We outline key components of the design, delivery and evaluation of a model of consultative clinical supervision for a team of genetic counsellors at Liverpool Women's NHS Foundation Trust, England, incorporating the criteria and recommendations of the Association of Genetic Nurses and Counsellors (AGNC). This integrative, multitheoretical, dual model, combining individual and team based supervision provided by consultative supervisors, contributed to local awards for excellence in patient care, team working and partnerships. The project was undertaken as a collaborative endeavour between the team and the team supervisor, the Head of Psychosocial Services at Alder Hey Children's NHS Foundation Trust, Liverpool. Normative, formative and summative evaluation was designed-in at the start of the programme by the supervisor. The Lead and Deputy Lead Genetic Counsellors, in their capacity as supervisees and senior practitioners with leadership and management responsibilities for the team, contributed principles from real-world, action-research and summative evaluation. Whilst this is specific to a particular team of UK NHS professionals, as a flexible and pragmatic model of reflective practice designed to support and develop healthcare professionals, the principles, framework and structural components which informed the model, and the data it has produced, are likely to be of wider interest in the genetic counselling community and beyond. There is particular significance for the wellbeing and continuing professional development of staff and the enhancement of the of quality patient care.

EP06.05
Challenges for cancer genetic counselling: findings from Portuguese oncogenetic services

Á. Mendes[1], *L. Sousa*[1], *M. Paneque*[2]*;*
[1]*University of Aveiro - Department of Health Sciences, Aveiro, Portugal,* [2]*Centre for Predictive and Preventive Genetics, IBMC, University of Porto, Porto, Portugal.*

Cancer risk counselling has grown rapidly in recent years to become a major area of specialisation within genetic counselling. In some countries, oncogenetic services are still not provided by specifically trained professionals. Psychosocial support is only partially made available for individuals and families throughout genetic counselling protocols. We examined the current practice of oncogenetic counselling through the professionals' views and ascertained the needs for the provision of psychosocial support in cancer genetics services. A qualitative study was designed; semi-structured focus groups and individual interviews were performed involving 30 professionals from Portuguese healthcare institutions where oncogenetic counselling is offered (geneticists, gynaecologists, oncologists, nurses, psychologists and genetic counsellor trainees). Current practice, unmet service needs and issues for improving practice were the major themes identified in participants' perceptions. Findings suggest: professionals' practice is aligned with the teaching model; the genetic counselling agenda is predominantly informative-based with a nondirective focus; a scarce workforce of adequately trained psychosocial professionals, aggravated by other structural and organizational constraints are serious drawbacks to consistent psychosocial delivery; multidisciplinary teams working in genetics were stated as priority, along with genetics education for healthcare professionals in primary care. Cancer genetics healthcare needs an adequate training and organization towards collaborative standards of care and functional forms of access for patients. Portuguese genetic counsellors have recently completed their training and may therefore ease some of the needs. This study may contribute for envisioning paths for the integration of a psychosocial-oriented stance in oncogenetic services.

EP06.06

Knowledge and attitudes of Italian nurses toward Genetics

L. Godino[1], *D. Turchetti*[1], *H. Skirton*[2];
[1]Medical Genetics, Bologna, Italy, [2]Plymouth University, Plymouth, United Kingdom.

In order to explore the understanding and attitudes of Italian nurses and midwives toward genetic healthcare, a cross-sectional survey using a self-administered questionnaire was carried out in Bologna, Italy, in 2010. In 2011 the survey was extended to a larger population of Italian nurses by using a questionnaire uploaded to the Survey MonkeyTM website. Specialist genetic nurses currently work in many countries; however there are very few genetic nurses in Italy and the knowledge of Italian nurses to provide care for people with or at risk for genetic conditions in unclear.

Out of 102 (85%) nurses and midwives responding to first study, 61% believed genetic counselling was only an informative and advisory process, while 53.9% did not specify; 62% (n=63) did not identify nurses' role in genetic healthcare, but 28% (n=26) believed nurses could provide information and support.

The second study was completed by 385 nurses, the majority (40.4%, n=131) correctly answered four of five questions on knowledge of genetics. Knowledge scores did not change by age, but was positively correlated with academic qualification. Only a minority (26.8%, n=103) of respondents believed genetics was very relevant to the nursing role.

The findings of these studies indicate that although nurses have the basic knowledge of genetics, they need more education not only on genetics topics, but also on the transferability of those into nursing care.

EP06.07

The Home Coming of Genetic Counsellors: The Cyprus Experience

V. C. Anastasiadou[1,2], *T. Delikurt Tuncalp*[1], *E. Spanou Aristidou*[1], *A. Kotti*[2], *G. Tanteles*[1];
[1]Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus, [2]Archbishop Makarios III Medical Centre, Nicosia, Cyprus.

The impact of culture in genetic counselling and cultural competence of genetic counsellors are important topics masters level training programs and academic research. They are also crucial in clinical settings. Genetic counsellors are being taught to become self-aware of other ethnic/cultural groups, to acknowledge similarities and differences between their own and other cultures and to understand how such similarities/differences impact socially and/or institutionally the care of diverse patients.

Although, masters-level programs are steadily emerging in several countries, most genetic counsellors are still or have been trained in countries other than their own home-country, such as United States (US) and United Kingdom (UK), where these programs are well-established. These counsellors adopt a professional-culture that is shaped by the healthcare and social culture of their host-country. It has been noted that not enough attention has been given to how such genetic counsellors "readapt" to their own culture, both socially and professionally, after returning to their home country.

Our Clinical Genetics Clinic (CGC) gives emphasis to cultural competence, especially as our patient load culturally so diverse. Among the team are two masters-level genetic counsellors; a Greek-Cypriot and a Turkish-Cypriot genetic counsellor who have been trained in the US and UK. Both genetic counsellors have similar and different experiences about training overseas and returning to their own country. The poster addresses on these experiences and challenges faced in work-place and small community due to the clashes of their cultural identity specific to their own country/community and professional culture they acquired through their overseas training.

EP06.08

E-learning in Genetics - Multimedia Educational Training Program

C. Gug;
University of Medicine and Pharmacy "Victor Babes", Timisoara, Romania.

Telemedicine is born with the Internet.Tele-education is one of its application. An on-line learning infrastructure is considered essential for the delivery of educational programs in medical genetics.The use of a performing animation system allows the geneticists to explain the essence of the fundamental genetic phenomena. The flash technology was used to access animation on the Internet, as it already represents a standard in creating animation that has Internet impact. The navigation system of the FLASH animation allows each scene to be accessed separately using representative images of a scene as buttons. Respecting the scientific truth by taking into account the limits imposed by the technical possibilities may represent a true challenge for the people involved. For didactic purposes, the phenomena (mitosis, chromosome and chromatin structure, DNA replication and DNA repair) were divided into several stages. The number of the scenes is directly proportional with the complexity of the phenomenon. As learning in the traditional manner involves transmitting the information under the form of a text simultaneous with the scrolling image, a short explanation of the scene is inserted. The text is available in English and Romanian. The use of the multimedia (graphics and 3D animation) programes enhances teaching process of any fundamental genetic phenomenon and contributes to the computer supported training in the field of medical genetics.

EP7 Access to genetic services

EP07.01

Systematic review of research related to barriers to access to genetic services

T. Delikurt[1,2], *G. R. Williamson*[1], *V. Anastasiadou*[2], *H. Skirton*[1];
[1]School of Nursing and Midwifery, Faculty of Health, Education and Society, Plymouth University, Plymouth, United Kingdom, [2]Clinical Genetics Clinic, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus.

The genetic components of disease are being identified through rapid progress in genomic research and new scientific knowledge is quickly being translated into clinical practice. Demands on genetic services are increasing in parallel to these advances. There is a global challenge for healthcaresystems in different countries to efficiently integrate genetic services into their healthcare infrastructure, to utilise scientific advances and, most importantly, provide equitable access for citizens while minimising healthcare costs. To achieve this, it is important to identify which factors can prevent or influence patients' access to genetic services. As part of a doctoral study on the provision of genetic services for the Turkish Cypriot community in Cyprus, a systematic review of empirical evidence on barriers to accessing genetic services was conducted. Five electronic databases were searched for studies published in English in peer-reviewed journals between 2000 and 2010; 27 articles were included in the review. The majority of studies were undertaken in the United States (n=17), focused on cancer genetic services/counselling (n=17) and used quantitative methodology (n=19). Identified barriers were related to individuals (n=17), to institutional/healthcare professionals/systems (n=14) and to the community (n=5). There is diversity in how access to genetic services is researched and the majority of barriers we identified derived from studies that were not directly investigating barriers to access. More specific research on this topic is urgently needed to inform development of "targeted interventions" to enable equitable access to genetic services for individuals in a range of populations.

EP07.02

Patient Expectations and Attitudes towards a Specialist Genetic Eye Service

E. Clarke[1], *G. Hall*[2], *R. Combs*[1], *G. C. M. Black*[1,3];
[1]University of Manchester, Manchester, United Kingdom, [2]Genetic Medicine, Manchester Academic Health Science Centre, CMFT, Manchester, United Kingdom, [3]Manchester Academic Health Science Centre, CMFT, Manchester, United Kingdom.

BACKGROUND: Little research has explored the views of patients referred to specialist genetic eye clinics. Future service development must be informed by the perspectives of patients to ensure that services are accessible and meet their needs.

METHOD: Semi-structured telephone interviews were undertaken with patients referred to the Genetic Eye Clinic in Manchester, UK. Participants were interviewed before their first appointment. The interview transcripts were analysed using Interpretative Phenomenological Analysis (IPA).

RESULTS: Forty six people were invited to participate and 9 agreed to be

interviewed (response rate 20%): 5 participants were patients with a visual impairment; 4 were the parent/carer of a child patient. The major themes identified were: lack of preparation and restricted expectations due to unfamiliarity with the service; psychological adjustment to the diagnosis of an eye condition impacting on needs and expectations; concern about the future; hope for future treatments; and, positive attitudes towards genetics.
CONCLUSIONS: The participants had consistently positive attitudes towards genetic eye services, genetic testing and genetic research. However lack of preparation and knowledge of available services, particularly genetic counselling, meant families may not get the most out of their appointment. A leaflet, available in a range of formats, has been devised to improve patient experience. The results from this study improves our understanding of the counselling needs, expectations and attitudes towards genetics, including hopes for treatment, in families with inherited eye conditions.

EP07.03

The role of the Cardiac Genetics Nurse in Inherited Cardiac Conditions Services: impact on the quality of the patient and family experience

M. Kirk[1]*, A. Simpson*[2]*, M. Llewellyn*[2]*, E. Tonkin*[3]*, M. Longley*[2]*, D. Cohen*[4]*;*
[1]NHS National Genetics Education & Development Centre, University of Glamorgan, Pontypridd, United Kingdom, [2]Welsh Institute for Health and Social Care, Pontypridd, United Kingdom, [3]NHS National Genetics Education & Development Centre, Pontypridd, United Kingdom, [4]Health Economics Policy Research Unit, University of Glamorgan, Pontypridd, United Kingdom.

In 2008 the British Heart Foundation launched an initiative to fund nine Cardiac Genetic Nurse (CGN) posts across England (n=8) and Wales (n=1) for three years, in order to improve the quality of service provision to patients and families affected by inherited cardiac conditions. A single case study approach was taken to evaluate the initiative, collecting data from multiple sources. Themed semi-structured interviews were held with all CGNs, Cardiology and Genetics Clinical Leads from each of the nine sites, Genetic Counsellors and a patient representative, at key points during the project. A patient focus group was also held. Detailed thematic analysis of the qualitative data was conducted using NVivo 8.0. Three broad categories emerge from the data pertaining to the quality of patient/family experience:
1. 'Continuity' relates to the CGN role in providing support and continuity along the patient journey. Time, Giving clarity, and Managing anxiety and uncertainty, are important sub-themes.
2. 'Coordinating care for the patient and family' highlights the CGN role in providing patient and family centred care, with sub-themes of Preparing; Having the bigger picture; and Knowing the patient and family.
3. 'Coordinating care across the pathway' concerns the CGN role in coordinating the multidisciplinary team across the two specialties and linking with primary and secondary care and others.
The CGNs enhance the quality of the patient/family experience through an holistic approach to care, offering clarity and continuity along a potentially complex pathway, often at a time when patients and families will be feeling particularly vulnerable.

EP8 Ethical issues

EP08.01

Parental views on confidentiality when adolescents are seen alone in the metabolic clinic

F. Pearce[1,2]*, R. Duncan*[3,4]*, A. Derks*[5,6]*, M. Jekel*[5,6]*, S. Sawyer*[6,7]*, A. Boneh*[8,2]*;*
[1]Genetic Health, Parkville, Victoria, Australia, [2]Murdoch Children's Research Institute, Melbourne, Victoria, Australia, [3]Centre for Adolescent Health., Parkville, Victoria, Australia, [4]Department of Paediatrics, University of Melbourne, Victoria, Australia, [5]Radboud University, Nijmegen, Netherlands, [6]Centre for Adolescent Health., Melbourne, Victoria, Australia, [7]Department of Paediatrics, University of Melbourne, Melbourne, Victoria, Australia, [8]Metabolic Genetics, Victorian Genetic Health Services, Parkville, Victoria, Australia.

Clinical guidelines for health practitioners suggest that adolescents should be seen on their own for part of the clinic consultation. However, little is known of parental attitudes on this issue. We explored the views of parents of adolescents in our Metabolic Clinic, in which this is standard practice.
Of 40 eligible parents, 33 completed a questionnaire handed to them in clinic, seeking parental understanding of confidentiality, their views about when information should be shared with them and their perception of benefits/concerns of consulting with young people alone.
The main advantages parents identified in adolescents seeing clinicians alone were: practicing talking to the doctor alone; taking responsibility for their own health; helping them become more mature.
Concerns identified included the possibility of not being informed about important issues (including eating disorders, cigarette smoking, alcohol and illicit drug use, pregnancy, and problems with parents); not being informed of the treatment plan, and concerns about their child possibly not understanding the issues or not remembering the treatment plan. Parental understanding of a confidential consultation with young people alone was remarkably similar to that in a general adolescent clinic (N=86), but they were more likely to see the advantages of confidential discussions in promoting self management skills. However, they seemed more protective of their children, as evidenced by their expectation that medical consultations where their children are seen alone, should begin at a later age.

EP08.02

When to tell? - Disclosing Genetic Information

D. M. Petrie OAM*, D. Kouznetsova;*
Association of Genetic Support of Australasia (AGSA), Surry Hills NSW 2031, Australia.

Little research exists on when and how parents should go about disclosing genetic information to their affected children and siblings, as well as its impact. This presentation will detail quantitative and qualitative research amalgamated from reports sourced directly from the Association of Genetic Support of Australasia (AGSA) - a peak umbrella organisation established in 1988 for rare genetic conditions, and its extensive Rare Disease Database representing over 950 genetic conditions in 2,200 families.
This presentation will outline the dilemmas faced by parents upon receiving a genetic diagnosis for their child. Negative effects of withholding information from all family members will also be discussed. Recommendations for when to disclose genetic information, as well as strategies employed for information sharing will be discussed. Finally, implications for the health professional are diagnosis delivery, and the importance of securing access to an appropriate support group will be explored.

EP08.03

Sharing data from whole genome studies: empirical study of ethical implications

A. Middleton[1]*, M. Parker*[2]*, E. Bragin*[1]*, C. Wright*[1]*, H. Firth*[1]*, N. Carter*[1]*, M. Hurles*[1]*, On Behalf of the DDD Study*[1]*;*
[1]Wellcome Trust Sanger Institute, Cambridge, United Kingdom, [2]Ethox, University of Oxford, Oxford, United Kingdom.

Elements of a person's past, present and future medical health can now be revealed in a matter weeks via whole exome sequencing of a saliva/ blood sample. Such technology is frequently used in research to understand the genomic basis of disease and will very soon be used within clinical health services.
It has been considered good practice for many years to conduct genomic research anonymously and not share any individual results with research participants. However, there is mounting pressure to change this approach and begin to share individual results with research participants. There is, however, no clear guidance or evidence to suggest what sort of data research participants want - should it only relate to clinically actionable conditions or would participants be interested in receiving results with broader implications or even their raw sequence data? There is an urgent need for large-scale empirical research to gather evidence on what is reasonable, responsible and indeed ethical to share.
As a contribution to this process we have designed a mixed-methods study and have launched an innovative questionnaire (see www.genomethics.org) that uses film to explore the ethical implications of whole genome research. The questionnaire is accessed online. We are inviting genetic counsellors, genomic researchers, health professionals and lay members of the public worldwide to complete the questionnaire and are aiming for 20,000+ responses. This poster will introduce the study design, explain why the research into genome ethics is important and discuss the relevance of this to both the research and clinical genetics community.

EP08.04

A New Initiative for Genomics and Society Research

J. Kaye[1]*, E. M. Meslin*[2]*, B. M. Knoppers*[3]*, E. T. Juengst*[4]*, M. Deschênes*[5]*, A. Cambon-Thomsen*[6,7]*, D. Chalmers*[8]*, J. De Vries*[9]*, N. Hoppe*[10]*, A. Kent*[11]*, C. Adebamowo*[12,13]*, P. Marshall*[14]*, K. Kato*[15]*;*
[1]Department of Public Health, University of Oxford, Oxford, United Kingdom, [2]Indiana University, Bloomington, IN, United States, [3]McGill University, Montreal, QC, Canada, [4]University of North Carolina, Chapel Hill, NC, United States, [5]P3G, Montreal, QC, Canada, [6]INSERM, Toulouse, France, [7]Université de Toulouse, Toulouse, France, [8]University of Tasmania, Tasmania, Australia, [9]Faculty of Health Sciences, University of Cape Town, Cape Town, South Africa, [10]Leibniz Universitaet, Hanover, Germany, [11]Genetic Alliance UK, London, United Kingdom, [12]Institute of Human Virology, Garki, Nigeria, [13]University of Maryland, Baltimore, MD, United States, [14]Case Western Reserve University, Cleveland,

OH, United States, [15]Kyoto University, Kyoto, Japan.

Genomic science is advancing rapidly and is increasingly international, proactive and coordinated. In contrast, research into the ethical, legal and social implications (ELSI) of genomic science, a lynchpin of appropriate policy development, so far remains largely regional, reactive and fragmented. Given the achievements in terms of scholarship, policy information and public engagement that have emerged from ELSI's conventional research methodology so far, important progress can legitimately be expected if ELSI research adopts strategic, large-scale and collaborative approaches analogous to those that have characterised genomic science. This presentation will present an international initiative, which is developing an infrastructure and a research culture aimed at making large-scale ELSI research more efficient, effective and economical. The aims of this initiative are to:-

- facilitate new collaborations;
- increase output;
- provide tools to help coordinate endeavours;
- reflect the international character of genomic science appropriately; and
- avoid unnecessary research redundancy.

This will facilitate networking, critical reflection and the development of proactive strategies for international ELSI research in genomics and derived fundamental or translational sciences. In doing so, it will not only provide maps of the international ELSI landscape to inform and coordinate future research, but will also foster a new way of thinking and doing international ELSI research and fuel the rapid advance of ELSI research in the short, medium and long term.

EP08.05

Who's to blame? A reflection work about identification of genetic potential in high-performance athletes

***D. Delani**;*
Universidade Federal de Rondônia, Porto Velho, Brazil.

The sport in general is an activity that is gaining more importance and more people around the world. In order, growing, developing high-performance athletes, many companies invest in the preparation of these athletes for international competitions like the Olympics Games. In this sense, innovative studies both in the field of sports as in studies of health, seek to identify and recognize these genetic patterns in athletes in the various methods for indicating potential physical abilities required for different sports or genetic predisposition to diseases that may likely to affect its performance. Although innovative, and hold large financial interest, the ethical issues involved in this process should be discussed. A key role has to be devoted for assessing quality of laboratories and delivering information regarding such tests. Many other aspects have been discussed in the preparatory debates to the revision, such as consent issues or biobanks and are absent from the proposal. However these issues are among the most problematic in research and practice. Thus these work alerts discuss the consequences of this lack of regulation. Unless the delineation of responsibilities is clarified result may no longer be acceptable. How to delimit this seemingly, open-ended avenue of potential professional responsibility and possibly, liability? What are the mechanisms available? Moreover these without these assignments the results can cause irreversible damage to the candidates analyzed.

EP08.06

"A morass of considerations": Exploring attitudes towards primary care ethnicity-based haemoglobinopathy screening.

***S. M. Jans**[1], L. Henneman[1], A. de Jonge[1], C. G. van El[1], L. M. C. van Tuyl[2], M. C. Cornel[1], A. L. M. Lagro-Janssen[3];*
[1]EMGO Institute for Health and Care research, Amsterdam, Netherlands, [2]VU medical centre, Amsterdam, Netherlands, [3]Institute for Gender Studies, Radboud Medical centre, Nijmegen, Netherlands.

Background: Although advised by the WHO, the Netherlands does not have a national haemoglobinopathy carrier screening program. HbP carrier testing for those at risk is at best offered on the basis of anaemia without facilitating reproductive choice. Registration of ethnicity has been shown to be controversial and may complicate the introduction of a screening programme. However, other factors may also play a role.

Aim: To explore perceived barriers and attitudes amongst general practitioners (GPs) and midwives regarding ethnicity-based haemoglobinopathy carrier screening.

Method: Six focus groups with a total of 37 GPs and midwives were conducted, transcribed and content analysed using Atlas-ti.

Results: Both GPs and midwives struggled with correctly identifying ethnicities at risk leading to several complex considerations. Ethical concerns regarding privacy seem to originate from World War II memories when ethnic and religious registration facilitated deportation of Jewish citizens, coupled with the current political climate. Some midwives thought the ethnicity question might undermine the relationship with their clients. Despite this, both groups seemed positive and are familiar with identifying ethnicity and use this in individual patient care. Software programs prevent GPs from registering ethnicity of patients at risk. Financial implications for patients were also a concern.

Conclusion: Although health professionals are generally positive, ethical, financial and practical issues surrounding ethnicity-based HbP carrier screening need to be clarified before introducing such a programme. Primary care professionals can be targeted through professional organisations but need national policy support.
