SOUTHERN GREAT BASIN SEISMOLOGICAL DATA REPORT FOR 1981 AND PRELIMINARY DATA ANALYSIS

By

A. M. Rogers, S. C. Harmsen, W. J. Carr, and W. Spence

ABSTRACT

Earthquake data for the calendar year 1981 are reported for earthquakes occurring within and adjacent to the southern Great Basin seismograph network. Locations, magnitudes, and selected focal mechanisms for these events and events from prior years of network operations are presented and discussed in relation to the geologic framework of the region. These data are being collected to aid in the evaluation of the seismic hazard to a potential repository site at Yucca Mountain in the southwestern Nevada Test Site. The regional stress field orientation, as inferred from focal mechanisms, is characterized by a northwest-directed least compressive stress and a northeast-directed greatest compressive stress. We infer from this stress orientation that faults of north to northeast trend are most susceptible to slip. Faults of this orientation exist within the Yucca Mountain block, but they probably have not moved significantly in the last 500,000 years. Yucca Mountain lies within a fairly large area of relatively low level seismicity extending west to the Funeral Mountains, south to the Black Mountains and Nopah Range, and southeast to the Spring Mountains. One M 1.7 earthquake has been located in the Yucca Mountain block in about 1 year of intense monitoring. At present somewhat conflicting geologic, seismologic, and stress evidence hinder definitive conclusions about the seismic hazard at the proposed repository site.

INTRODUCTION

Seismological studies of the southern Great Basin (SGB) region are being conducted to assess the seismic and tectonic suitability of the Nevada Test Site (NTS) region for a nuclear waste repository. The project goals are to study the seismicity of the region and determine the seismic hazard to the facility. Because of the scarcity and inconsistent deployment of seismograph stations in this area in the past, few data have been available previously about the level of seismicity and its relation to faults. Furthermore, because of the extensive alluvium cover in the Basin and Range, many important faults are partially or completely hidden and difficult to evaluate geologically. Detailed seismic studies are required to help define seismic source zones that will be relevant to the assessment of the seismic hazard, particularly the hazard to the temporary support facilities of the repository. Although delineation of currently active fault zones does not assure that activity in the future will not shift to presently inactive zones, it is possible that by combining current earthquake patterns with the record of Quaternary faulting some prediction can be made of future tectonism.

In 1979 a 47-station seismic network (fig. 1) was installed within a 160-km radius of NTS to locate and study earthquakes. This network covers the tectonic features of greatest significance (fig. 2) relative to seismic-hazard assessment at NTS, including (1) Fish Lake Valley-Death Valley-Furnace Creek fault zones, (2) the apparent east-west belt of seismicity, and (3) the NTS "paleoseismic zone." Also shown on figure 2 are other major tectonic features that may or may not be vital in seismic-hazard assessment at NTS, but may be important to an understanding of regional tectonics. The regional extent of this network is necessary for tectonic studies and to provide seismological data in the event a site may be chosen off the NTS. In May 1981, a six-station supplemental mini-net was deployed on Yucca Mountain to lower the detection threshold and improve location accuracy for earthquakes at the candidate site.

The principal intent of this report is to make data obtained by the network generally available, to indicate the progress of ongoing research, and to present preliminary interpretations of these data. Appendices A, B, C, and D set forth the basic data related to earthquakes during the 1981 calendar year. These appendices record earthquake origin times, epicenters and focal depths, local magnitudes, and information pertaining to the quality of the locations; the phase readings, first motion directions, and durations used to compute the earthquake parameters are also included. The main body of this report presents and discusses these data, sometimes including past as well as more recent data in order to preserve continuity and perspective.

The data collected in the final quarter of this report period are of higher quality (fig. 3) because of the installation of a digital online detection and recording facility based on a DEC PDP 11-34 computer and associated peripheral equipment (Johnson, 1979). The digital data are analyzed using a DEC PDP 11-70 computer that is an existing part of the U.S. Geological Survey (USGS) computer facility. This method of data recording and analysis is a significant improvement over the old method employing 16 mm film recorders and requiring reader scanning of three 24-hour film records. The computer system continually scans the incoming real-time signals and saves data only when a triggering algorithm indicates that an earthquake has been detected. The reader is required to separate false triggers from earthquake triggers, display the digital traces on an oscilloscope screen, and take readings from the screen electronically that are saved in the computer memory. This technique has not only resulted in at least a doubling of the number of earthquakes that it is possible to detect and read (fig. 1), but has increased the accuracy of the process by eliminating errors caused by misreading times, incorrect association of a reading with the proper station, transcription errors, and key punching errors. The film records, however, continue to serve as a backup during periods when the computer fails. Computer failure averages about 20 minutes per day and usually occurs in block time intervals, occasionally lasting as long as 24 hours if they occur between operator visits on weekends.

ACKNOWLEDGMENTS

Robert Herrmann aided us for an extended period during a 6-month sabbatical in Golden and supplied the operational software library for the real-time

digital data acquisition on the PDP 11-34 computer and the digital processing software for the PDP 11-70 computer system. The original event detection algorithm and a magnitude estimation method were developed by Carl Johnson of the U.S. Geological Survey, who also provided advice on several occasions. Additional assistance on the digital system was given by Steve Malone and Eric Haug. James W. Dewey provided assistance in the joint hypocenter determination relocation of the 1966 earthquake series in southeastern Nevada.

Some local magnitude estimates of SGB earthquakes were obtained with the aid of Roy Miller, Kate Hutton, Ute Vetter, and William D. Richins. We also thank Richins and David S. Brumbaugh for supplying seismograms that aided in the determination of a focal mechanism for a felt earthquake near Alamo, Nev. Focal mechanism plots were generated using an adaptation of a computer program obtained from Stuart Sipkin.

Field equipment maintenance and calibration was provided by Don Morgan and Bill Johnson of the Stanwick Corporation, under the direction of Dee Overturf and Tom Bice of the USGS, who were also responsible for equipment service and calibration at the recording facility in Golden, Colo.

MAGNITUDE DETERMINATION

Magnitudes of earthquakes located within this network are computed from the duration of ground motion employing the relation:

$$M_D = -0.87 + 2.0 \log \bar{\tau} + 0.0035 \bar{\Delta}$$

where $\bar{\tau}$ = the geometric mean of the total signal duration in seconds from all stations recording the event, that is, the time between the first motion and the point at which the signal is lost in the background noise; $\bar{\Delta}$ = the arithmetic mean distance in kilometers between epicenter and the stations. Although the relation above was developed for a slightly different definition of duration (Lee, and others, 1972), the correspondence between duration magnitude, M_D, and Richter magnitude, M_L, is satisfactory (fig. 4). The M_L magnitudes in figure 4 were reported by the California Institute of Technology, the University of California at Berkeley, and the University of Utah for earthquakes with magnitudes exceeding about M_L 3. M_L magnitudes for smaller earthquakes are equivalent Richter magnitudes and were calculated from SGB network amplitudes that were converted to equivalent Wood-Anderson seismograph amplitudes (Brune and Allen, 1967; Eaton, and others, 1970). Figure 4 shows that our M_D overestimates M_L by about 0.25 magnitude units, except at the higher end of the observed magnitude range where M_L and M_D appear to be about equal. The corrections to the equivalent Richter magnitudes suggested by Thatcher (1973) would increase M_L between 0 and 0.4 magnitude units, and would likely result in a closer correspondence between M_D and M_L than shown. The correction cannot be made, however, without additional information such as the frequency bandwidth of the maximum trace amplitudes and the high frequency asymptote of the earthquake spectral density. Even without this correction, the relation given above for M_D appears to closely estimate M_L in the magnitude range $1 \leq M_L \leq 4+$. According to Bakun and Lindh (1977), M_D for values less than M 1 will underestimate M_L. The magnitudes in this range, thus, are only relative measures of size and not true estimates of M_L.

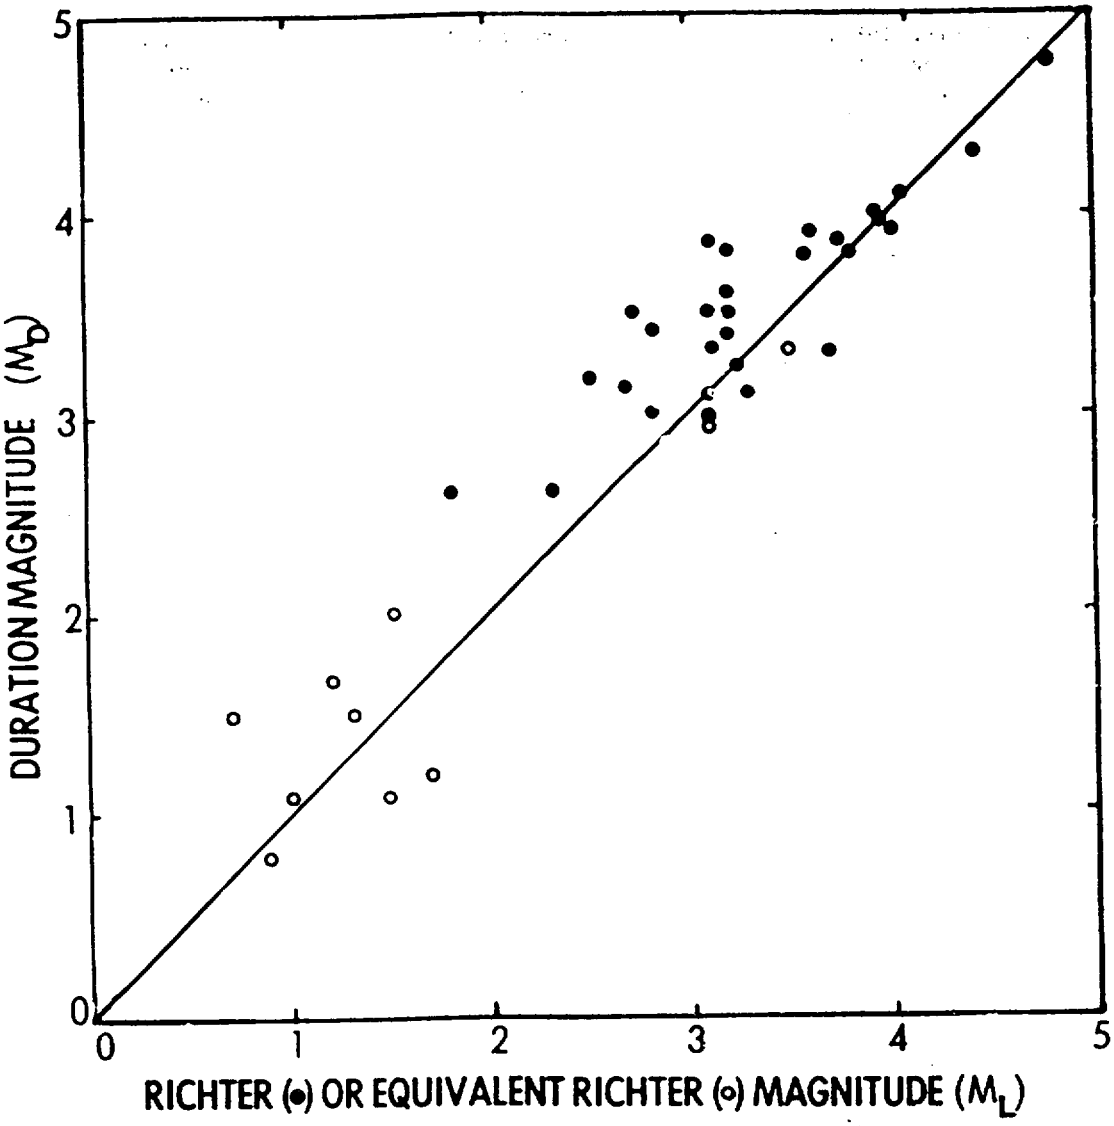

Figure 4.--Comparison of duration magnitude M_D with Richter magnitude M_L.

EARTHQUAKE LOCATION PROCEDURES

Earthquakes in this study were located using the computer program HYPO71 (Lee and Lahr, 1975) with program parameters and crustal model as given in appendix B. Both P- and S-wave phase readings were employed when an improved hypocentral solution resulted (that is, lower root-mean-square (RMS) travel-time residuals and smaller standard errors), otherwise only P-times were used. During 1981, 401 earthquakes were located. These events have magnitudes ranging between 0.4 and 4.3, and they have a horizontal modal standard error of 0.5 km and a depth modal standard error of 1.0 km. The quality (Q) distribution of 1981 earthquake locations, as defined in appendix D, is as follows:

Q	Number	Percent
A	3	0.7
B	142	35.6
C	186	46.6
D	68	17.0

The relative location errors of hypocenters presented in this report have been reduced by the use of a revised crustal velocity model and station corrections. We used the program called VELEST 2 (Ellsworth, 1977; Ellsworth and Roecker, 1981) to simultaneously invert for selected hypocenters, a velocity model and station corrections. The initial velocity model is given below and is considerably different than that used previously (Rogers and others, 1981).

Depth to top of layer from sea level (km)	V_p (km/s)
0.0	3.8
1.0	5.9
3.0	6.15
24.0	6.9
32.0	7.8

This model is based on previous refraction data (Roller and Healy, 1963) and interpretation of reflection phases in those data by L. C. Pakiser (oral commun., 1983). The near-surface 3.8-km/s layer is based on rock core velocities taken from drill holes at the Nevada Test Site (Rod Carroll, oral commun., 1982). The lower crustal layer, beginning at a depth of 24 km, is based on Pakiser's observation of reflections in Roller and Healy's (1963) chemical explosion data. Reflections from this horizon are generally obscured in nuclear explosion data by the high-energy levels in the early parts of the recorded signal, leading to past speculation that much of the southern Great Basin crust consisted of a single, low-velocity layer (Prodehl, 1970). The model we adopted is essentially two-layered (two major velocity contrasts excluding the surface layer) and is compatible with accepted data on the northern Great Basin crustal structure (Prodehl, 1970).

For the inversion experiment, we selected 50 of the best-recorded and geographically most widely distributed earthquakes. A Yucca Flat nuclear event was also included with fixed hypocenter, but free origin time, because it was determined that fixing the nuclear explosion origin time resulted in strong negative bias in the station terms. This result using the present crustal model is likely due to relatively shallower Paleozoic rocks beneath Yucca Flat, especially on the west side of Yucca fault, compared to the region as a whole. Traveltimes from nuclear events also show fair correlation with the shotpoint velocity (Taylor, 1983) indicating that near-surface velocity structure produces some of the bias in nuclear event traveltimes. Accordingly, the inversion was performed with minimal constraint from nuclear shot data. The station terms resulting from the final inversion are shown in figure 5. The mean delay at each station is the result of traveltime differences along diverse ray paths from a wide range of azimuths (the program corrects for station elevation). It is likely, therefore, that the delays reflect mostly near surface velocity changes. For this reason we employ the delays as station corrections to help improve the earthquake locations in a relocation of the entire data catalog (1978-81). Using these station terms to correct arrival times has resulted in a tightening of seismicity trends and clusters and a reduction of the RMS residuals and standard errors.

Velocity variations were strongly damped during the inversion, forcing their effect to be absorbed in the mean station residuals. This procedure was required because, when velocity variations were not strongly damped, geologically implausible velocities resulted and the average RMS errors in the hypocenter solutions were not significantly improved compared to the highly damped velocity model. It is surmised that lateral velocity variations introduce first-order perturbations of traveltimes that are not accommodated by a one-dimensional model; therefore, freeing the velocities in the inversion does not lead to an improvement in the model or the locations. The solution to this problem will involve a three-dimensional velocity inversion, which is currently under study.

Employing the above P-wave crustal velocity model and station correction terms, we derived the corresponding S-wave velocity model from P- and S-wave station times using Wadati diagrams (Kisslinger and Engdahl, 1973) for six well recorded earthquakes. As shown in figure 6, a V_p/V_s ratio of 1.71 was obtained having a low-standard error. The linearity of the data and the low data scatter are good support for our assumption that Poisson's ratio does not vary significantly within the crust in the SGE.

DESCRIPTION OF EARTHQUAKE LOCATIONS, FOCAL MECHANISMS AND THEIR RELATION TO MAPPED SURFACE FAULTING

Seismicity maps showing the relation between tectonic features, focal mechanisms and epicenters are shown in figures 7-12, and plate 1. Figure 7 also shows the regions of the detailed figures 8-12. The focal mechanism data are shown in figures 16-18. The revised crustal model and relocated earthquake hypocenters provided the impetus to reevaluate the focal mechanisms presented in a previous report (Rogers and others, 1981), leading to modification of some mechanisms and rejection of others. Both the earthquake locations and focal mechanisms presented in this report should take precedence

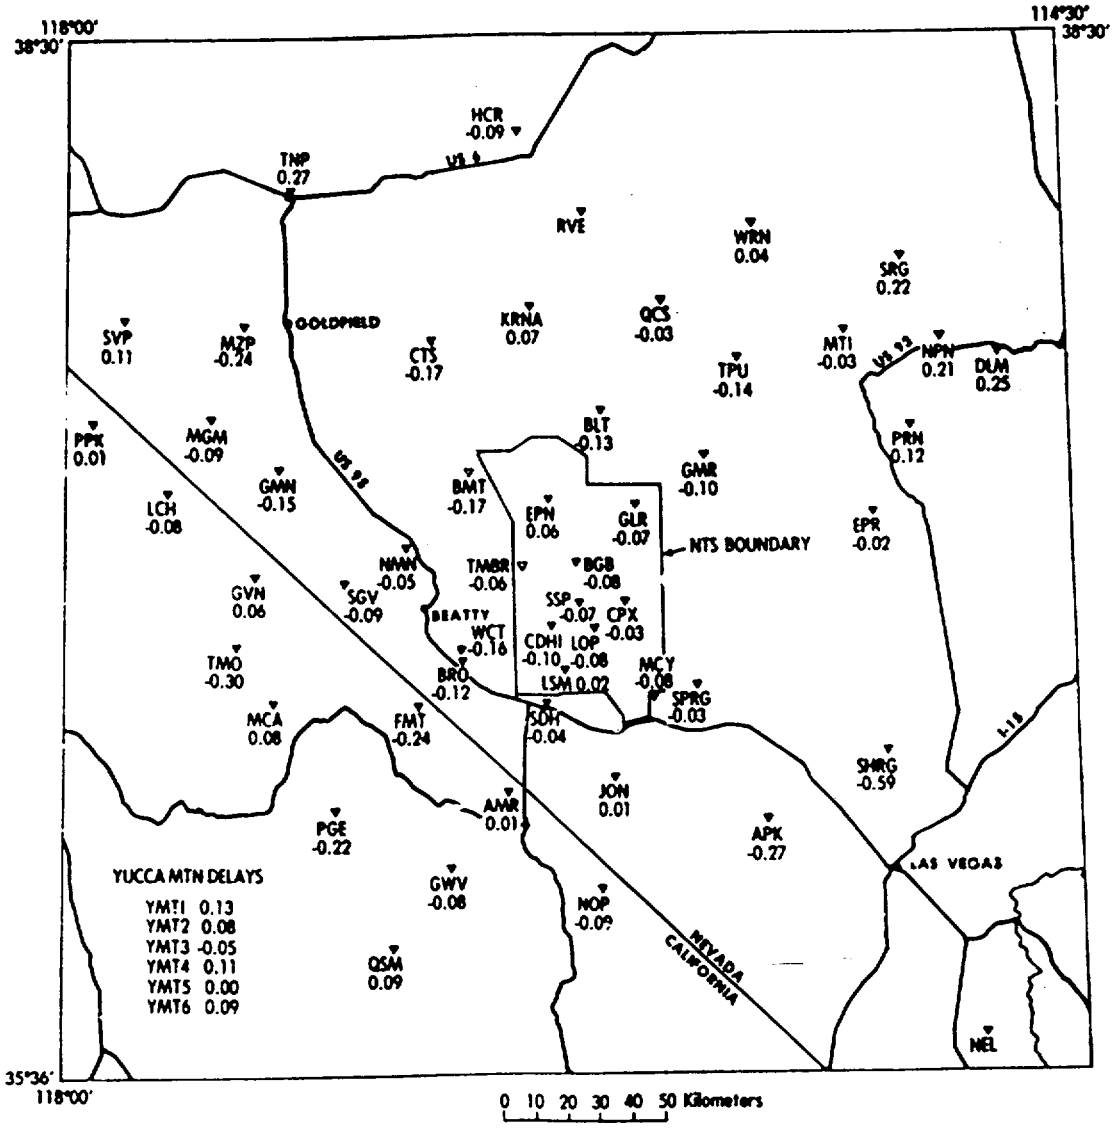

Figure 5.--Station delays resulting from the simultaneous location of 50 widely scattered well-recorded earthquakes and one fixed location Yucca Flat nuclear event.

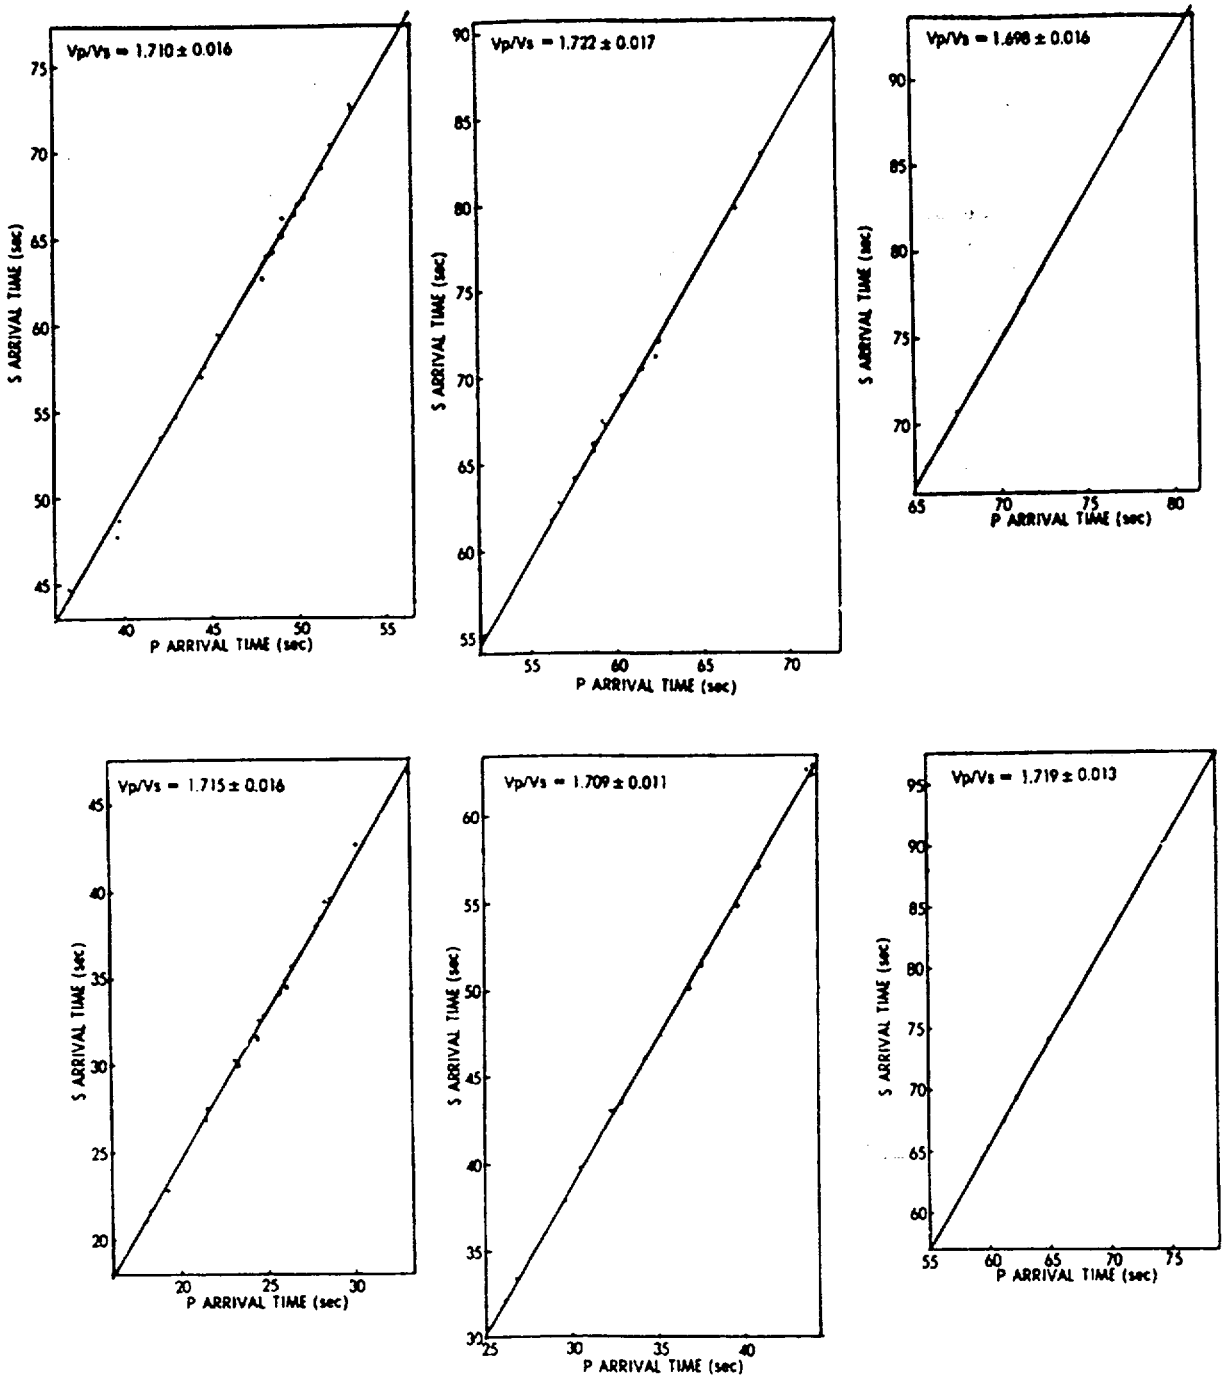

Figure 6.—S-arrival time vs. P-arrival time for six well-recorded earthquakes.

over those results previously reported. It is observed from these maps (especially fig. 7 and pl. 1) that seismicity is widespread throughout the SGB, although, as noted in past reports, there are areas of quiescence or near quiescence. The principal pattern is one of widespread diffuse seismicity punctuated by tight clusters of earthquakes, each generally containing one or more of the largest events recorded to date (M_L 4-4.5). Fewer numbers of earthquakes occur near the northern and southern margins of the network giving the appearance of a seismic bridge or belt connecting the Intermountain seismic zone with the Nevada seismic zone. This band of earthquakes, termed the southern Nevada east-west seismic belt (Smith, 1978), is more apparent on a regional scale map and was first noted in the pre-network data. The tectonic significance of seismicity in this zone is not yet understood.

Earthquakes induced by nuclear explosions continue to occur at Pahute Mesa and Yucca Flat (fig. 11). The nuclear events have been removed from our catalogs and maps. The seismicity maps in this report are contaminated in the Pahute Mesa and Yucca Flat regions by induced seismicity from nuclear explosions. Research by Hamilton and others (1971) and Rogers and others (1977) indicated that underground nuclear explosions aftershocks appear to be restricted to within 6 to 14 km from ground zero. The number of aftershocks occurring also appears to decrease to the background level within less than 15 days. However, no clear-cut way of removing these earthquakes from the catalog has yet been devised. A more detailed evaluation of this problem is planned and will be presented in a future report. Except for this activity, the most active areas are the Pahranagat shear zone (PZ) (fig. 8), the Mine Mountain (MM)--Cane Spring (CS)--Rock Valley (RV)--Frenchman Flat (FF) fault systems (fig. 9), the Thirsty Canyon (TC) (fig. 11), Sarcobatus Flat (SF) (fig. 12) and western Gold Flat (GF) areas (fig. 11), and a region along the California-Nevada border near Gold Mountain (GM) (fig. 12). The PZ, MM-CS-RV-FF, and GM zones are geologically and seismologically similar because they are characterized by major northeast-trending left-lateral faults that localize a large percentage of the regional earthquakes. In the PZ the majority of epicenters appear to be underlain by short north- to north-northeast-trending fault segments lying between the major northeast-striking shear zones (fig. 8). These epicenter locations, together with the two focal mechanisms in this area, suggest that the mode of faulting is right-lateral strike slip on north-trending faults.

An earthquake producing a strike-slip focal mechanism occurred beneath Frenchman Flat (B, fig. 9). The northwest-trending Yucca Frenchman (YFF) shear zone passes about 2 km to the northeast of this earthquake and is characterized by right-lateral bending of northeast-trending fault zones and a general change in structural grain. Faults on the north side of YFF trend northerly, and faults on the south side of YFF trend northeasterly. The north-trending focal mechanism fault plane coincides with the general structural grain occurring on the north side of the YFF, and the east-northeast-trending plane agrees with the structural grain to the south of YFF. Because alluvium covers the area around the epicenter, it is not possible to unequivocally select the correct fault plane. If the east-northeast-trending plane is preferred, left-lateral strike slip is required. Two historical earthquakes in this region, the 1971 Massachusetts Mountain and

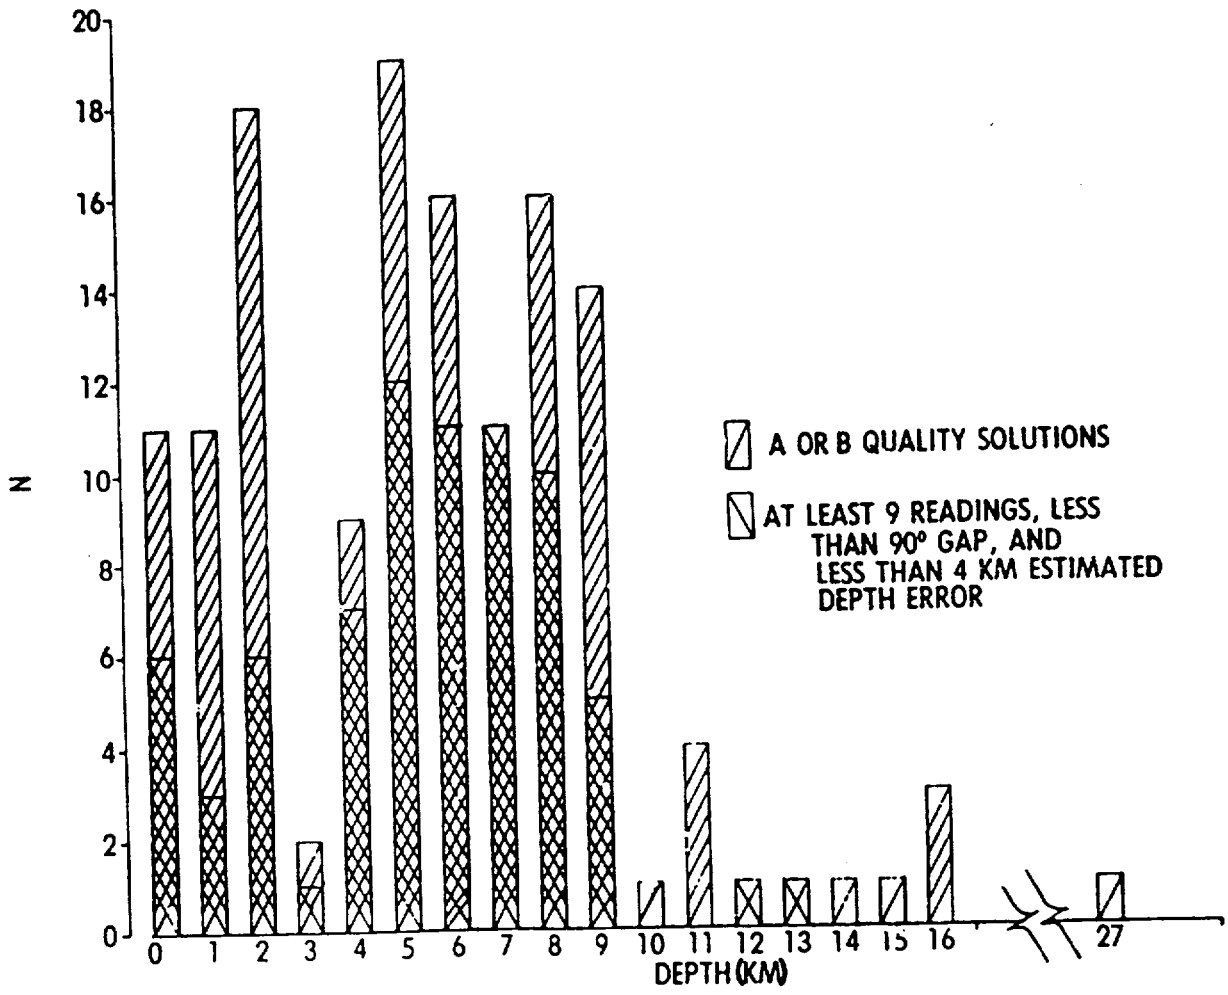

Figure 13.--Distribution of focal depths below sea level for well-located earthquakes in the southern Great Basin. For clarity the bars are spaced apart, although the depth intervals are continuous. For instance, the depth intervals start with 0-0.5, 0.5-1.5, and so on.

1973 Ranger Mountain (both M ~ 4), produced strike-slip focal mechanisms with fault plane orientations similar to that observed here. For the 1971 earthquake, roughly 4 km north of earthquake B (fig. 9), Carr (1974) preferred the east-northeast-striking focal plane. As with earthquake B (fig. 9), a preferred focal plane could not be chosen for the 1973 earthquake (Carr, 1974).

A mechanism for an earthquake located in Jackass Flats (C, fig. 9) indicates strike slip, although the proper fault plane cannot be determined. Neither fault plane, however, would indicate slip on the Mine Mountain fault zone, in spite of the fact that epicenters appear to be near the projection of the surface trace of this fault. An earthquake at nearby Lookout Peak indicates a strike-slip mechanism (A, fig. 9) and could be associated with right-lateral motion on one of several mapped north-trending faults. Some earthquakes south of Little Skull Mountain, and events northwest of Mercury, occur on and near the trace of the RV fault and near the projected intersection of the CS and the RV faults suggesting association with those structures. No focal mechanisms have yet been obtained for these events because they are of low magnitude. Although no evidence exists in this data set that the northeast shear zones are active, except the localization of events in these zones, it is known from previous studies that Quaternary fault scarps and earthquakes do occur on northeast-trending zones in the SGB. Two regional examples of normal fault earthquakes on northeast-trending faults were observed on Pahute Mesa (Hamilton and others, 1971) and at Lake Mead (Rogers and Lee, 1976).

The clearest evidence of earthquake fault plane orientation occurs in five active zones where epicenter lineations are observed. Alinement of earthquakes and focal mechanisms in Indian Springs valley (fig. 10), Thirsty Canyon (fig. 11), and three Sarcobatus Flat locations (fig. 12, B, C, D; pl. 1) suggest right-lateral strike slip on north-striking faults. In addition, earthquakes at Thirsty Canyon are close to a mapped fault of north strike.

A focal mechanism for a Gold Mountain M 4.0 earthquake (A, fig. 12) indicates strike slip with a small component of normal faulting. The epicenter lies in a region of east- to northeast-trending faults, so that this trend is preferred with left-lateral strike slip.

Fault orientation appears to be more important than age in microearthquake occurrence in the Nevada portion of the SGB (pl. 1). For instance, most faults of northwest orientation are inactive, including the Las Vegas Valley shear zone, and the La Madre fault zone bordering the Spring Mountains. By comparison, from evidence of late Quaternary displacement or current seismicity, many faults of north to northeast orientation are active, such as Yucca fault, faults flanking Bare Mountain, Rock Valley and Mine Mountain, the Pahranagat shear zone and faults southwest of Gold Mountain. The youngest surface displacement on these faults ranges in age from pre-Quaternary to Holocene (YF) (pl. 1).

EARTHQUAKE DEPTHS

As noted previously (Rogers and others, 1981), earthquake focal depths in the SGB appear to have a bimodal distribution (fig. 13), with peaks in the number of earthquakes occurring at about 2 km and 5 km below sea level. Very few well-located earthquakes have depths greater than 10 km. This pattern is persistent, although different crustal models have been employed and station delays are now incorporated into the location procedures. Some events within the shallower zone may be artificially constrained because of a layer boundary within that zone and the location procedure, but it is unlikely that this effect is important for all the earthquakes in that depth range because the peaks in the distribution do not occur at a layer boundary.

Most of the strike-slip mechanisms are for earthquakes occurring in the deeper active zone (4-9 km). Only two of the single event mechanisms have depths less than 5 km. The Thirsty Canyon and Sarcobatus Flat composite focal mechanisms are derived from earthquakes spanning both depth ranges. In this small sample, therefore, strike-slip faulting does not appear to be depth limited as found for western Nevada (Vetter and Ryall, 1983).

TEMPORAL PATTERNS OF SEISMICITY

The 1979 Pahranagat earthquake series (fig. 8) followed a foreshock-main shock-aftershock (FMA) pattern with a main shock of about M 4 (Rogers and others, 1981). The region was nearly quiescient in 1980. On January 16, 1981, an M 4 occurred near the southeastern limit of the 1979 aftershock zone (figs. 5 and 6) but had no foreshocks or aftershocks. An M 4 occurred in this zone on December 28, 1981, about 10 km east-southeast of the 1979 series. This earthquake followed the FMA pattern and was accompanied by 10 aftershocks and 1 foreshock.

The Thirsty Canyon sequence (fig. 11) began a day after the first Pahranagat series, on August 13, 1979. This cluster of 38 earthquakes occurred more as a swarm than as a FMA style series, consisting of a large number of M 2 earthquakes with no distinct main shock.

Three distinct series have occurred in Sarcobatus Flat (fig. 12) 50-75 km northwest of Yucca Mountain. The first series (B, fig. 12) on the north side of Sarcobatus Flat began in December 1979 with an M 4.0 earthquake followed by seven aftershocks. Southeast of this group, near the middle of Sarcobatus Flat (C, fig. 12), an M 3.4 earthquake on March 10, 1981, was followed by three M 3+ events on April 3 and 4, and seven additional M <3 events in June, July, August, and November. The cluster of earthquakes in the southern portion of Sarcobatus Flat (D, fig. 12) was comprised by an FMA series of 12 foreshocks beginning on October 13, 1981, followed by an M 4.0 main shock on October 15 and 34 M $\leq$3.4 aftershocks to December 11.

In the Gold Mountain area (A, fig. 12), 33 earthquakes occurred (M <3.0) between December 1978 and November 1980. On January 23, 1981, an M 4.0 earthquake occurred in this zone followed by two aftershocks (M <3.0). Sixteen more events followed between April and December 1981.

The contrast between the southeastern NTS activity and the zones just discussed is notable. Since the installation of the network, there has been a nearly continuous series of earthquakes occurring in southeastern NTS. This activity has a larger proportion of small magnitude earthquakes than any other part of the region. No earthquakes larger than M 3.4 have occurred in this zone during the monitoring period and only four larger than 3.0 have occurred. The data suggest that the "b-value" for the southeastern NTS region may be higher than that for the entire network area (fig. 14), although, at present, not enough data has been collected to estimate the recurrence relation for this subregion. A second feature of the seismicity in this zone is that significant changes in the rates of seismicity appear to occur as indicated by the ratios of small (M <2) to large (M $\geq$2) earthquakes (table 1). Here we assume that even though the number of earthquakes at magnitudes less than 2 is incomplete, this incompleteness is invariant with the time period for the first two periods. A one degree-of-freedom χ^2 test on a 2 x 2 contingency table of the number of earthquakes in each magnitude class and time period (for the first two time periods) shows that we must reject the hypothesis that the number of earthquakes in each magnitude class is independent of the time interval at a 1 percent significance level. The ratio of small-to-large events has fluctuated from values relatively high to low to intermediate. In terms of the recurrence curve, in the second period the number of earthquakes at low magnitudes decreased simultaneously with a decrease in the b-value. If the difference between the first and the second period were due to a decrease in network operation efficiency, one would expect both size categories to decrease in the second period. If the third period changes were due to the installation of digital detection and recording facilities, one would expect both size categories to increase as they did for the region as a whole (fig. 3). Because the observed results in both cases are contrary to the results expected due to operational changes, it seems probable that the temporal changes are real.

Table 1.--Comparison of earthquake rates in two magnitude ranges for earthquakes in the southern NTS region (36.5°-36.9° N., 115.7°-116.5° W.)

Time period	Rates (number earthquakes/month) M >2	M <2
1.) Aug. 1979 - Sept. 1980	1.1	7.9
2.) Oct. 1980 - Sept. 1981	2.9	1.3
3.) Oct. 1981 - June 1982	2.1	5.0

A possible interpretation of these results is that changes in source stress conditions occurred regionally, such that, in the second period, stress was stored along fault zones for longer intervals and released by relatively larger events than in the first interval. The required source conditions might occur as synchronous subregional changes in the normal stress across active faults of similar orientation. Observations of regional changes in earthquake occurrences were noted in the SGB near the Pahranagat shear zone by

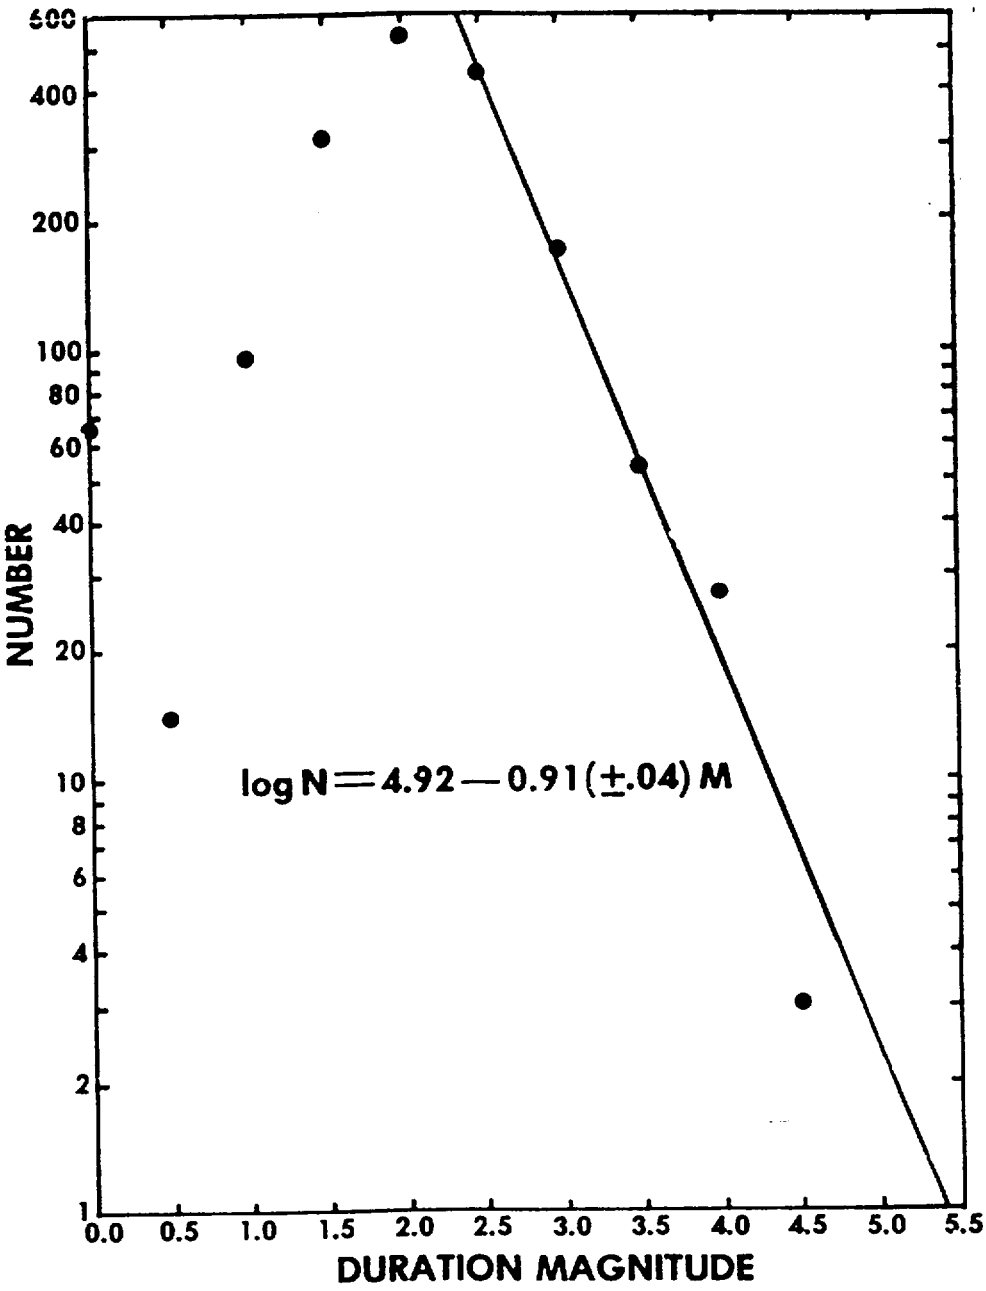

Figure 14.—Frequency of recurrence of earthquakes in the monitored region for the period August 1979 to June 1982.

Molnar and others (1969). Coupling between active zones also seems apparent in the northern Great Basin, as suggested by W. Gawthrop (written commun., 1980). The Cedar Mountain (1932, M 7.2) and Excelsior Mountain (1934, M 6.3) earthquakes, 50 km apart, appear to be related temporally and spatially, although the style of faulting for the two events differed considerably. More closely related in time and space are the two Rainbow Mountain earthquakes (M 6.8), the Dixie Valley (M 6.8) and Fairview Peak (M 7.2) earthquakes. All these events occurred in 1954 on north- and north-northeast-trending faults in an area about 50 km across. Coupling between paleostructures in mountain ranges of the northern Great Basin has also been suggested by Wallace (1978).

The recurrence curve in figure 14 is derived using a maximum likelihood technique assuming a minimum and maximum magnitude of 2.5 and 6.0, respectively (Bender, 1983). These recurrence data show that only 3 earthquakes in the range 4.25 to 5.25 have occurred, although the recurrence curve predicts approximately 10. The probability of this result is about 1 percent (Bender, 1983). In fact, excluding nuclear event aftershocks, fewer than five M 5+ earthquakes have occurred in the presently monitored zone during 40 years of historic record that are reliable (Rogers and others, 1977). Several interpretations of these data are possible. First, a maximum magnitude may exist for this region in the range 5 to 6, and, therefore, the frequency of events at the upper magnitudes does not follow the recurrence curve of figure 14. Second, there has been a recent increase (from 1979 to present) in the number of earthquakes occurring, which could explain the discrepancy in the number of historic M 5+ events, but does not explain the lack of M 4.25+ earthquakes in the current record. Third, it is possible to obtain a bent recurrence curve by combining zones with differing b-values, lower magnitude thresholds, and (or) maximum magnitudes. At present a choice cannot be made between the three possibilities. Additional data and more detailed analysis are necessary to evaluate these interpretations.

DISCUSSION

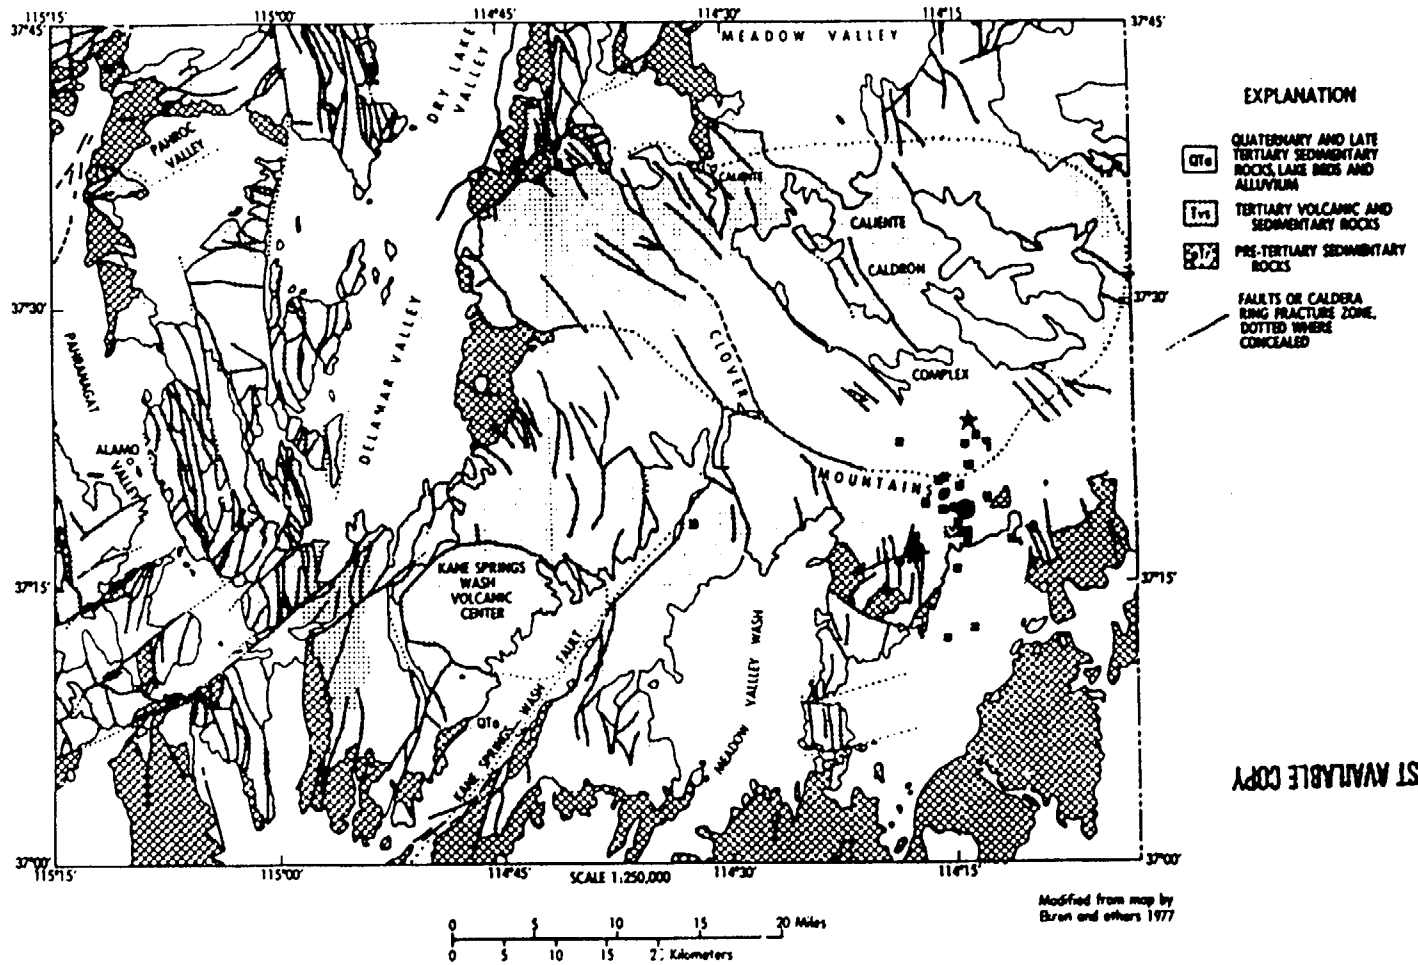
Although Yucca Mountain and a large area to the west and south are relatively quiet seismically, data in this report together with the historic record of seismicity in this region, add to the increasing body of evidence suggesting that north- to northeast-trending faults are the most seismogenic in this region. The age of the last surface movement of a fault does not necessarily correlate with the degree of present seismicity on it, as indicated by the abundant seismicity on faults with no record of Quaternary displacement. Thus, a preliminary conclusion could be made that the north-trending faults at Yucca Mountain should be considered potentially active even though geologic evidence and present near absence of seismicity indicate they are not active. The length of faults at and near Yucca Mountain and the historic record would permit a M 6-7 (Mark and Bonilla, 1977) earthquake there. Two earthquakes of about M 6 have occurred within the east-west seismic belt at Death Valley in 1908 (Richter, 1958) (110 km southwest of the site) and near the Nevada-Utah border in 1966 (Beck, 1970) (210 km northeast of the site).

We relocated the 1966 earthquake series by employing the joint epicenter method (Dewey and Spence, 1979), using a regional traveltime model. The main

shock (M = 6.1, USGS) was followed by an extensive aftershock series (fig. 15) in a single zone with a north-northeast orientation, as opposed to the finding of two active patches of aftershocks well-removed from the cluster of aftershocks surrounding the main shock (Beck, 1970). The focal mechanism of the 1966 main shock indicates nearly pure strike slip on either a vertical north-northeast-striking fault (right-lateral) or a nearly vertical east-southeast-trending fault (left-lateral) (Smith and Lindh, 1978). Although little is known of the geology in the epicentral region, transcurrent northeast-trending faults do occur there together with north-trending faults (Ekren and others, 1977). Because of the orientation of the 1966 aftershock zone and the existence in this region of north-trending faults, we conclude that the most likely faulting for the 1966 main shock was nearly pure right-lateral strike slip on a vertical north-northeast-trending fault.

In some respects the evidence for seismic hazard from the geologic record is in conflict with that from the seismic record. From the seismic evidence we must conclude that any faults of north to northeast trend are potentially active in the current stress field, whereas, the geologic data suggest that faults of this orientation, such as those at Yucca Mountain, have not had large (>1 m) surface displacement in the last 500,000 years, and have had no surface displacement in the last 40,000 years. That such disparities in fault activity are possible is the conclusion of studies in the northern Great Basin as well (Wallace, 1978). Even in active zones, areas exist that have been stable for hundreds of thousands of years. Until more is known about why areas are stable or unstable in the same region, however, it is not possible to rule out significant future seismic activity on faults at Yucca Mountain. This position is taken partly because (1) stress measurements at Yucca Mountain indicate that faults there may be near failure (Healy and others, 1982), and (2) faults of orientation and style similar to those at Yucca Mountain exist on Pahute Mesa, where extensive stress release has occurred after nuclear tests on faults approaching 10 km in length. Although movement on these faults was induced by nuclear explosions, the extent of faulting, the size of fault displacements, and the magnitude and depths of accompanying aftershocks indicate that these faults were tectonically stressed near the failure point, with slip being triggered by additional stresses produced by the nuclear explosions.

It should be noted that stress data alone cannot be used to conclude that earthquakes are likely in a given area. Important factors in rock failure along faults are the coefficient of friction and pore pressure. The former is derived from laboratory measurements, the latter assumes a hydrostatic condition due to the thickness of the saturated zone. Furthermore, the conditions required for a large earthquake to occur are (1) shear stresses approaching that required for failure over a large area of a fault zone, and (2) significant displacement at the time of failure. Alternatively, stresses could be relieved aseismically by fault creep, or in a series of numerous very small events. Abundant evidence suggests that scarps in the Great Basin are produced by large earthquakes, not creep (Bucknam and others, 1980; Crone, 1983), and there is very little evidence that creep is a significant mode of stress release in the Great Basin (R. C. Bucknam, oral commun., 1983). For instance, significant creep events on any of the numerous faults that are crossed by cultural features would be easily noted. Some Basin and Range



GENERALIZED GEOLOGIC MAP OF THE CLOVER MOUNTAIN-PAHRANAGAT-PAHROC REGION, SOUTHEASTERN LINCOLN COUNTY NEVADA

Figure 15.--Locations of the 1966 earthquake series in southeastern Nevada in relation to the geological structures mapped by Ekren and others (1977). Main shock is shown by star and two aftershocks of M >5 are shown by large filled circles. Symbols showing locations of the smaller aftershocks are based on the length of the semimajor axis, a, of the joint hypocenter confidence ellipse on the computed coordinates (Dewey and Spence, 1979), for each event: ▪ for a < 12 km, and • for a ≥ 12 km.

scarps are inferred to have resulted from historic earthquakes as large as M 8. Taken together, the stress data, the historic seismicity, and the indication from current seismicity that fault activity is more dependent on fault orientation than fault age suggest that the potential for significant seismicity on Yucca Mountain faults should be considered.

Earthquakes in the southern Great Basin occur at depths as much as 10 km, but no spatial coherence has yet been observed in the focal depths, with each active zone generally displaying the full range of depths for the best located events. As yet, no evidence has been obtained that earthquakes in this region are occurring on listric faults, with decreasing dip as depth increases. We therefore conclude that earthquakes are occurring on faults of significant vertical extent, suggesting the potential for the occurrence of a large earthquake.

Inactivity on the northwest-trending Death Valley-Furnace Creek zone (figs. 1 and 2) is a paradox in the sense that, although quiescence would be predicted there based on the current southern Great Basin stress orientation, the existence of numercus Holocene scarps on these faults indicates this fault zone is active (Hunt and Mabey, 1966; G. E. Brogan, written commun., 1979). Geologic evidence, then, suggests that the stress orientation in the Death Valley region is rotated in such a fashion to be more favorable to the formation of the observed scarps. A stress orientation more like that in the San Andreas region than that in the southern Great Basin is required, further suggesting that quiescence on the Death Valley-Furnace Creek fault zone is due to relatively recent stress release there. The zone could be compared to that section of the San Andreas fault zone that ruptured in 1857, but is presently quiescent. Although no direct evidence from this study has been obtained to support rotation of the stress field in Death Valley, Zoback and Zoback (1980) examined a large body of data and concluded that a more east-west least principal stress was likely in this region, although they placed the province border farther to the west. The Walter and Weaver (1980) study of the Coso volcanic field, 80 km west of Death Valley, also suggests that a change in the stress field orientation occurs between the San Andreas and NTS. The Coso field earthquakes exhibit right-lateral strike slip on northwest-trending faults and normal faulting on north-striking faults. Because the geologic evidence suggests that this stress orientation may extend to the Death Valley-Furnace Creek region, a stress rotation is inferred to occur over a short distance between Death Valley and NTS.

SUMMARY

1. Over 1,600 earthquakes have been located within the network from 1979 to mid-1982; magnitudes ranged between 0 and about 4. The occurrence of earthquakes is widespread in the SGB, confirming the existence of the "east-west" seismic belt, first noted in the historical record, that connects the Intermountain and Nevada seismic zones.
2. The pattern of seismicity is characterized by a diffuse background level of earthquakes, punctuated by several zones of more compact and intense activity. Some of these concentrations of earthquakes have occurred as foreshock-main shock-aftershock series (M_L ~4 main shocks), and others have had no distinguishing event.

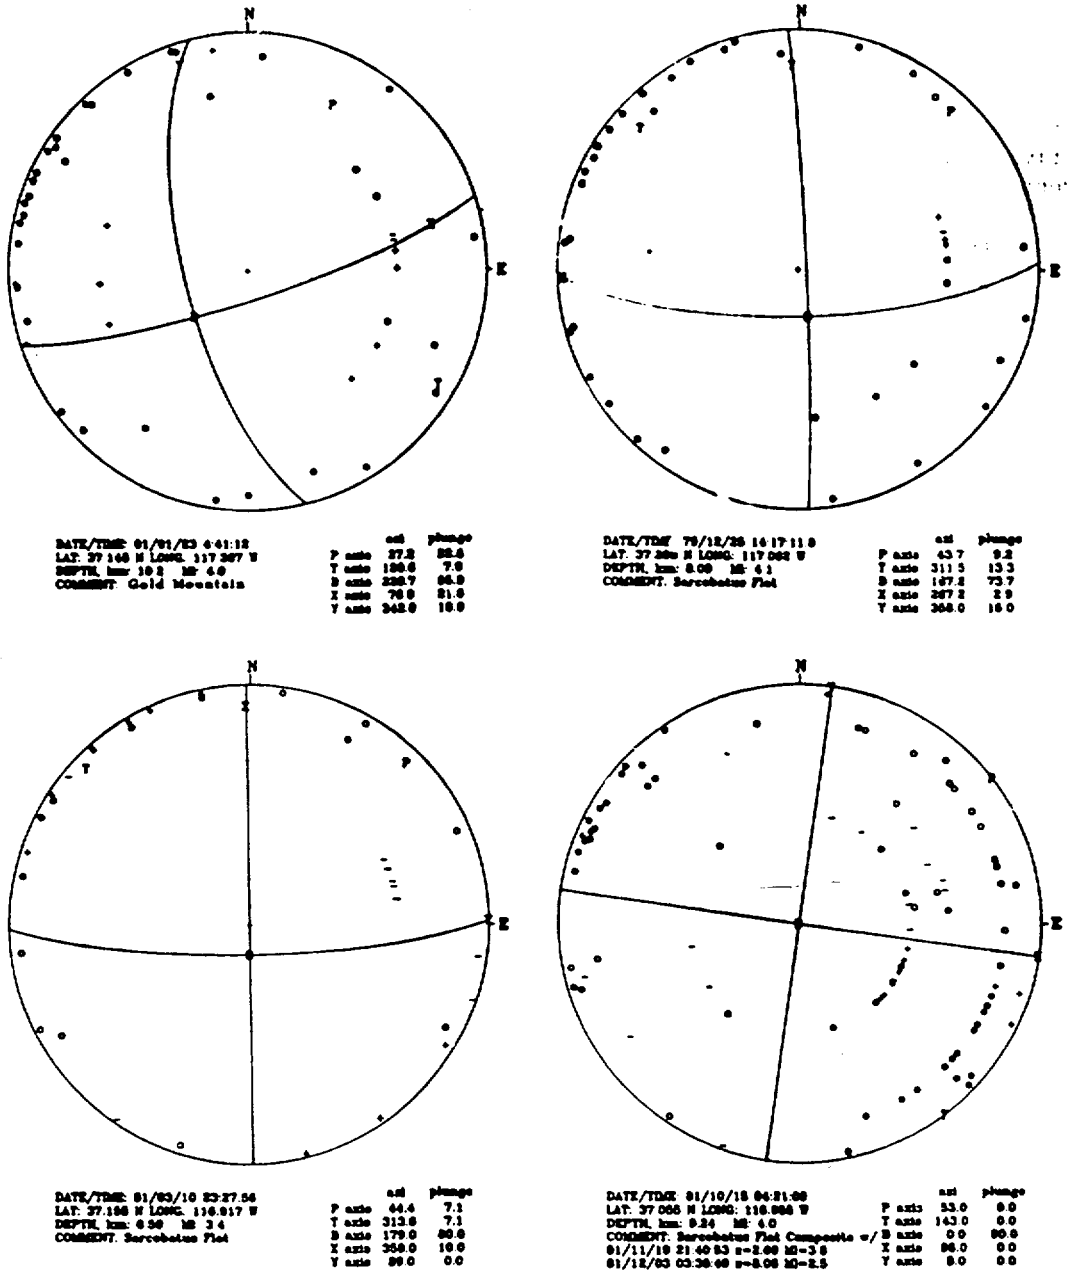


Figure 16.—Lower hemisphere focal mechanism data for mechanisms shown in figures 8-12. Solid dots are compressions and open circles are dilatations.

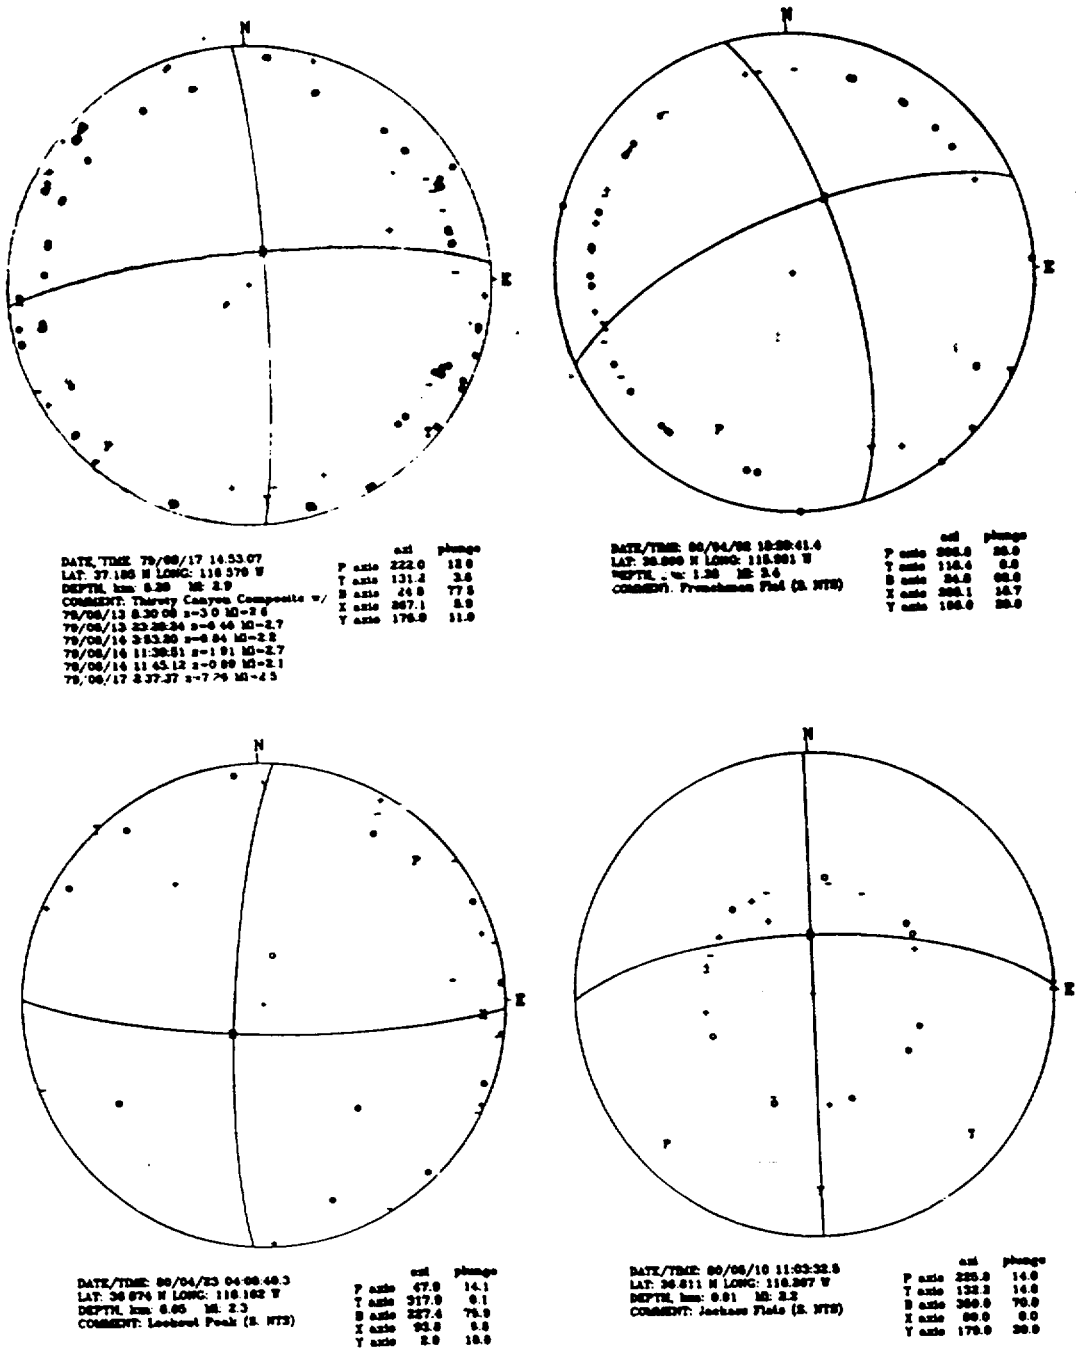

Figure 17.—Lower hemisphere focal mechanism data for mechanisms shown in figures 8-12. Solid dots are comprssions and open circles are dilatations.

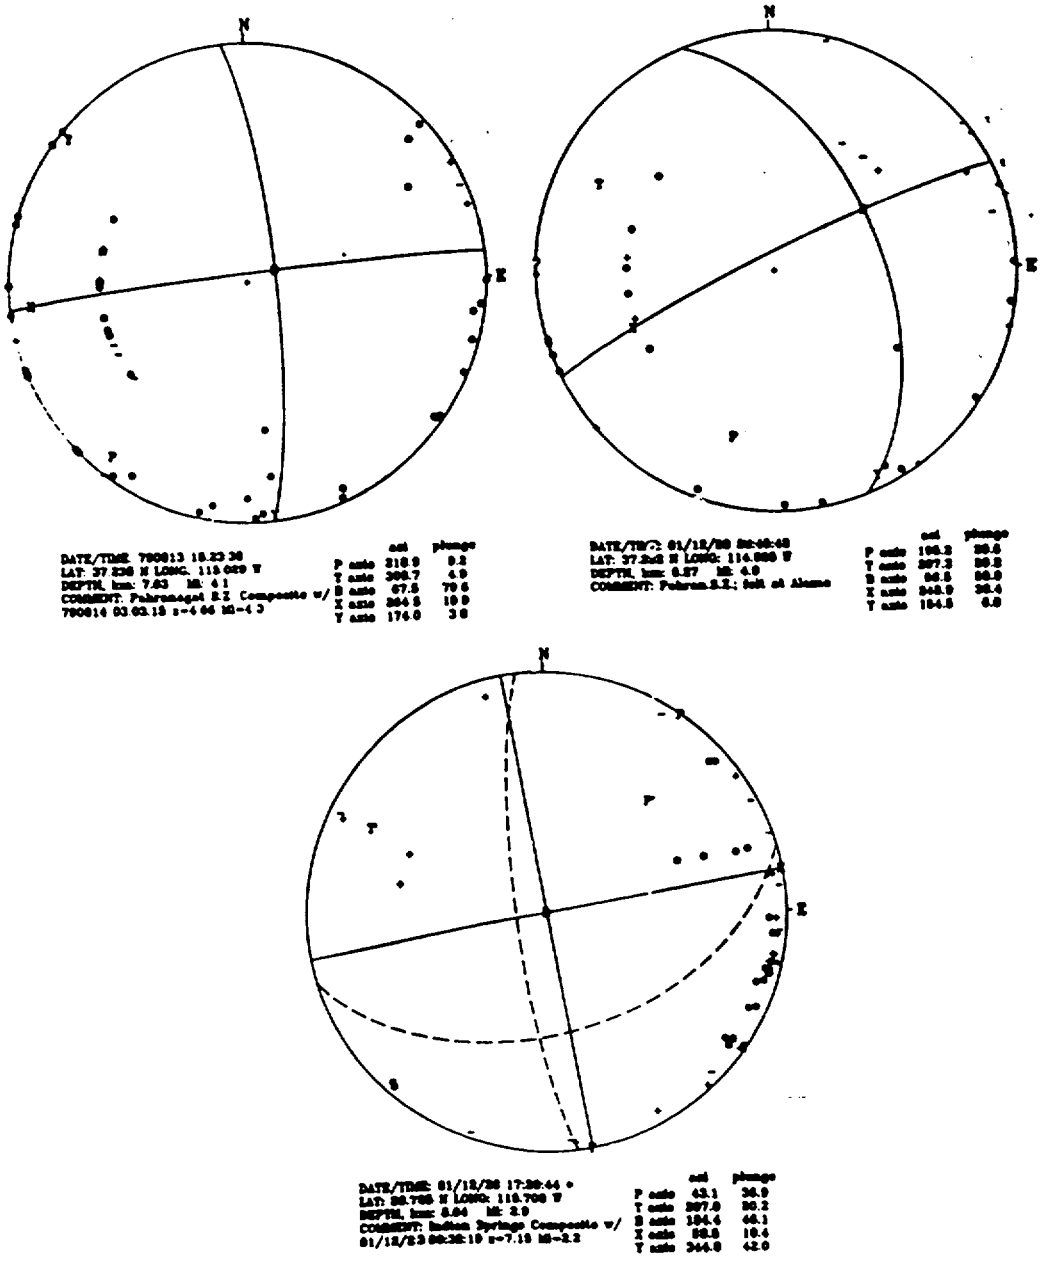

Figure 18.—Local hemisphere focal mechanism data for mechanisms shown in figures 8-12. Solid dots are compressions and open circles are dilatations.

3. The most seismically active areas occur in regions of major Tertiary northeast-trending left-lateral shear. Three important zones in this catagory are the Pahranagat, southern NTS, and Gold Mountain shear zones. Although some earthquakes are probably occurring on the northeast-trending faults, the larger earthquakes in these zones, for which focal mechanisms are available, have occurred on shorter intervening fault segments with a north strike.
4. Seismicity also occurs in north-trending faults zones. These earthquakes occur on or near segments of north-trending faults such as the Thirsty Canyon fault, Yucca fault, and Pahute Mesa faults (north-northeast trending) or are visible as north-trending epicenter lineations such as at Indian Springs Valley and Sarcobatus Flat.
5. Yucca Mountain lies within a broad zone of low-level seismicity extending on the west to the Funeral Mountains, on the south to the Black Mountains and Nopah Range. Another region of relative quiescence extends from near Gold Flat to Tonopah.
6. Focal mechanisms, epicenter lineations, and epicenter-fault associations indicate that earthquakes occur principally as right-lateral strike-slip events on north-trending faults. A focal mechanism for an M ~6 earthquake near the Nevada-Utah border in 1966 also indicated strike slip on a north-northeast-trending fault. Two M 4 earthquakes in 1971 and 1973 in southeast NTS were strike slip. Artifically induced earthquakes at Pahute Mesa and Lake Mead are either strike slip on north-trending faults or normal faulting on northeast-striking faults, indicating the likelihood that the northeast-trending faults are also active or potentially active.
7. A least principal stress with northwest orientation, and a greatest and intermediate principal stress of about equal magnitude are implied by the results to date. With this stress configuration faults of northwest orientation are less likely to produce earthquakes, a result that is supported by the current and historic seismicity, and by scarcity of northwest-striking Quaternary fault scarps east of Death Valley. The Death Valley-Furnace Creek, La Madre, and Las Vegas Valley shear zones are not presently producing earthquakes, although the presence of Holocene scarps on the Death Valley-Furnace Creek zone suggest that present quiescence there may be due to causes other than fault orientation.
8. From the historical seismicity of the southern Great Basin (two earthquakes of M ~6), and length of active faults, a maximum magnitude of M 6-7 is inferred for the SGB. Earthquake depths range between 0 and about 10 km; very few well-located events are deeper than 10 km. This observation suggests that faults of significant width are active in the SGB and supports the conclusion that a large earthquake is possible.
9. The only earthquake that has been located at Yucca Mountain in about 1 year of intensive monitoring has a magnitude of about 1.7. Faults there do not exhibit evidence of significant movement in at least the last 500,000 years, although their trend would permit slip in the present-day stress field similar to that resulting from historic and present-day seismicity on other north-to-northeast-trending faults in the SGB.

[1]Pertains to develocorder films.

[2]Pertains to data reported in this bulletin.

APPENDIX B

Input parameters to HYPO 71

HYPOCENTER PARAMETERS FOR LOCAL EVENTS ARE COMPUTED BY THE COMPUTER PROGRAM HYPO71 (LEE AND LAHR, 1975), MODIFIED TO COMPUTE RAY-PATH TIMES TO THE ACTUAL STATION ELEVATIONS. THE CRUSTAL MODEL EMPLOYED IN THE 1981 DATA REPORT IS:

DEPTH TO TOP OF LAYER (KM), FROM SEA LEVEL (0.0 KM)	P-WAVE VELOCITY (KM/SEC)
STATION ELEVATION	3.8
1.0	5.9
3.0	6.15
24.0	6.9
32.0	7.8

VALUES OF TEST VARIABLES EMPLOYED IN HYPO71 ARE:

TEST(1) = 0.1 SEC	TEST(5) = 5. KM	TEST (9) = 0.0035
TEST(2) = 30.0 KM	TEST(6) = 1.0	TEST(10) = 100. KM
TEST(3) = 0.5	TEST(7) = -0.87	TEST(11) = 8.
TEST(4) = 0.05 KM	TEST(8) = 2.00	TEST(12) = 0.5
		TEST(13) = 1. KM

PERTINENT CONTROL CARD OPTIONS ARE:

ZTR = 5.0 KM

XNEAR = 10 KM

XFAR = 220 KM

POS = 1.71 (P TO S VELOCITY RATIO)

* *

EXPLANATION OF HYPOCENTER SOLUTION COLUMN HEADINGS

DATE - DAY, MONTH, AND YEAR IN COORDINATED UNIVERSAL TIME (UTC)

STA - STATION CODE

PHASE - PHASE IDENTIFICATION
I OR E INDICATES THE CHARACTER OF PHASE ARRIVAL
(I = IMPULSIVE, E = EMERGENT)

TIME - ARRIVAL TIME OF PHASE IN HOURS, MINUTES, AND SECONDS (COORDINATED UNIVERSAL TIME)

AMP - PEAK VOLTAGE RESPONSE OF SEISMOMETER SYSTEM TO MAXIMUM SURFACE-WAVE AMPLITUDE, IN DIGITAL COUNTS. 2048 COUNTS REPRESENTS A 5 VOLT RESPONSE. NOT USED IN THIS BULLETIN.

PER - PERIOD OF PHASE, IN HUNDREDTH'S OF A SECOND

XMAG - STATION MAGNITUDE COMPUTED BY THE METHOD OF EATON, O'NEILL, AND MURDOCK (1970). NOT USED IN THIS BULLETIN

DUR - DURATION, IN SECONDS, OF CODA OF WAVE TRAIN FROM A LOCAL EVENT

FMAG - STATION MAGNITUDE COMPUTED BY THE METHOD OF LEE, BENNETT, AND MEAGHER (1972)

$$FMAG = -0.87 + 2.0 \cdot LOG(DUR) + .0035 \cdot DIST$$

EMPLOYING PRELIMINARY VALUES OF CONSTANTS DETERMINED BY LEE, BENNETT, and MEAGHER (1972)

DIST - GREAT CIRCLE DISTANCE TO EVENT, IN KILOMETERS

AZI - STATION-TO-EPICENTER AZIMUTH TAKEN CLOCKWISE FROM NORTH, IN DEGREES

AIN - ANGLE OF INCIDENCE TO DOWNWARD VERTICAL, IN DEGREES

TOBS - OBSERVED TRAVEL-TIME (O), IN SECONDS

TCAL - CALCULATED TRAVEL-TIME (C), IN SECONDS

RES - PHASE TRAVEL-TIME RESIDUAL, IN SECONDS (O-C)

REMARKS- DESCRIPTIVE INFORMATION.

EXPLANATION OF PHASE READING COLUMN HEADINGS

HYPOCENTERS ARE LISTED IN CHRONOLOGICAL ORDER.
HYPOCENTER INFORMATION IS ARRANGED AS FOLLOWS:

DATE	ORIGIN TIME	RMS	AD	Mb		TYPE OF SOLUTION
	LATITUDE	ERH	ERH	A	L	
	LONGITUDE	ERT	GAP	AVFM	LS	GEOGRAPHIC LOCATION
	DEPTH	ERZ	NR	AVFM	LD	
PHASE DATA						

EXPLANATION OF HYPOCENTER SOLUTION VARIABLE NAMES

RMS = ROOT-MEAN-SQUARE OF TRAVEL-TIME RESIDUALS, IN SECONDS

ERH = STANDARD ERROR IN LATITUDE, IN KILOMETERS

ERT = STANDARD ERROR IN LONGITUDE, IN KILOMETERS

ERZ = STANDARD ERROR IN DEPTH, IN KILOMETERS

NR = NUMBER OF STATION READINGS

ERH = STANDARD ERROR OF EPICENTER, IN KILOMETERS
APPROXIMATION (LEE AND LAHR, 1975)

GAP = LARGEST AZIMUTHAL SEPARATION BETWEEN STATIONS, IN DEGREES

Mb = AVERAGE BODY-WAVE MAGNITUDE, FROM TELESEISMIC P-WAVE
AMPLITUDES OR EMAX PG PHASE AMPLITUDES

A = AVERAGE SURFACE-WAVE MAGNITUDE (MS) IF EVENT IS A TELESEISM;
A IS LOCAL MAGNITUDE (ML) OTHERWISE

AVFM= AVERAGE MAGNITUDE COMPUTED BY IML METHOD OF LEE, BENNETT, AND
MEAGHER (1972)

LD = NUMBER OF STATION READINGS USED FOR COMPUTING AVFM

AVFM= AVERAGE MAGNITUDE COMPUTED BY THE METHOD OF EATON, O'NEILL, AND
MUNDKUR (1970)

b = SOLUTION QUALITY OF HYPOCENTER

Q IS THE AVERAGE OF QS AND QD, WHERE:

QS = STATISTICAL RATING OF SOLUTION

QD = STATISTICAL RATING OF STATION DISTRIBUTION.

QUALITY RATINGS:

Q	EPICENTER	FOCAL DEPTH
-	---	---
A	EXCELLENT	GOOD
B	GOOD	FAIR
C	FAIR	POOR
D	POOR	POOR

QS	RMS	ERH	ERZ
--	---	---	---
A	<0.15	<1.0	<2.0
B	<0.30	<2.5	<5.0
C	<0.50	<5.0	
D	OTHERS		

QD	ND	GAP	DERR (ERROR IN DEPTH)
--	--	---	----
A	>6	< 90	<DEPTH OR 5 KM
B	>6	<135	<2*DEPTH OR 10 KM
C	>6	<180	< 50 KM
D	OTHERS		

EXPLANATION OF HYPOCENTER SUMMARY NOTATION

F = DEPTH WAS ALLOWED TO GO FREE OR REMAINED AT THE STARTING DEPTH (15 KM)

G = DEPTH WAS HELD AT A FIXED DEPTH

S = BLAST; DEPTH IS AT OR NEAR 0 KILOMETERS

APPENDIX E

1981 teleseismic and regional events recorded by the digital system

1981 TELESEISMS AND REGIONAL EVENTS

The following teleseismic and regional earthquakes were recorded by the SGB digital system and the data archived.

DATE (UTC) YR	MO	DA	ORIGIN TIME HR	MIN	SEC	GEOGRAPHIC COORDINATES LAT	LONG	MAG
*81	10	08	12	19	27.2	38.01N	113.22W	3.0ML
*81	10	20	5	03	06.1	38.54N	116.69W	3.2ML
*81	10	22	23	35	29.41	35.43N	118.19W	3.6ML
*81	11	14	20	24	04.3	37.53N	114.47W	2.1ML
81	12	10	09	33	20.2	37.428N	118.463W	3.5ML
81	12	11	13	51	27.8	37.377N	118.458W	2.9ML
81	12	24	5	33	21.5	29.956S	177.701W	6.1MB
81	12	26	17	05	32.8	29.812S	177.854W	6.3MB

The teleseismic locations were taken from the U.S. Geological Survey preliminary determination of epicenters reports No. 50-81 and 52-81. The regional events were located using the SGB network. The regional events with asterisks preceding the dates were also included in the local hypocenter listing for 1981.

Beginning in early February, 1982, all digitally recorded regional and teleseismic events have been routinely archived.
