Abstract

Horizontal gene transfer via plasmids could favour cooperation in bacteria, because transfer of a cooperative gene turns non-cooperative cheats into cooperators. This hypothesis has received support from both theoretical and genomic analyses. In contrast, with a comparative analysis across 51 diverse species, we found that genes for extracellular proteins, which are likely to act as cooperative 'public goods', were not more likely to be carried on either: (i) plasmids compared to chromosomes; or (ii) plasmids that transfer at higher rates. Our results were supported by theoretical modelling which showed that while horizontal gene transfer can help cooperative genes initially invade a population, it does not favour the longer-term maintenance of cooperation. Instead, we found that genes for extracellular proteins were more likely to be on plasmids when they coded for pathogenic virulence traits, in pathogenic bacteria with a broad host-range. Taken together, these results support an alternate hypothesis, that plasmid gene location confers benefits other than horizontal gene transfer.

Introduction

The growth and success of many bacterial populations depends upon the production of cooperative 'public goods'[1–4]. Public goods are molecules whose secretion provides a benefit to the local group of cells. Examples include iron-scavenging siderophores[5], exotoxins that disintegrate host cell membranes[6,7], and elastases that break down connective tissues[8–10]. A problem is that cooperation can be exploited by 'cheats': cells which avoid the cost of producing public goods but can still use and benefit from those produced by cooperative cells[3,11,12]. What prevents cheats from outcompeting cooperators, and ultimately destabilising cooperation?

In bacteria, some genetic elements are able to move between cells[13]. This horizontal gene transfer has been suggested as a mechanism to help stabilize the production of cooperative public goods[14–18] (Figure 1a). If a gene coding for the production of a public good can be transferred horizontally, it would allow cheats to be 'infected' with the cooperative gene and turned into cooperators, increasing genetic relatedness at the cooperative locus. Theoretical models have shown that this can facilitate the invasion of cooperative genes, in conditions where they would not be favoured on chromosomes[14–18]. Experiments have supported this prediction[18]. In addition, bioinformatic analyses across a range of species found that genes that code for extracellular proteins, many of which act as public goods, are more likely to be found on plasmids than the chromosome[15,19,20].

There are, however, three potential problems for the hypothesis that horizontal gene transfer favours cooperation. First, previous bioinformatic analyses made important first steps, but are not conclusive. One study examined only a single species, which may not be representative of all bacteria[15]. Two additional studies examined multiple species, but assumed that genes and genomes from the same and different species can be treated as independent data points, in a way that could have led to spurious results[19,20]. Statistical tests typically assume that data points are independent, and even slight non-independence can lead to heavily biased results (type I errors)[21,22]. There is an extensive literature in the field of evolutionary biology showing that species share characteristics inherited though common descent, rather than through independent evolution, and so cannot be considered independent data points[23–25]. Genomes are nested within species, and genes are nested within genomes, multiplying this problem of non-independence, analogous to the problem of pseudoreplication in experimental studies[26–29].

Phylogenetically-controlled bioinformatic analyses are required to address this problem of non-independence, and test the robustness of previous conclusions.

Second, from a theoretical perspective, while horizontal gene transfer can favour the initial invasion of cooperation, it is not clear if it favours the maintenance of cooperation in the long run[16]. For example, after a plasmid carrying a cooperative gene has spread through a population, a loss of function mutation could easily lead to a cheat plasmid evolving, which could then potentially outcompete the plasmid carrying the cooperative gene[16,30]. Theory is required that examines the maintenance as well as the invasion of cooperation, while accounting for important biological details, such as how plasmid transmission depends on the population frequency of the plasmid.

Third, there are alternative hypotheses for why genes coding for extracellular proteins might be preferentially carried on plasmids in some species (Figure 1)[20,31]. Bacteria can rapidly adapt to new and/or changing environments by acquiring new genes via horizontal gene transfer, and losing genes no longer required but costly to maintain (Figure 1b)[32–34]. Genes which facilitate adaptation to environmental variability are often those which code for molecules secreted outside the cell[34–37]. Consequently, we might expect to find genes for extracellular proteins on plasmids to facilitate rapid gain and loss of genes depending on environmental conditions, and not because they are cooperative *per se*. Alternatively, genes may be favoured to be on plasmids for reasons other than horizontal gene transfer (Figure 1c)[38]. For example, a higher plasmid copy number offers a mechanism for more expression of a gene, potentially even conditionally, in response to certain environmental conditions[38]. The benefit of being able to regulate gene expression in this way could be higher in genes which code for molecules that are secreted outside the cell, when different quantities of molecule are required in different environments.

We addressed all three of these potential problems for the hypothesis that horizontal gene transfer favours cooperation. We first tested two predictions that would be expected to hold if horizontal gene transfer favours cooperation. Specifically, cooperative genes would be more likely to be found on: (i) plasmids relative to chromosomes; (ii) more mobile plasmids relative to less mobile plasmids[14–20]. We used phylogeny-based statistical methods that control for the problem of non-independence, analysing 1632 genomes from 51 bacterial species, to examine the location of genes that code for extracellular proteins. We then used theoretical models, to

examine whether horizontal gene transfer facilitates the evolution as well as the initial spread of cooperation.

Finally, we also tested alternative hypotheses for why genes coding for extracellular proteins might be preferentially carried on plasmids. We used three measures of environmental variability to ask whether species which had more variable environments were those most likely to carry genes for extracellular proteins on their plasmids. Additionally, we examined one of these measures in more detail, to help determine whether genes for extracellular proteins were located on plasmids so that they could be gained and lost easily (Figure 1b), or instead because of some additional benefit conferred by plasmid carriage (Figure 1c).

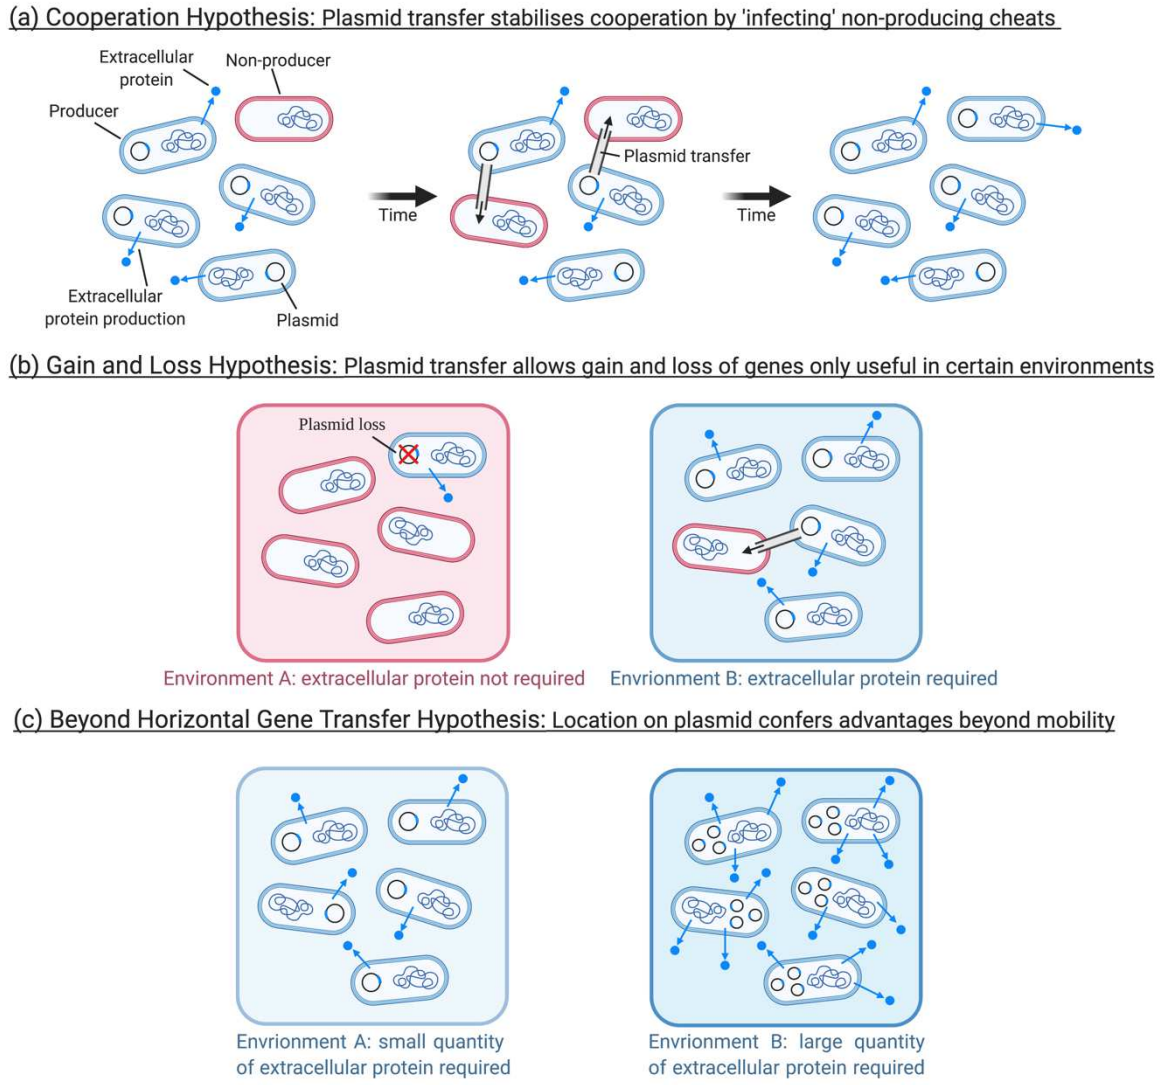

Figure 1. Three hypotheses for why selection might favour genes coding for extracellular proteins to be located on plasmids.

(a) Cooperation Hypothesis. Blue cells produce extracellular proteins which act as cooperative public goods, while red cells are 'cheats' which exploit this cooperation. Over time cheats grow faster than cooperators since they forgo the cost of public good production. However, because the gene for the extracellular protein is located on a plasmid, cooperators can transfer the gene to the cheats, turning them into cooperators, increasing genetic relatedness at the cooperative locus, and stabilising cooperation. (b) Gain and Loss Hypothesis. The production of the extracellular protein is required in some environments, but not others. Transitions between these environments can result from temporal or spatial change. Cells are selected to either lose (Environment A) or gain (Environment B) the plasmid coding for the production of the extracellular protein. (c) Beyond Horizontal Gene Transfer Hypothesis. The location of a gene on a plasmid could provide a number of benefits, other than the possibility for horizontal gene transfer[38]. For example, when the quantity of extracellular protein required varies across environments (A versus B), plasmid copy number could be varied to adjust production[38].

Results

Genomic Analyses.

We use the approach developed by Nogueira *et al.*[15,19,20], of using PSORTb[39] to predict the subcellular location of every protein encoded by 1632 complete genomes from 51 diverse bacterial species (Figure S1; Table S3). We are also building upon the work of researchers who pointed out that extracellular (secreted) proteins are likely to provide a benefit to the local population of cells, and hence act as cooperative public goods[2,15,19,20,40]. The advantage of this method is that it allows a large number of genes to be examined, across multiple species.

Overall, we found the average bacterial genome had 2696 protein-coding genes on the chromosome(s), and 223 on the plasmid(s) (Table 1). Of these, an average of 57 genes (~2%) coded for the production of an extracellular protein. These patterns are very similar to those found previously[15,19,20]. We followed methods from previous studies by assuming that genes coding for extracellular proteins are more likely to represent public goods, since the diffusion of these secreted proteins will often mean their effects are shared among neighbouring cells[3,15,19,20].

	Extracellular	Non-Extracellular	% Extracellular
Chromosome(s)	52	2644	1.9%
Plasmid(s)	5	218	2.4%

Table 1. Summary of location of genes coding for extracellular proteins across species. We calculated the mean number of genes coding for extracellular proteins and non-extracellular proteins for all genomes in each species. We then calculated the mean of these species means to give the values in the above table. The values above therefore provide an indication of the location of genes coding for extracellular proteins in an average genome, controlling for number of genomes per species. Genes with unknown protein localisations were not included (Chromosome: 26.2%; Plasmid: 38.3%).

Extracellular proteins are not overrepresented on plasmids.

We found that extracellular proteins were not more likely to be carried on plasmids compared to chromosomes (Figure 2). The difference in the proportion of genes that coded for extracellular proteins between plasmid and chromosome was not significantly different from zero across all species (MCMCglmm[41]; posterior mean = 0.004, 95% CI = -0.063 to 0.057, pMCMC= 0.87; n = 1632 genomes; R^2 of species sample size = 0.47, R^2 of phylogeny = 0.17; Table S2, row 1). This result was robust to alternative forms of analysis. We also found no significant difference when we: (i) compared chromosomes to plasmids of only certain mobilities (Fig S4; Table S2, rows 20-22); (ii) analysed our data by two alternative methods, by looking at the ratio of proportions instead of the difference, or by considering only whether the plasmid proportion was greater than the chromosome proportion, removing any effect of the magnitude of this difference (Figure S5; Table S2, rows 2 and 3).

The lack of an overall significant result was clear when looking at the raw data for the different species that we examined (Figure 2; Figure S5). There was considerable variation across species in the location of genes coding for extracellular proteins. Overall, extracellular proteins were more likely to be on plasmids in 51% of species (26/51), and more likely to be on the chromosome(s) in 49% (25/51) of species (Figure S5). For example, in *Bacillus anthracis* genes coding for extracellular proteins were three times more likely to be on plasmids, whereas in *Acinetobacter baumannii* genes coding for extracellular proteins were three times more

likely to be on the chromosome(s) (Figure S5). Clearly, across species, genes coding for extracellular proteins are not consistently more likely to be on plasmids.

As a control, we also analysed the genomic location of the genes coding for all other classes of protein (Figure S1). Specifically, we analysed genes that coded for the production of Cytoplasmic, Cytoplasmic Membrane, Periplasmic, Outer Membrane and Cell Wall proteins. We found that none of these protein localisations were significantly overrepresented on plasmids or chromosomes across the 51 species (Figure S6; Table S2, rows 5-10). Plasmids are highly variable in the genes they carry.

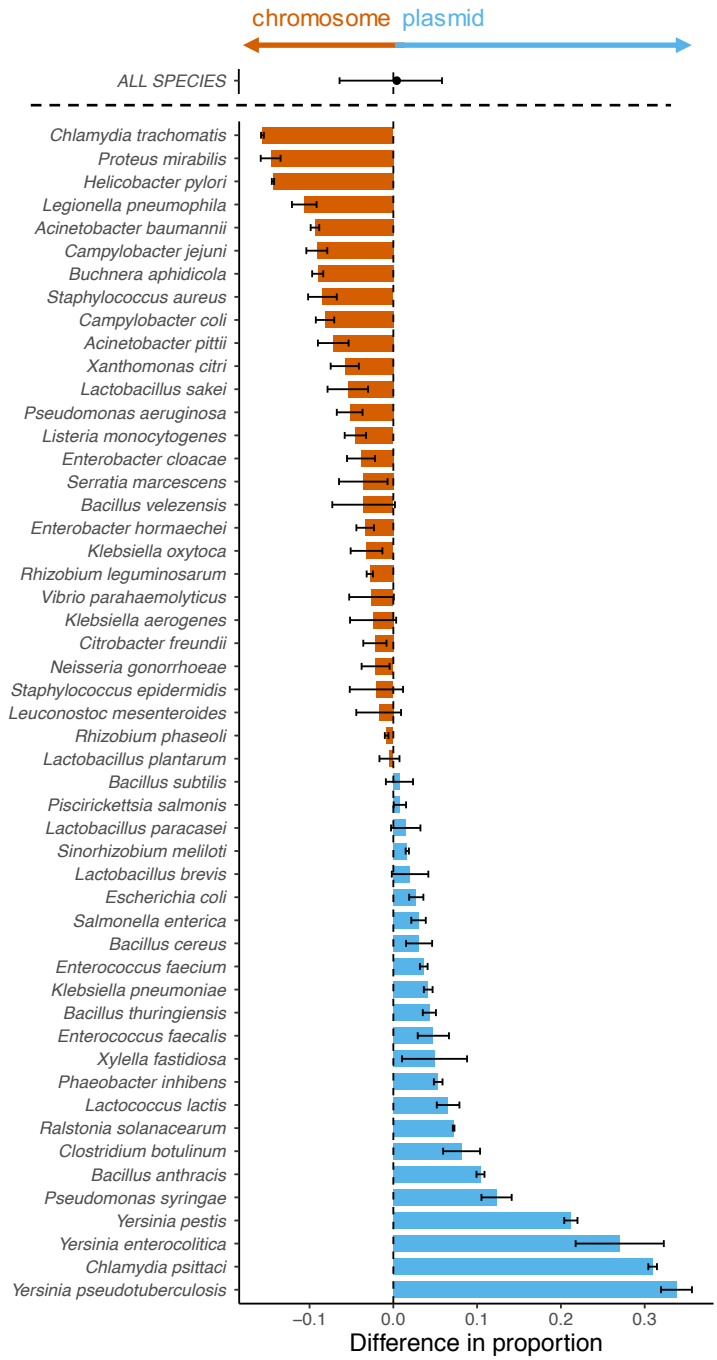

Fig 2. Extracellular proteins are not overrepresented on plasmids. For each species we calculated the mean difference between plasmid(s) and chromosomes in the proportion of genes coding for extracellular proteins. Species in blue have a difference greater than zero, meaning their plasmid genes code for a greater proportion of extracellular proteins than chromosome genes. Species in red have a difference less than zero, meaning their chromosome genes code for a greater proportion of extracellular proteins than plasmid genes. Error bars indicate the standard error. The dot and error bar at the top of the graph indicate the mean difference and 95% Credible Interval given by a MCMCglmm analysis across all species,

controlling for phylogeny and sample size. We arcsine square root transformed proportion data before calculating the difference. Overall, there is no consistent trend that genes coding for extracellular proteins are more likely to be carried on plasmids (i.e. no consistent trend towards species in blue).

Importance of controlling for non-independence of genomes. Our results contrast with previous studies, which found that plasmid genes code for proportionally more extracellular proteins than chromosomes[15,19,20]. The first of these studies found this pattern across 20 *Escherichia coli* genomes[15]. We also found that genes coding for extracellular proteins in *E. coli* were more likely to be found on plasmids (Figure 2; Figure S5). However, Figure 2 shows that this is not a consistent pattern across species: approximately half (25/51) of the species we analysed showed a pattern in the opposite direction, with genes coding for extracellular proteins more likely to be on their chromosome(s) than their plasmid(s).

Two subsequent, multi-species studies found that plasmid genes were significantly more likely to code for extracellular proteins than chromosome genes[19,20]. These studies used statistical tests such as Wilcoxon signed-rank test to ask whether there was a consistent pattern, using bacterial genomes as independent data points. When we analysed our data with the same statistical methods used in these studies, we also obtained a significant result (Wilcoxon signed-rank test; V= 826530, p-value <0.001, R^2 = 0.385; n = 1632 plasmid-chromosome pairs). When analysing other questions, Garcia-Garcera & Rocha[20] used MCMCglmm to control for phylogeny.

Why does using bacterial genomes as independent data points lead to a significant result? By using a Wilcoxon signed-rank test, at the level of the genome, we are implicitly assuming that all the genomes analysed are: (i) independent from one another; (ii) a representative sample of bacteria in nature. Neither of these are true for multi-species genomic datasets. First, due to shared ancestry, species are not independent from one another, and so neither are genomes in such analyses[24,42]. Even a slight lack of independence can lead to heavily biased results in statistical analyses and spurious conclusions[21]. Second, genomic databases tend to have a disproportionate abundance of certain species and genera. This will bias the results towards commonly sequenced species.

Consequently, when asking questions across species, it is inappropriate to treat all the genomes in genomic datasets as independent data points. When we performed an analysis analogous to the Wilcoxon signed-rank test, using the same untransformed data which produced a significant result above, but controlled for the number of genomes per species and the non-independence of species, we no longer found any significant difference between the proportion of plasmid and chromosome genes coding for extracellular proteins (MCMCglmm; posterior mean = 0.017, 95% CI = -0.021 to 0.057, pMCMC = 0.332; n = 1632 plasmid-chromosome paired differences in extracellular proportion; R^2: species sample size = 0.46, phylogeny = 0.34; Table S2, row 4). Furthermore, we found that the number of genomes per species and the non-independence of species explained 46% and 34% of the variation in data respectively (paired plasmid and chromosome differences across our 1632 genomes). Taken together, this illustrates that it is not our data which disagrees with previous studies, but instead our use of statistical analyses appropriate for multi-genome, multi-species datasets[23–25].

These data also illustrate the importance of examining effect sizes, and not just whether results are statistically significant. With large sample sizes it is possible to get results that are significant but not biologically important. One rule of thumb is to assume that a result is only biologically significant if the percentage of variance explained is >10% (i.e. $R^2>0.1$)[43]. When bacterial genomes are assumed to be independent data points in across species analyses, this leads to inflated sample sizes. Consequently, even when results are statistically significant at $P<0.05$, they can still only explain 1-2% of the variation in the data, which is clearly not biologically significant. The flip side of such considerations is that effects sizes and examination of raw data at the species level (e.g. Figure 2) are also useful checks against non-significant results due to a lack of statistical power (type II errors).

Plasmids with higher mobility do not carry more genes for extracellular proteins.

We then tested another prediction of the cooperation hypothesis: cooperation is more likely to be favoured when coded for on more mobile plasmids[14–18]. We used data from the MOBsuite database to assign plasmids to one of three levels of mobility (Fig 3a)[44,45]. We classify: conjugative plasmids, which carry all genes necessary to transfer, as the most mobile; mobilizable plasmids, which are dependent upon conjugative plasmids' machinery to transfer,

255 to have intermediate mobility; non-mobilizable plasmids, which cannot be transferred via
256 conjugation, to be the least mobile (Fig 3a)[44,46].
257
258 Genes coding for extracellular proteins were not more likely to be on plasmids with higher
259 transfer rates (Figure 3b). Examining the slope of the regression between plasmid mobility and
260 the proportion of genes coding for extracellular proteins, we found no consistent pattern across
261 species (MCMCglmm; posterior mean = 0.006, 95% CI = -0.040 to 0.052, pMCMC = 0.73; n
262 = 40; Table S2, row 11). This lack of a significant relationship was robust to different forms of
263 analysis, including an examination of the means of each mobility type of each species (Figure
264 S7; Table S2, row 12). A caveat here is that our estimates of transfer rates across different types
265 of plasmid is relative, and it would be very useful to obtain quantitative estimates of transfer
266 rates.
267

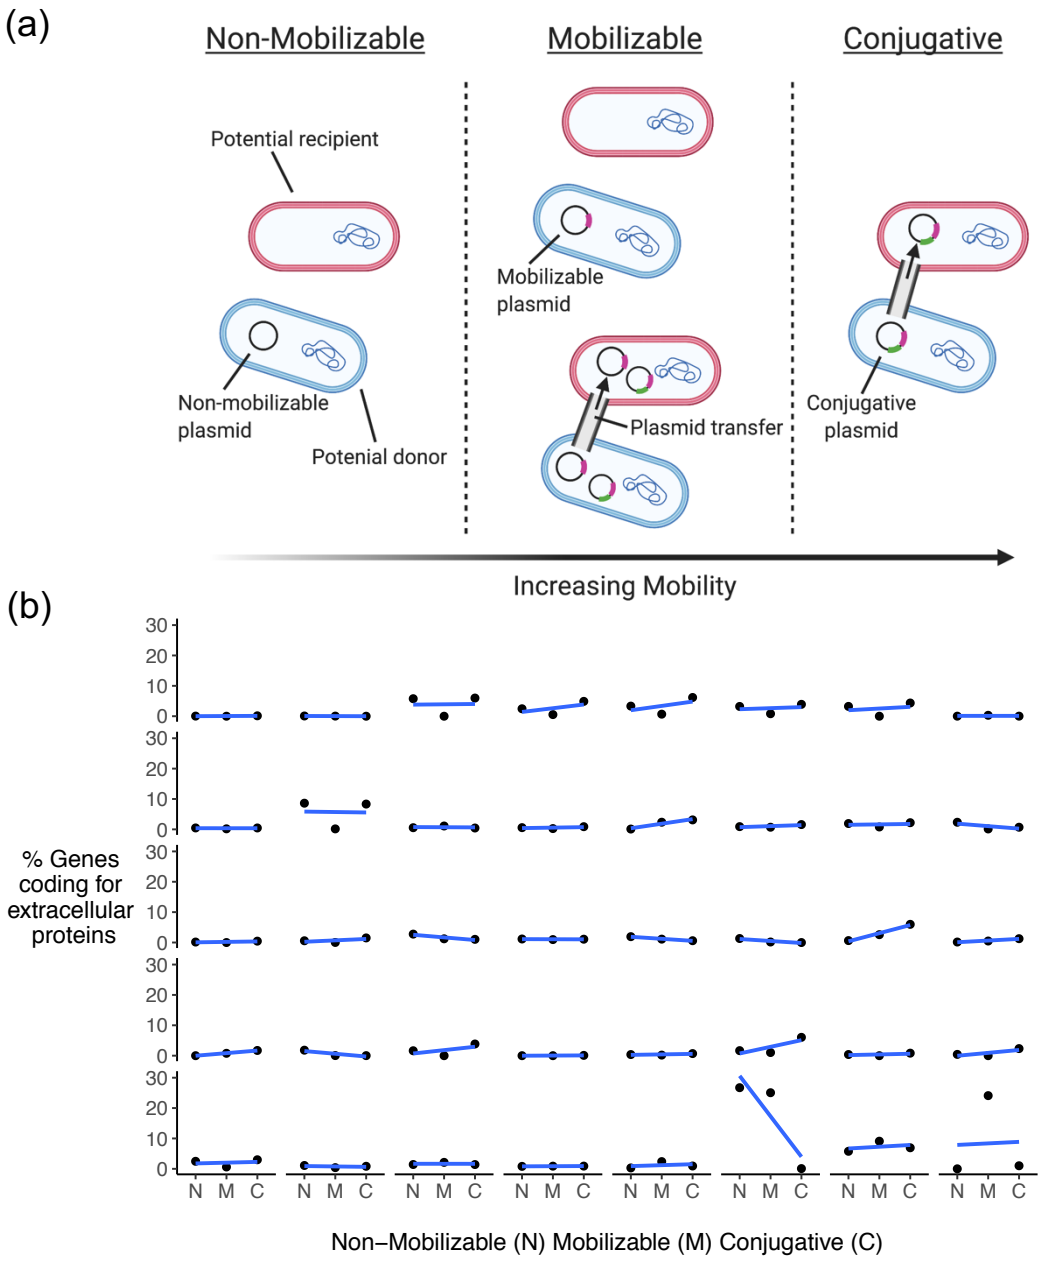

Figure 3. Plasmid mobility and extracellular proteins. (a) We divided plasmids into three mobility types: non-mobilizable (lowest or no mobility); mobilizable (intermediate mobility); conjugative (highest mobility). Blue cells are potential plasmid donors, while red cells are potential recipients. Each panel shows when plasmid transfer is possible for one of the three plasmid mobility types. Non-mobilizable plasmids cannot be transferred. Mobilizable plasmids cannot be transferred alone, but they carry enough genes to 'hijack' the machinery of a conjugative plasmid that is in the same cell. Conjugative plasmids carry all genes necessary to transfer independently. (b) The 40 species which carried plasmids of all three mobilities are

shown, with a panel for each of these species. Dots in each panel indicate the mean % of genes coding for extracellular proteins of all plasmids of each mobility level. The blue lines are the linear regression of these three points. We arcsine square root transformed proportion data before calculating the mean for each species, and then back-transformed these values for display of the data. Overall, there is no consistent trend for genes that code for extracellular proteins to be on more mobile plasmids.

Theoretical Stability of Cooperation

We examined whether cooperative genes should be overrepresented on plasmids, relative to the chromosome. First, horizontal gene transfer on a plasmid could allow cooperation to be favoured in conditions where it would otherwise not be favoured[14–17]. For example, because plasmid transfer can turn non-cooperators in to cooperators, and increase relatedness at the loci for cooperation[17]. Second, even if horizontal gene transfer did not increase the range of biological scenarios (parameter space) where cooperation was favoured, there could be selection for cooperation to be coded for on a plasmid, rather than a chromosome.

We followed the lifecycle assumptions of Mc Ginty *et al*.[17], assuming that the population is divided into patches, which are each founded by N independent cells (Supp. Info. 4). Cells reproduce clonally until there are a large number of cells per patch, after which they disperse. Cells can carry a plasmid which is transferred with probability β between paired cells, and which is costly (C_C) to carry. Individuals with the gene for cooperation produce a public good, at a cost C_G, which generates a benefit B that is shared between all members of the patch. The gene for cooperation can be on the plasmid or chromosome.

Consistent with previous analyses, we found that horizontal gene transfer on a plasmid can initially help cooperation invade (Figure 4). Horizontal gene transfer increased the frequency of cooperation, by turning non-cooperators into cooperators, which also increases relatedness at the cooperative locus[14–18,47].

In contrast, we found that transfer on a plasmid did not increase the range of parameter space where cooperation was maintained at evolutionary equilibrium (Fig 4a) (Supp. Info. 4). Specifically, cooperation was only favoured when RB-C_G>0, where R is the genetic relatedness at the chromosomal (individual) level ($R=1/N$). Cooperation was therefore only favoured when

it provided a kin selected benefit at the level of the chromosome (individual), as predicted by Hamilton's rule[48,49].

Our model therefore suggests that horizontal gene transfer can help cooperation initially invade, but then does not help maintain cooperation in the long term. As a plasmid approaches fixation, any benefit of horizontal gene transfer is lost. Consequently, competition between plasmids with and without a cooperative gene (cooperators and cheats) becomes analogous to the scenario in which the gene for cooperation is on the chromosome. An analogous result was also found in a meta-population model by Mc Ginty *et al*.[16]. Our prediction has been supported experimentally by Bakkeren *et al*.[30], who found that location on a conjugative plasmid could help a cooperative trait invade in *Salmonella* Typhimurium (*S*.Tm), but that this was only stable with strong population bottlenecks (high relatedness).

In addition, we found that, when cooperation is favoured, cooperative traits are not more likely to be favoured on, or transferred to, plasmids. The reason is that, when cooperation is favoured, non-cooperators (cheats) are purged from the population, which means there is no extra fitness benefit of coding for the cooperative trait on a plasmid rather than the chromosome. Consequently, our results suggest that horizontal gene transfer doesn't necessarily favour cooperation. Our results differ from previous theory because we have examined both: (i) a greater range of genetic architectures, especially plasmids that do not encode cooperation; and (ii) the evolutionary stability (maintenance) of cooperation, not just its initial invasion, while explicitly modelling plasmid transmission (Supp. Info. 4)[16,47].

More generally, with regard to whether we should expect plasmids and chromosomes to be in conflict, our results emphasise that at evolutionary equilibrium, the fitness interests of plasmids and chromosomes can be expected to align. Although, there could be interesting transient dynamics, where conflict leads to cooperation being favoured temporarily (Figure 4b). Another important factor is the rate of horizontal gene transfer. While plasmids clearly transmit fast enough to influence evolution, the transfer rates per cell per generation do not appear high enough to significantly influence relatedness at the locus for cooperation[50].

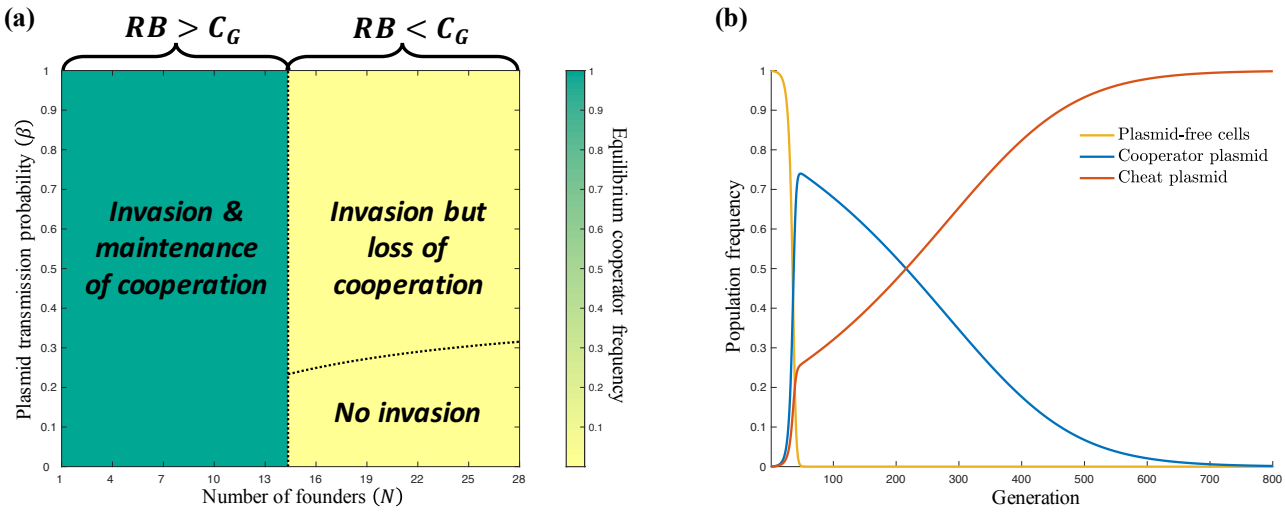

Figure 4. Plasmids facilitate the invasion but not the maintenance of cooperation. In parts (a) and (b), we plot the results of our theoretical model. (a) Cooperation is only maintained at equilibrium (green shaded area) when it is favoured at the chromosomal level $RB > C_G$, which is unaffected by plasmid transfer (β). (b) Plasmids can facilitate the invasion and initial spread of cooperation (blue line shoots above red line), but cooperative plasmids are eventually outcompeted by cheat plasmids (red line goes to 1). To generate the plots in (a) and (b), we assumed the following parameter values: (a & b) $B = 1.435, C_G = 0.1, C_C = 0.2$; (b) $\beta = 0.5, \mathrm{N} = 16$.

Alternate hypotheses.

Finally, we examined whether alternate hypotheses may better explain the considerable variation in the location of genes coding for extracellular proteins across species. Species which live in more variable environments may be more likely to carry extracellular genes on plasmids. This could be expected for different reasons, including plasmid transfer allowing genes for different environments to be gained and lost (Figure 1b), or plasmids conferring some other advantage not associated with horizontal gene transfer, such as allowing copy number to be conditionally adjusted (Figure 1c)[31,32,38,51]. There are a number of different ways to classify environmental variability, and so we used three different methods.

Broad host-range pathogens are most likely to carry genes for extracellular proteins on plasmids. We first used the diversity of pathogen hosts as a proxy for environmental variability. Although this does not capture all environmental variability experienced by species

in our data set, pathogenicity is a key aspect of bacterial lifestyle that has been suggested to be important for plasmid gene content, such as antibiotic resistance and virulence factors[6,40,52,53]. We divided species into three categories: pathogens with broad host-range, pathogens with narrow host-range, and non-pathogens. Broad host-range pathogens are expected to encounter more variable environments than narrow host-range pathogens.

We found that pathogens with a broad host-range were more likely to carry genes coding for extracellular proteins on their plasmids, compared with both narrow host-range pathogens and non-pathogens (Fig 5). Specifically, we compared the difference in the proportion of genes coding for extracellular proteins between plasmid(s) and chromosome(s) across these three categories of species (MCMCglmm; Narrow compared to Broad host-range pathogens: posterior mean = -0.222, 95% CI = -0.322 to -0.123, pMCMC = <0.001; Non-pathogens compared to Broad host-range pathogens: posterior mean = -0.161, 95% CI = -0.252 to -0.067, pMCMC = <0.001; n = 701 genomes; R^2 of pathogenicity/host-range = 0.35, R^2 of species sample size = 0.28, R^2 of phylogeny = 0.11; Table S2, row 23). There was no significant difference between narrow host-range pathogens and non-pathogens in the proportion of genes coding for extracellular proteins on their plasmids compared to chromosome(s) (MCMCglmm; Non-pathogens compared to Narrow host-range pathogens: posterior mean = 0.031, 95% CI = -0.065 to 0.127, pMCMC = 0.482; n = 389; Table S2, row 25). These patterns hold irrespective of whether we included species that we could not reliably classify into either category, such as opportunistic pathogens, in our analyses (Figure S10).

Plasmids of broad host-range pathogens carry many pathogenicity genes. We suspected that the additional extracellular proteins coded for by plasmids of broad host-range species, compared to narrow host-range species, may be particularly involved in facilitating pathogenicity[40,52,53]. To investigate this, we used the program MP3[54] to assign a each extracellular protein as either ‘pathogenic’ or ‘non-pathogenic’.

We found that plasmids of broad host-range pathogens were particularly enriched with extracellular proteins involved in facilitating pathogenicity, compared to plasmids of narrow host-range species (Figure 6). Specifically, we found that pathogens with a broad host-range were significantly more likely to code for pathogenic extracellular proteins on their plasmids compared to narrow host-range species (Figure 6a) (MCMCglmm; Narrow compared to Broad host-range pathogens: posterior mean = -0.209, 95% CI = -0.350 to -0.086, pMCMC = 0.012;

n=474 genomes; Table S2, row 26). In contrast, the relative location of non-pathogenic extracellular proteins did not vary between broad and narrow host-range pathogens (Figure 6b) (MCMCglmm; Narrow compared to Broad host-range pathogens: posterior mean = -0.036, 95% CI = -0.115 to 0.040, pMCMC = 0.296; n=474 genomes; Table S2, row 27). Consequently, the excess of genes coding for extracellular proteins on the plasmids of broad host-range species (Figure 5) appears to arise due to an excess of pathogenicity genes coding for extracellular proteins (Figure 6).

Most genomic databases are biased towards species that interact with and/or infect humans, so we examined whether these species had driven the above results. In our dataset, 5 out of 10 broad host-range species and 3 out of 5 narrow host-range species can infect humans. We found no significant difference in how likely both pathogenic and non-pathogenic extracellular proteins were to be on plasmids of human pathogens compared to non-human pathogens. We also found that while host-range had a significant effect on how likely plasmids were to code for pathogenic extracellular proteins, whether a species could infect humans had no significant effect (Table S2, rows 28 to 30).

Pathogenic extracellular proteins could be preferentially coded for on plasmids to facilitate their gain and loss (Figure 1b: Gain and loss hypothesis), or because of some other benefit provided by being carried on a plasmid (Figure 1c: Beyond horizontal gene transfer hypothesis). We tested these possibilities by examining whether pathogenic extracellular proteins were more likely to be on plasmids that transfer at higher rates. This would be predicted by the gain and loss hypothesis, but not the beyond horizontal gene transfer hypothesis. We found that plasmids with higher mobility did not code for more pathogenic extracellular proteins. Specifically, across broad host-range pathogen species, the slope of the regression between plasmid mobility and the proportion of genes coding for pathogenic extracellular proteins was not consistently positive (Figure S11) (MCMCglmm; posterior mean = -0.020, 95% CI = -0.224 to 0.185, pMCMC = 0.774; n=7; Table S2, row 31). This lack of a significant relationship was robust to additional forms of analysis, such as considering all pathogenic species, including narrow host-range pathogens and those not carrying plasmids of all three mobility types (Figure S12; Table S2, rows 32 and 33).

Taken together, our results are most consistent with the hypothesis that genes coding for extracellular proteins are overrepresented on plasmids when plasmid carriage provides a

benefit other than mobility (Figure 1c). A number of other factors may influence which genes are carried on plasmids, beyond horizontal gene transfer. First, there is evidence that increasing the copy number of plasmids can lead to increasing rates of evolution in the genes they carry[55], and it also may act as a mechanism to increase the expression of genes carried on plasmids[56,57]. For example, increased expression of genes coding for extracellular public goods such as virulence factors could help invasion of a host and utilisation of host resources. This could be particularly beneficial for broad host-range pathogens that frequently invade a variety of different hosts. Copy number of plasmids has also recently been shown to lead to genetic dominance effects[51], with likely implications for the phenotypes of genes selected for plasmid carriage[51]. Second, plasmids compete with their bacterial hosts for resources such as replication machinery and nucleotides[58,59]. To resolve this competition, plasmids should be under selection to reduce their cost to the host, with a likely impact on their gene content. For example, extracellular proteins are, on average, cheaper to produce than intracellular proteins[15,20]. Plasmid-host competition could consequently select for plasmids to carry more genes coding for cheaper proteins, and so more extracellular proteins. Taken together, there are a number of factors which will allow plasmids to facilitate pathogenicity and adaptation to new and variable environments. Our conclusion here should be seen as tentative, as some form of the gain and loss hypothesis (Figure 1b) could still be argued to be consistent with the data, if it is just the potential for horizontal gene transfer that matters, and not the rate.

456 **Figure 5. Environmental variability and the location of genes coding for extracellular**
457 **proteins.** We have divided species into either pathogens or non-pathogens, with pathogens
458 further categorised into those with a narrow or broad host-range. The y-axis shows the
459 difference in the proportion of genes on plasmids and chromosomes coding for extracellular
460 proteins. Each dot is the mean for all genomes in a species. Species in blue are those with
461 extracellular proteins overrepresented on plasmids, while species in red are those with
462 extracellular proteins overrepresented on chromosomes. The black bars indicate the mean for
463 all species in each category. Overall, pathogens with a broad host-range are more likely to have
464 genes coding for extracellular proteins on their plasmids.

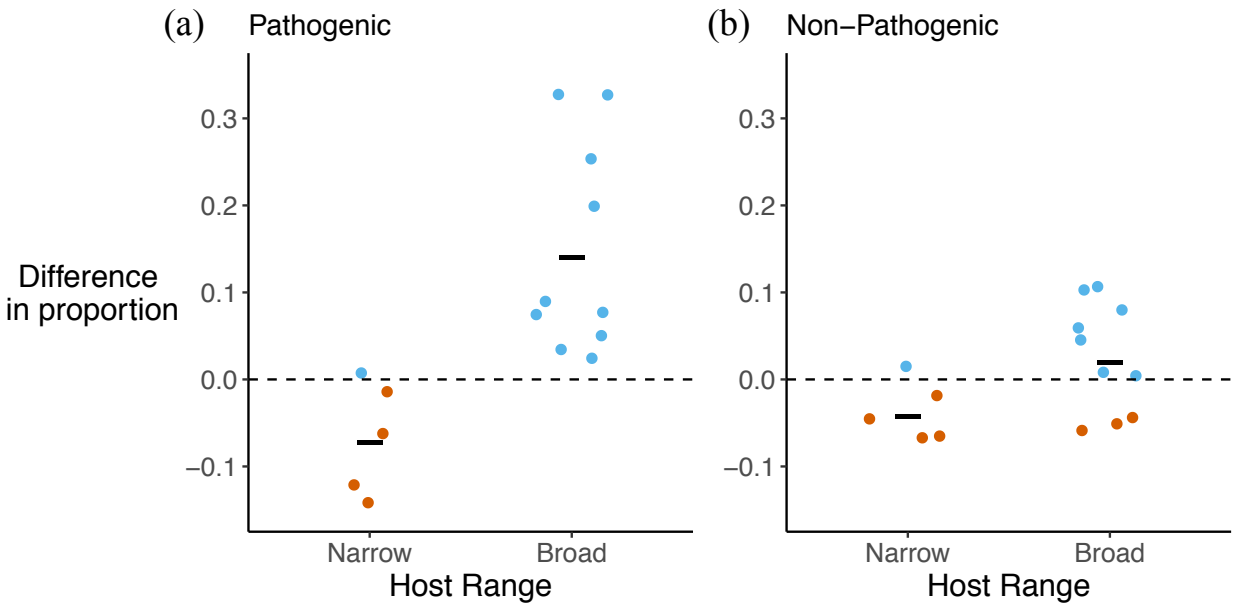

Figure 6. The location of genes coding for pathogenic and non-pathogenic extracellular proteins, in species with broad and narrow host-ranges. We categorised pathogenic species into those with either a broad or narrow host-range. The y-axes in (a) and (b) show the difference in the proportion of genes coding for extracellular proteins on plasmids and chromosomes which are predicted by MP3 as either (a) pathogenic or (b) non-pathogenic. Higher values indicate that extracellular proteins are more likely to be coded for by plasmids. Each dot is the mean for all genomes in a species. Species in blue are those with the relevant subset of extracellular proteins overrepresented on plasmids, while species in red are those with the subset of extracellular proteins overrepresented on chromosomes. Overall, there is a significant difference between broad and narrow host-range species in the location of genes coding for pathogenic extracellular proteins, but no difference for non-pathogenic extracellular proteins.

Number of environments and core vs accessory genes. We also looked at two additional measures of environmental variability: (i) the number of five broad environments a species was sequenced in[20,60,61]; (ii) the proportion of a species' genomes that is composed of 'core' genes, which are those found in all genomes of the species – species which experience more variable environments appear to have relatively smaller core genomes[32]. We found no significant correlation between either of these measures and the likelihood that genes coding for extracellular proteins were carried on plasmids (Figure S13) (Supp. Info. 1; Table S2, rows 35 and 37). Garcia-Garcera & Rocha[20] previously analysed a different but related question,

examining the type of environment, and also used a MCMCglmm to control for the phylogenetic structure of the data (Supp. Info. 1).

Complementary Analyses

There a number of directions in which our analyses could be expanded. We focused on plasmids because they have been the focus of previous theoretical and empirical work[14,16–18]. Other mobile genetic elements include bacteriophages and integrative conjugative elements[62,63]. Comparing core and accessory genes could be a potential way to lump all causes of horizontal gene transfer[15,19]. We considered the relative transfer rates among mobility types; quantitative estimates of plasmid transfer rates would be very useful for further examination of plasmid mobility[46,50,64–66]. We followed previous genomic studies by using extracellular proteins as indicators of cooperative traits[2,15,19,20]. The advantages of this approach are that: (i) we could compare our results with those from previous studies; (ii) secretion systems are highly conserved, allowing us to examine a large number of species, where detailed genetic annotations are lacking; (iii) cooperation mediated by extracellular proteins is usually controlled by only one gene, making them potentially more suitable for plasmid carriage compared to cassettes of multiple genes[67,68]. However, while extracellular proteins are likely to be cooperative traits, not all cooperative genes code for extracellular proteins (e.g. secondary metabolites such as siderophores), and not all extracellular proteins are involved in cooperation (e.g. those involved in motility such as flagellin). It would be very useful to examine more detailed annotations of social genes, and expand to other mobile genetic elements.

Discussion

We found no support for the hypothesis that horizontal gene transfer favours cooperation. Our genomic analyses showed that extracellular proteins are not: (i) overrepresented on plasmids compared to chromosomes; (ii) more likely to be carried by plasmids that transfer at higher rates. These patterns could be explained by theoretical modelling, which showed that while horizontal gene transfer may help cooperation to initially invade a population, it does not then help the maintenance of cooperation in the long term. Once plasmids become common, cheat plasmids that do not code for cooperation are able to outcompete cooperative plasmids, analogous to selection at the level of the chromosome[16]. Our prediction has also been supported experimentally by Bakkeren *et al.*[30], in *Salmonella* Typhimurium (*S*.Tm), who observed cooperation invading on a plasmid, but then being outcompeted by newly emerging non-

cooperative cheats. In contrast, we found that genes coding for extracellular proteins involved in pathogenicity and virulence are preferentially located on plasmids in pathogens with a broad host-range. These pathogenic virulence genes were not preferentially located on plasmids that transfer at a higher rate, suggesting that the benefit of being located on a plasmid is something other than horizontal gene transfer, such as the ability to vary copy number.

Methods

Genome Collection

We retrieved 1632 complete genomes comprising 51 bacterial species from GenBank RefSeq (https://www.ncbi.nlm.nih.gov) between February-November 2019. We used species on panX (http://pangenome.tuebingen.mpg.de)[69] as a list of potential species for our dataset, since these comprise the most sequenced bacterial species. To allow comparison of chromosome and plasmid genes within the same genome, we only retrieved genomes that contained at least one plasmid sequence. We included species with 10 or more RefSeq genomes with one or more plasmids available in our analysis. We retrieved up to 100 genomes for each species; this was either all complete genomes available for the species, or a random sample where more than 100 were available. Where two or more genomes had the same strain name, we randomly retrieved one genome to reduce the risk of pseudoreplication.

Prediction of Subcellular Location of Proteins

We used PSORTb v.3[39] to predict the subcellular location of every protein encoded by each genome in our dataset. We used a Docker image of PSORTb developed by the Brinkman Lab, available at: https://github.com/brinkmanlab/psortb_commandline_docker. We chose PSORTb because it is widely regarded as one of the best performing programs of its kind[70]. It has also been used in previous analyses to identify 'cooperative' genes and/or extracellular proteins in bacteria[15,20]. The program has a number of modules which are trained to recognise particular features of proteins. Results from these modules are combined to give a Final Prediction for each protein. We consulted the literature to confirm the Gram stain of each of our species. For Gram-positive species, PSORTb assigns proteins to one of four locations within the cell: cytoplasmic, cytoplasmic membrane, extracellular or cell wall (Figure S1). The locations for Gram-negative species are the same, except that cell wall is replaced with outer membrane and periplasmic, meaning there are five possible locations for proteins of Gram-negative species (Figure S1). We used these predicted locations throughout all subsequent

552 analyses in this work. PSORTb could not reliably assign a subcellular location to 27% of
553 proteins we analysed, giving a final prediction of 'unknown' (Table S1). Unless explicitly
554 stated, we did not include these unknown proteins in our analyses.
555
556 ## Predicting Plasmid Mobility
557 We also predicted the mobility of every plasmid in our dataset using the MOB-typer tool of
558 the program MOBsuite[44]. This searches for features of plasmid sequences including the origin
559 of transfer (oriT), relaxase and mating-pair formation to give each plasmid one of three
560 mobility predictions: (i) conjugative, where plasmids encode all machinery required to transfer
561 via conjugation; (ii) mobilizable, where plasmids do not encode all machinery, but encode oriT
562 and/or relaxase, allowing them to 'hijack' another plasmid's conjugation machinery and
563 mobilize; (iii) non-mobilizable, where plasmids do not encode the genes necessary to be
564 mobilized by themselves or other plasmids, and so cannot transfer via conjugation. 628 of the
565 4150 plasmids in our dataset were flagged as 'unverified' against the MOBsuite dataset,
566 meaning their mobility prediction was unreliable and they were not included. This left 3522
567 plasmids for subsequent analysis.
568
569 ## Effect of Mobility on Plasmid Extracellular Protein Content
570 We next examined how plasmid mobility correlates with each plasmid's extracellular protein
571 proportion. As part of its mobility prediction, MOBsuite[44] identifies sequences within each
572 plasmid involved with conjugation. To control for the possibility that conjugative plasmids, by
573 definition of being conjugative, must carry genes controlling this process, we subtracted the
574 total number of these sequences from the total number of proteins when calculating the
575 extracellular proportion of each plasmid. This is a highly conservative control, since it assumes
576 none of the proteins predicted as extracellular are involved in conjugation. We did all analyses
577 on these data with and without removing these mating-pair accessions to ensure any results
578 were not affected by factors unrelated to plasmids' extracellular protein content.
579
580 Additionally, we used the plasmid mobility predictions to ask whether differences in the
581 mobility of species' plasmids correlated with whether genes encoding extracellular proteins
582 are overrepresented on plasmids compared to chromosomes. We calculated the proportion of
583 plasmids in each genome capable of transferring via conjugation (conjugative and mobilizable

plasmids), and averaged across all genomes to give a general measure of the mobility of each species' plasmids.

Measures of Bacterial Lifestyle and Environmental Variability

We classified a species as pathogenic if it was described in the literature as an obligate or facultative pathogen. Given some bacterial species only rarely act as pathogens, such as opportunistic pathogens, we only included species where we could be sure pathogenicity was a key aspect of their lifestyle and a regular selection pressure acting on their genome content. For this reason, we decided not to include species described as opportunistic pathogens in the literature and those which frequently live as commensals in their hosts. We classified non-pathogens as species which are strictly environmental (never live in hosts) or strictly mutualists and/or commensals (never cause pathogenicity in their hosts). There were 26 species we could not definitively assign to either of these categories. These were not included in our main analyses, although we carried out additional analyses to ensure that removing these species did not bias our results (Figure S10).

To estimate the host-range of pathogens, we used information from the literature to determine the maximum taxonomic level of hosts each species is able to invade. We defined narrow host-range species as those which can invade either only one host species, or host species within the same genus or family. In contrast, we defined broad-host range pathogens as those capable of invading host species within the same order, class or phylum. For example, *Xanthomonas citri* acts as a plant pathogen within the genus Citrus[71], while *Pseudomonas syringae* acts as plant pathogen across multiple orders of flowering plants[72]. For more details and references to the literature used for this classification, please see Table S3.

We completed additional analyses for other two measures and proxies of environmental variability, the details and results of which can be found in Supp. Info. 1. In brief, we used previously published data which classified the habitat diversity of species using 16S RNA environmental datasets across five broad habitats: water, wastewater, sediment, soil and host[60,61]. We also supplemented this with information from the literature for species not included in the published data. We used this to ask whether species which lived in multiple habitats had genes encoding extracellular proteins more overrepresented on their plasmids.

We also looked at bacterial pangenomes as a proxy for environmental variability, since it has been noted that species with a high % of accessory genes, defined as genes found in only a subset of genomes within a species, are generally those with more variable environments. All pangenome data was collected from panX[69] (http://pangenome.tuebingen.mpg.de), since this calculates the pangenome using the same method across all of our species.

Pathogenicity categorisation of extracellular proteins

We used MP3[54] to examine the pathogenicity of extracellular protein-coding genes in broad host-range and narrow host-range pathogens. MP3 uses two modules to produce a 'Hybrid' prediction for each protein: either 'Pathogenic' or 'Non-Pathogenic'. We used MP3 with default parameters to gain this prediction for every extracellular protein in all genomes of broad and narrow host-range species. MP3 was unable to give a prediction for approximately 9% of extracellular proteins, and so these were not included in this analysis.

For each genome in broad and narrow host-range pathogens, we summed the MP3 predictions to give the total number of 'Pathogenic' and 'Non-Pathogenic' extracellular proteins on the chromosome and on the plasmid(s). We then calculated the proportions of plasmid and chromosome genes which code for 'Pathogenic' and 'Non-Pathogenic' extracellular proteins.

Statistical analyses

MCMCglmm. Many commonly used statistical methods in biology require data points to be independent from one another. However, due to shared ancestry, species cannot be considered as independent data points[24]. Recently developed statistical methods now allow for phylogenetic relationships to be controlled for within mixed effects models. For all statistical analyses we used the MCMCglmm (Markov Chain Monte Carlo generalised linear mixed effects model) package in R with phylogeny and sample size as random effects[41,73]. We extracted from each model the posterior mean, 95% Credible Intervals (functionally similar to 95% Confidence Intervals), and the pMCMC value (generally interpreted in a similar way to a 'p-value'). We also calculated R^2 values for models of particular interest using methods described in[74,75]. A detailed description of MCMCglmm can be found elsewhere[41,73].

The response variable in all of our analyses is either a proportion or a measure calculated from proportions. Proportion data is bound between 0 and 1 and has a non-normal distribution. To

control for this, all proportion data in our analyses has been arcsine square root transformed to improve normality.

Phylogeny. To control for species relationships, we generated a phylogeny including all 51 species in our dataset (Fig S2). We used a recently published maximum likelihood tree using 16S ribosomal protein data as the basis for our phylogeny[76]. This tree of life typically had only one representative species per genus. We used the R package 'ape' to extract all branches matching species in our dataset[77]. In cases where the genus representative was different to the species in our dataset, we swapped the tip name with our species, since all members of the same genus are equally related to members of a sister genus. In cases where we had multiple species within a single genus in our dataset, we used the R package 'phylotools' to add these species as additional branches into their genus[78]. We used published phylogenies from the literature to add any within-genus clustering of species' branches. We used this phylogeny in nexus format for all our MCMCglmm analyses (Fig S2, Table S2). Methods are also available to control for uncertainty in phylogenetic reconstruction[79,80], although we have not done this here.

Acknowledgements

We thank: Craig MacLean, Kevin Foster, Laurence Belcher, Chunhui Hao, and especially Eduardo Rocha for their helpful comments; James Robertson for providing plasmid mobility data from the MOBsuite database; the BBSRC (A.E.D.), ERC (J.L.T., T.W.S., A.S.G., M.G. and S.A.W.), and NSERC-CRSNG of Canada (G.W.) for funding. Conceptual figures were created with Biorender.com.

Author Contributions

A.E.D., J.L.T., A.S.G., S.A.W and M.G. conceived the genomic analyses and interpreted results. A.E.D. and J.L.T. collected and analysed genomic data, and A.E.D. produced the corresponding figures. T.W.S, G.W. and S.A.W. conceived the theoretical modelling and interpreted results. T.W.S. completed the formal theoretical modelling. A.E.D., J.L.T, T.W.S., S.A.W., and M.G. wrote and/or edited the manuscript. A.E.D. wrote and put together S1, S2 and S3, and T.W.S. wrote and put together S4. All authors commented on and approved the manuscript for submission.

Competing Interests

The authors declare no competing interests.

Data Availability Statement

The datasets generated and/or analysed (including accession codes) during the current study are available from the corresponding author on request, and will be made available when published.

Figures

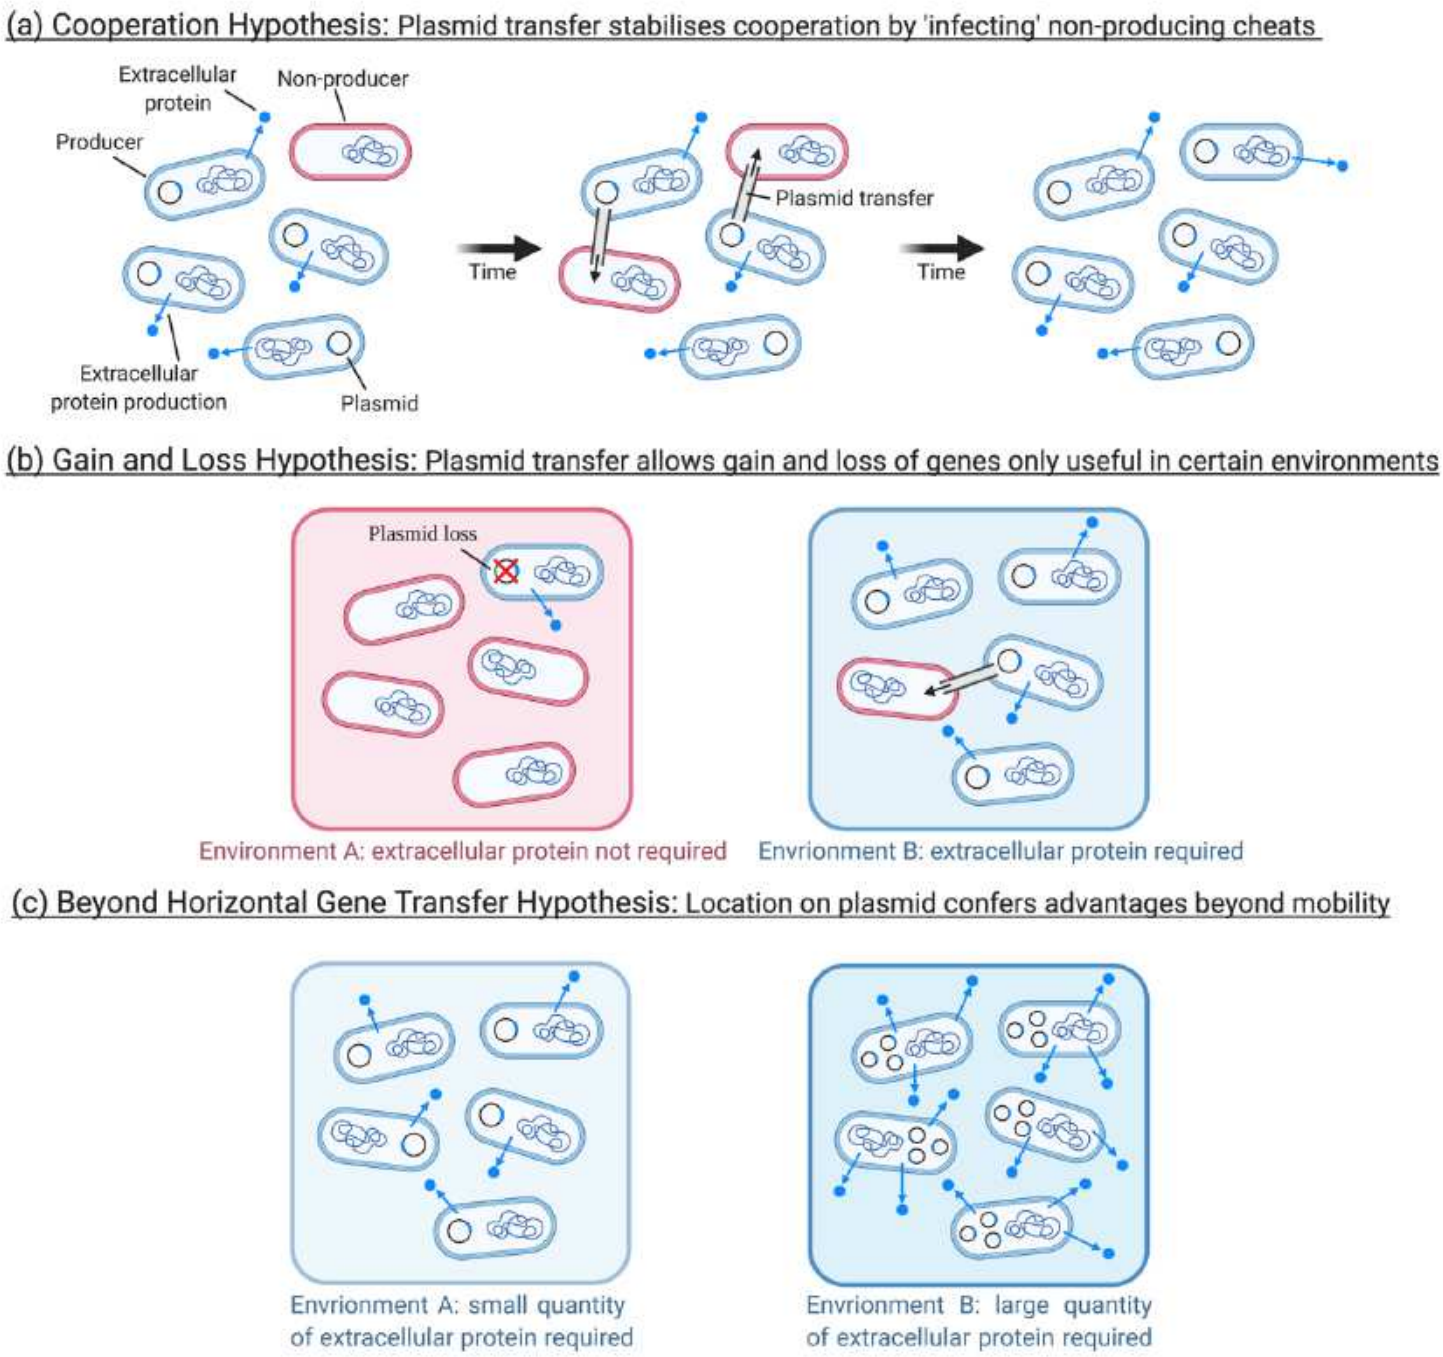

Figure 1

Three hypotheses for why selection might favour genes coding for extracellular proteins to be located on plasmids. (a) Cooperation Hypothesis. Blue cells produce extracellular proteins which act as cooperative public goods, while red cells are ‘cheats’ which exploit this cooperation. Over time cheats grow faster than cooperators since they forgo the cost of public good production. However, because the gene for the extracellular protein is located on a plasmid, cooperators can transfer the gene to the cheats, turning them into cooperators, increasing genetic relatedness at the cooperative locus, and stabilising

cooperation. (b) Gain and Loss Hypothesis. The production of the extracellular protein is required in some environments, but not others. Transitions between these environments can result from temporal or spatial change. Cells are selected to either lose (Environment A) or gain (Environment B) the plasmid coding for the production of the extracellular protein. (c) Beyond Horizontal Gene Transfer Hypothesis. The location of a gene on a plasmid could provide a number of benefits, other than the possibility for horizontal gene transfer38. For example, when the quantity of extracellular protein required varies across environments (A versus B), plasmid copy number could be varied to adjust production38.

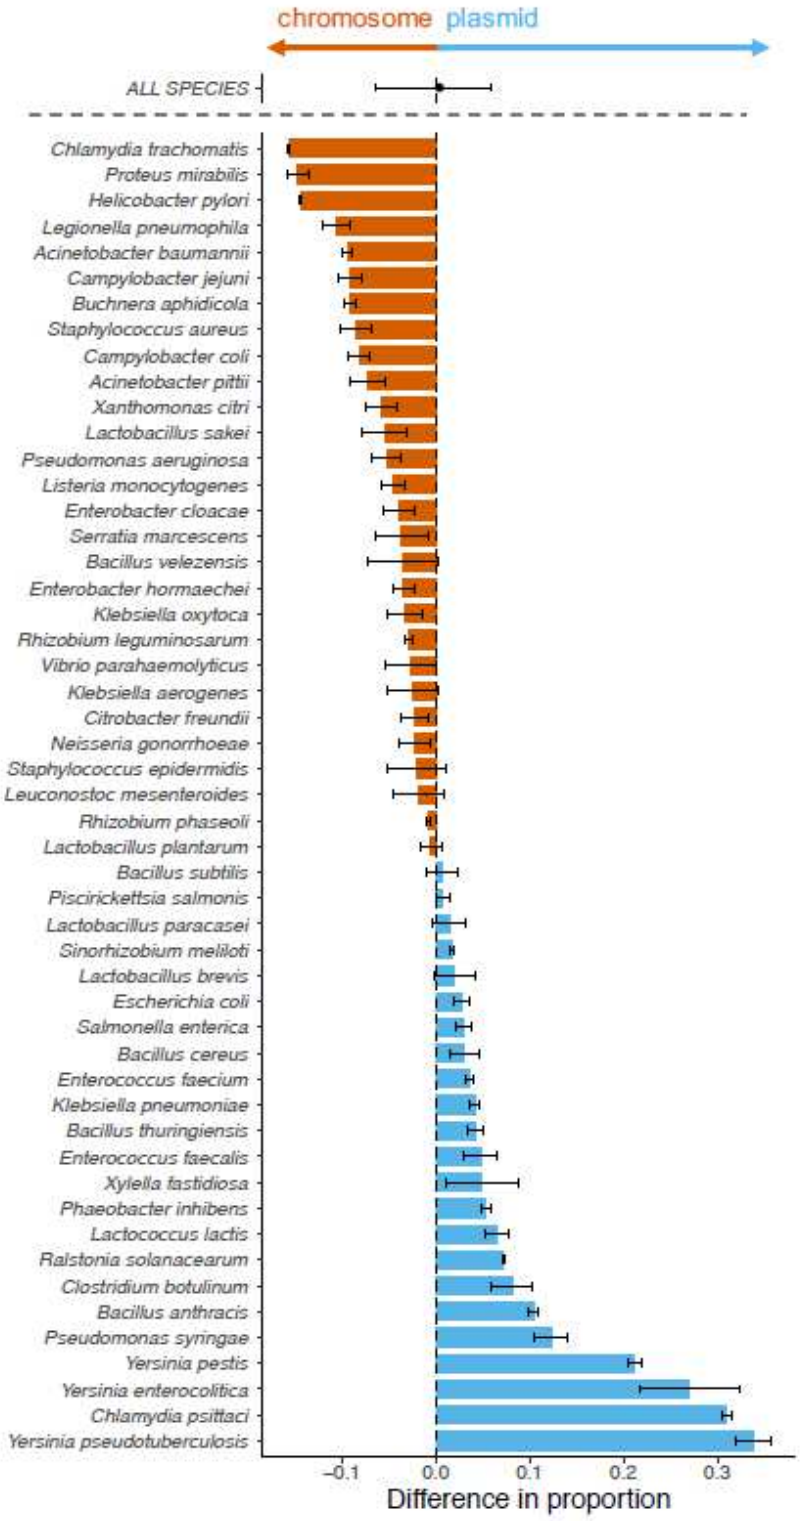

Figure 2

Extracellular proteins are not overrepresented on plasmids. For each species we calculated the mean difference between plasmid(s) and chromosomes in the proportion of genes coding for extracellular proteins. Species in blue have a difference greater than zero, meaning their plasmid genes code for a greater proportion of extracellular proteins than chromosome genes. Species in red have a difference less than zero, meaning their chromosome genes code for a greater proportion of extracellular proteins than plasmid genes. Error bars indicate the standard error. The dot and error bar at the top of the graph indicate the mean difference and 95% Credible Interval given by a MCMCglmm analysis across all species, controlling for phylogeny and sample size. We arcsine square root transformed proportion data before calculating the difference. Overall, there is no consistent trend that genes coding for extracellular proteins are more likely to be carried on plasmids (i.e. no consistent trend towards species in blue).

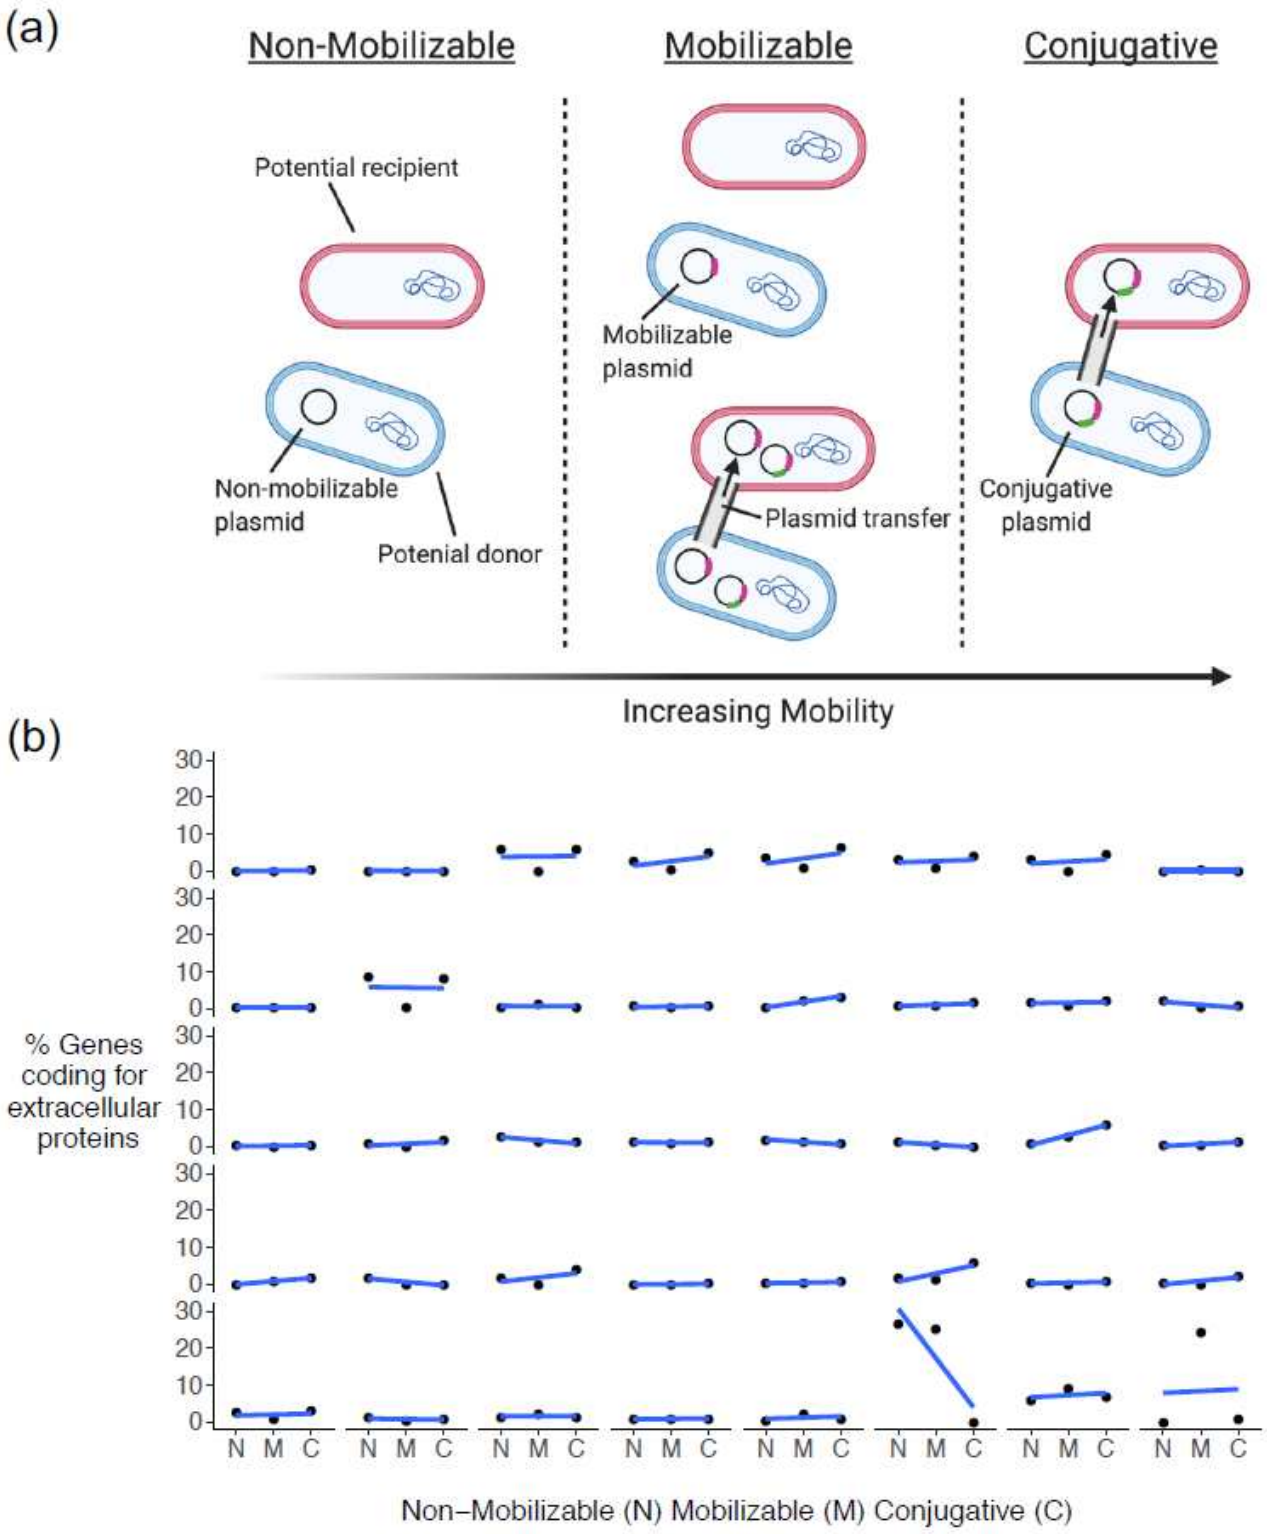

Figure 3

Plasmid mobility and extracellular proteins. (a) We divided plasmids into three mobility types: non-mobilizable (lowest or no mobility); mobilizable (intermediate mobility); conjugative (highest mobility). Blue cells are potential plasmid donors, while red cells are potential recipients. Each panel shows when plasmid transfer is possible for one of the three plasmid mobility types. Non-mobilizable plasmids cannot be transferred. Mobilizable plasmids cannot be transferred alone, but they carry enough genes to 'hijack'

the machinery of a conjugative plasmid that is in the same cell. Conjugative plasmids carry all genes necessary to transfer independently. (b) The 40 species which carried plasmids of all three mobilities are shown, with a panel for each of these species. Dots in each panel indicate the mean % of genes coding for extracellular proteins of all plasmids of each mobility level. The blue lines are the linear regression of these three points. We arcsine square root transformed proportion data before calculating the mean for each species, and then back-transformed these values for display of the data. Overall, there is no consistent trend for genes that code for extracellular proteins to be on more mobile plasmids.

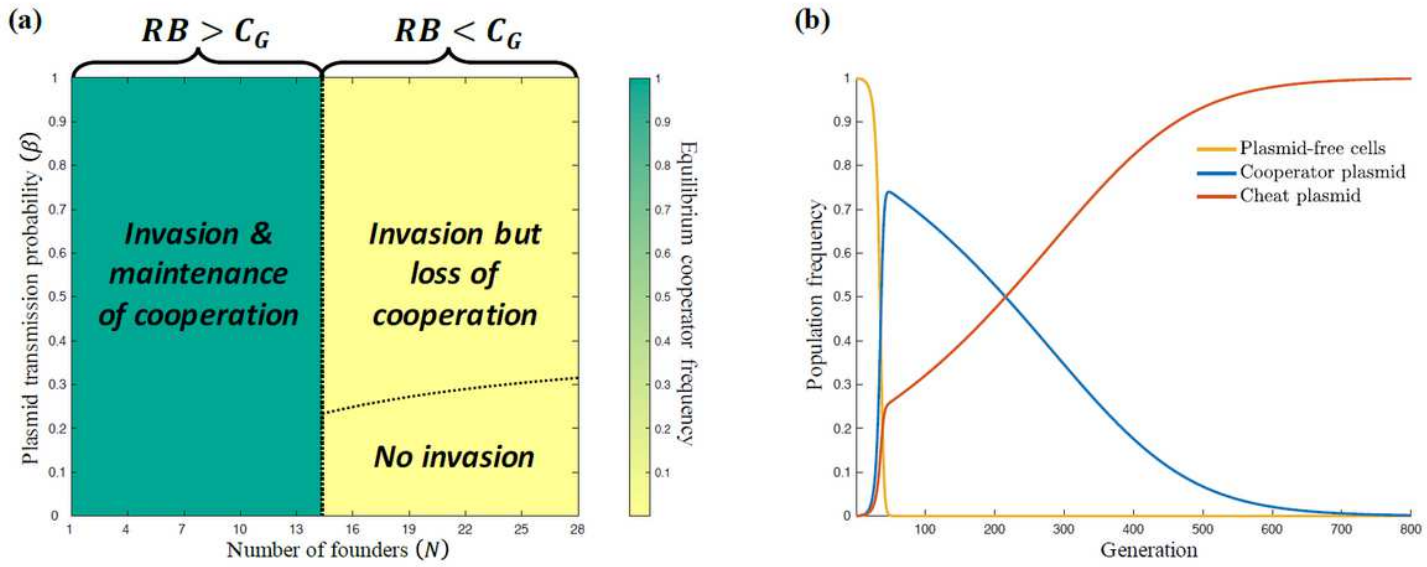

Figure 4

Plasmids facilitate the invasion but not the maintenance of cooperation. In parts (a) and (b), we plot the results of our theoretical model. (a) Cooperation is only maintained at equilibrium (green shaded area) when it is favoured at the chromosomal level □□ > □%, which is unaffected by plasmid transfer (β). (b) Plasmids can facilitate the invasion and initial spread of cooperation (blue line shoots above red line), but cooperative plasmids are eventually outcompeted by cheat plasmids (red line goes to 1). To generate the plots in (a) and (b), we assumed the following parameter values: (a & b) □ = 1.435,□% = 0.1, □/ = 0.2; (b) β = 0.5,N = 16.

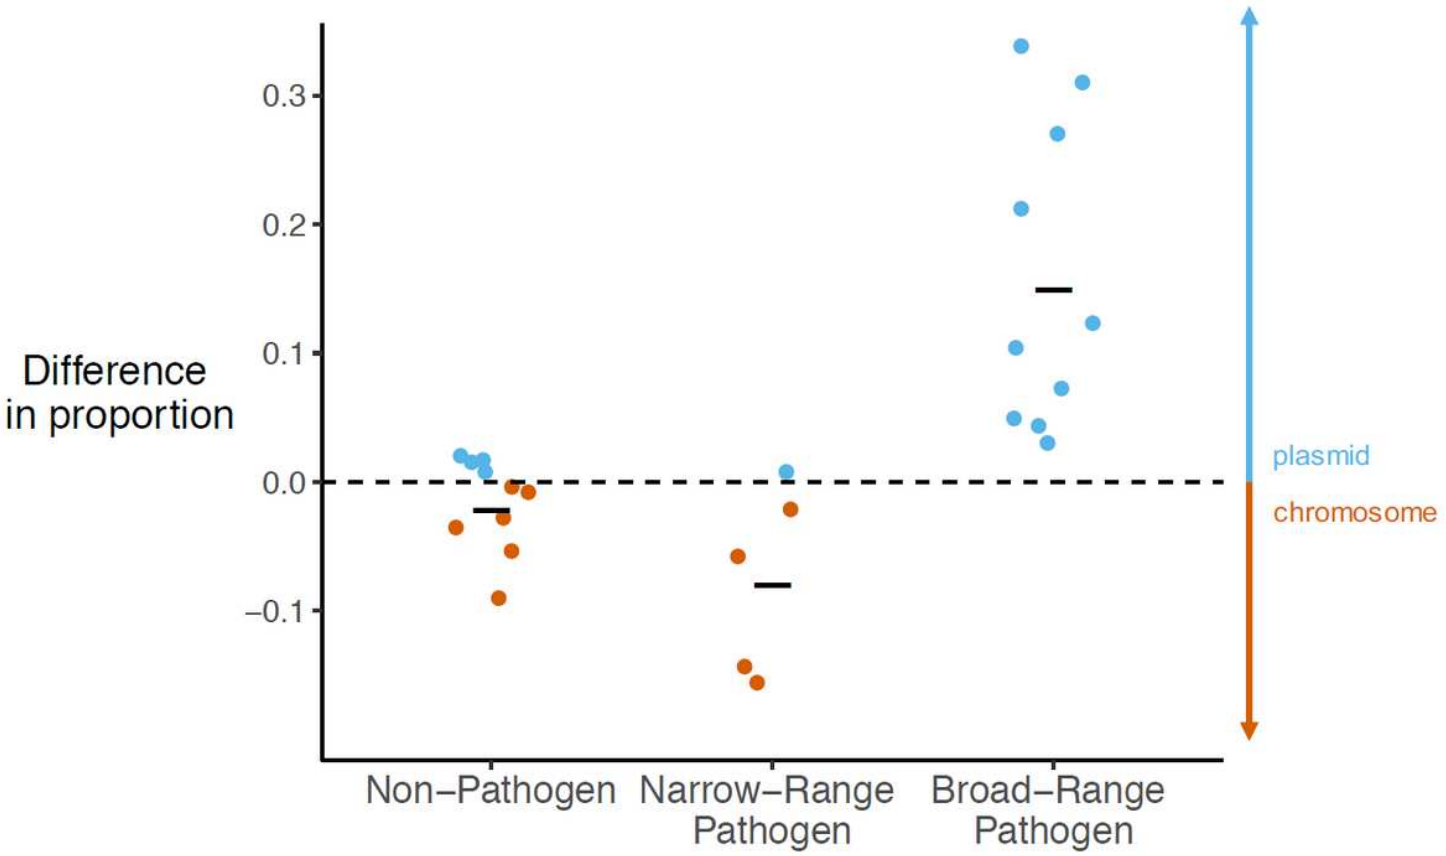

Figure 5

Environmental variability and the location of genes coding for extracellular proteins. We have divided species into either pathogens or non-pathogens, with pathogens further categorised into those with a narrow or broad host-range. The y-axis shows the difference in the proportion of genes on plasmids and chromosomes coding for extracellular proteins. Each dot is the mean for all genomes in a species. Species in blue are those with extracellular proteins overrepresented on plasmids, while species in red are those with extracellular proteins overrepresented on chromosomes. The black bars indicate the mean for all species in each category. Overall, pathogens with a broad host-range are more likely to have genes coding for extracellular proteins on their plasmids.

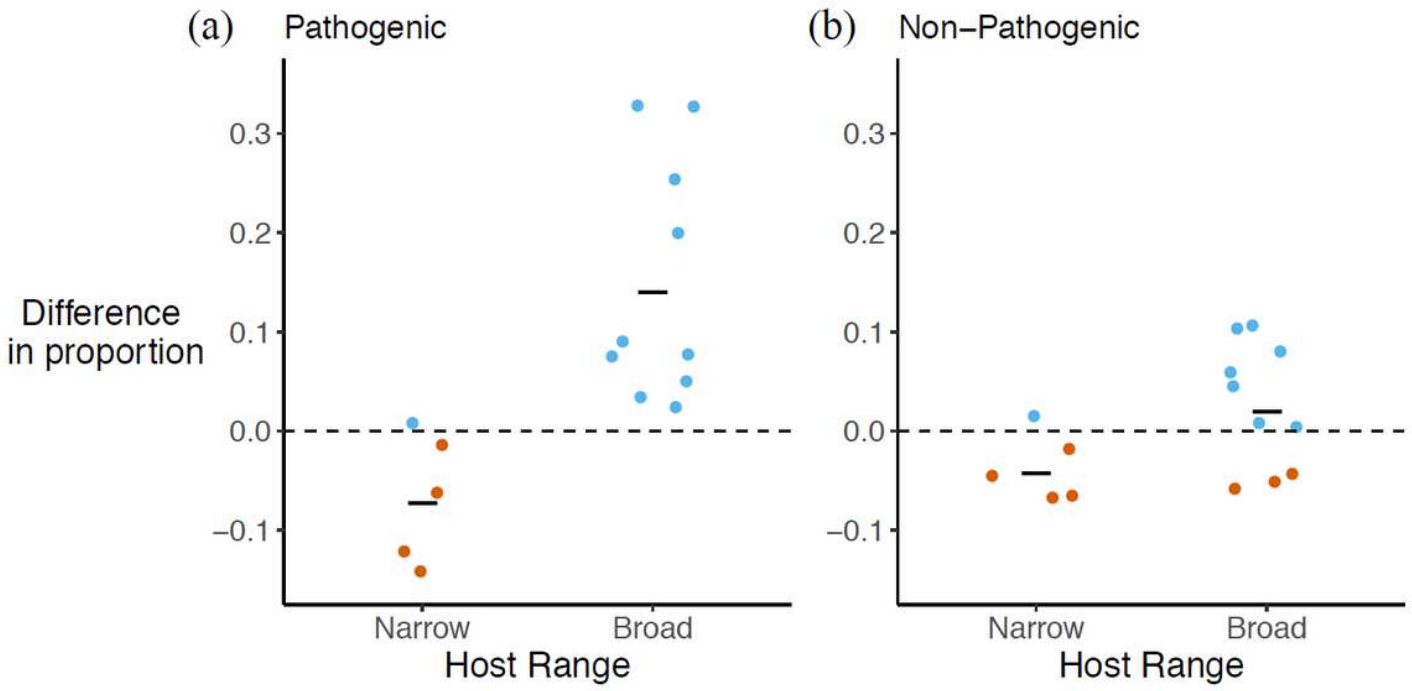

Figure 6

The location of genes coding for pathogenic and non-pathogenic extracellular proteins, in species with broad and narrow host-ranges. We categorised pathogenic species into those with either a broad or narrow host-range. The y-axes in (a) and (b) show the difference in the proportion of genes coding for extracellular proteins on plasmids and chromosomes which are predicted by MP3 as either (a) pathogenic or (b) non-pathogenic. Higher values indicate that extracellular proteins are more likely to be coded for by plasmids. Each dot is the mean for all genomes in a species. Species in blue are those with the relevant subset of extracellular proteins overrepresented on plasmids, while species in red are those with the subset of extracellular proteins overrepresented on chromosomes. Overall, there is a significant difference between broad and narrow host-range species in the location of genes coding for pathogenic extracellular proteins, but no difference for non-pathogenic extracellular proteins.
