Abstract—*Psiguria* is a genus of lianas found throughout the Neotropics from sea level to 2,100 m, in dry or wet forests, in both light gaps and shade. *Psiguria* and its sister genera, *Gurania* and *Helmontia*, are unique among Cucurbitaceae having brightly colored flowers and butterfly and hummingbird pollinators. Historically, taxonomic revisions have described as many as 29 species, but this number has been inflated by misleading characteristics such as variable leaf and flower morphology. A thorough morphological investigation of 758 herbarium specimens and individuals from both greenhouse and natural settings, combined with a recent molecular phylogeny, supports the delineation of six species. In this revision, a review of over 35 yr of publications addressing ecological and natural history studies focusing on *Psiguria* is presented. A description and a distribution map of each species is provided along with two taxonomic keys: one that utilizes male flowers, and another that incorporates leaf characteristics and geographic distribution but uniquely identifies species according to DNA barcodes. With a list of characters that distinguish all pairs of geographically overlapping species, botanists and ecologists finally have the tools to confidently identify species of *Psiguria*.

Keywords—DNA barcoding, *Guraniinae*, *Heliconius*, *Helmontia*, tropical vines.

Psiguria Arn. is a genus of perennial, Neotropical vines occurring in dry and wet forests at elevations up to 2,100 m. The genus is most closely related to *Gurania* Cogn. and *Helmontia* Cogn. (Kocyan et al. 2007). The three were once classified as the tribe Guraniinae (Jeffrey 1963), but are now embedded in Coniandrae (Jeffrey 2005). Historically, taxonomic works have described as many as 29 species of *Psiguria*, but misleading characteristics such as leaf and flower morphology that varies over the life of an individual and a monoecious reproductive system consisting of temporally and spatially separated flowers have led to an inflated number. Six species are recognized here based on morphological studies, and a recent molecular phylogeny of *Psiguria* supported this number (Steele et al. 2010).

Psiguria is rare throughout its geographical range with distances between individuals of one km or more at the level of the forest floor (pers. obs.). The vines can grow up into the canopy, but it is unknown how extensive *Psiguria* growth is at that level. The plants are typically seen growing over the tops of shrubs, climbing with tendrils that wrap around the stems and leaves of other plants. Young *Psiguria* vines are herbaceous with membranous leaves, while older plants of some species become woody, and some mature leaves can be leathery. The leaves are arranged alternately along the stem, and can reach lengths of 75 mm and widths of 53 mm. Leaves are typically glabrous, but minute, soft trichomes may be seen along the veins and margins of some species. A number of different leaf shapes occur on the various species, and even on the same individual. It is not uncommon to see a simple, shallowly trilobed leaf adjacent to one that is trifoliolate, and this variation is inconsistent among individuals of the same species. This is one reason why leaf characters alone cannot be used to distinguish species confidently, although historically they were used in taxonomic keys to *Psiguria* (e.g. Cogniaux 1916; Hampshire 1992). The vines have simple tendrils, which emerge from the stem at a 90 degree angle from the leaf node. Vegetative structures are bright green, and stems and tendrils on some species have small, darker green speckles or longitudinal splotches.

From some leaf nodes, male flowers emerge on long pedunculate racemes or spikes. Male flowers are seen in nature much more often than female flowers; therefore, their char-

acteristics are best used to identify species of *Psiguria*. Two characteristics that have been overlooked in previous keys are the number of flowers per millimeter along the peduncle and the length of pedicels. In some species, flowers occur so close together that more than one flower scar may be observed per millimeter. Additionally, some species are apedicellate while others have pedicels up to 19 mm long.

Both male and female flowers are salverform, with a tubular green calyx tube and spreading petals. Petals may be various shades of pink, red, or orange. The calices of some species have darker green speckles, and sepal shapes and lengths may vary. These two characteristics were used by Wunderlin (1978) and, because they were found to be consistent, are included in the present keys. Another characteristic used by Wunderlin (1978) was the shape of the calyx tube, cylindrical or flask-shaped; however, widespread sampling revealed that this characteristic is inconsistent and may vary between flowers on the same inflorescence.

Inside the male flowers are only two anthers attached to the inner floral tube. The shape of the anthers (straight or folded) and the pubescence of small anther appendages near the tube throat were originally used by Cogniaux (1916) to distinguish species. While folded anther shape definitively separates *Psiguria pedata* (L.) R. A. Howard from all other species of *Psiguria*, in which the anthers are straight, the examination of many specimens revealed that the pubescence of the anther appendage is inconsistent.

Female flowers typically emerge at nodes on the apex of the vine that may be leafless or continue to produce mature leaves. At a given time, many female flowers may be open on a plant and at a node. Flowers are epigynous with a stigma that is divided into two, and these sections are further divided into two. The stigmatic surfaces are rugose, and their ends may just be seen emerging from the tube of a mature flower. Upon fertilization, the inferior ovary develops into a small, indehiscent, cucumber-like fruit that may be dark green or green and white striped. Because female flowers are rarely seen in nature, their morphological characteristics have not typically been used for identifying species of *Psiguria*.

Nomenclatural History—Linnaeus (1759) described three species, currently placed in *Psiguria*, under *Cucumis trilobatus* L., *C. trifoliata* L., and *C. pedatus* L. Von Jacquin (1760)

moved these to *Anguria* Jacq., a later homonym of *Anguria* Mill. (Miller 1754). Linnaeus (1762) published these three species under the name *Anguria*. De Necker (1790) realized that this generic name was incorrectly applied to these taxa, and he first published the name *Psiguria* in *Elementa Botanica*; however, the International Code of Botanical Nomenclature (ICBN) has suppressed all names in that publication (McNeill et al. 2006). Arnott (1841) published *Psiguria* Arn., but he did not list any binomials. Despite this, and because Linnaeus (1762) had used the name *Anguria*, in the mid to late-1800s, several additional species were described under *Anguria* (Roemer 1846; von Schlechtendal 1851; Cogniaux 1876, 1881). In 1916, the most recent and complete taxonomic revision of *Anguria* was published by Cogniaux in which the group was divided into two genera, *Anguria* (29 species) and *Gurania* (73 species), based on morphological differences.

Rickett and Stafleu (1960) first noted that *Anguria* was illegitimate, but Jeffrey (1962), in his discussion of the history of the name *Anguria*, proposed conserving the name *Psiguria*, but only if Cogniaux's (1916) split into two genera stood up to taxonomic scrutiny. Additionally, Jeffrey (1962) explained that, because von Jacquin's (1763) description of the fruit in his original generic diagnosis was derived from *A. pedata*, the lectotype for *Anguria* should be *A. pedata*. Along with other publications that indicated the equivalence of *Psiguria* with *Anguria* (Willis and Shaw 1966; Dandy 1967), Howard (1973) corroborated Jeffrey's (1962) assertion that many *Anguria* species needed to be transferred to *Psiguria*, and he made three new combinations in *Psiguria*; *P. pedata*, *P. trilobata* (L.) R. A. Howard, and *P. jacquiniana* (Schltdl.) R. A. Howard with the first name de facto becoming the type. In 1978, Wunderlin made three more combinations; *P. bignoniacea* (Poepp. & Endl.) Wunderlin, *P. longipedunculata* (Cogn.) Wunderlin, and *P. warscewiczzii* (Hook. f.) Wunderlin. In the same year, Jeffrey (1978) circumscribed *Psiguria* (applied to those species previously described under *Anguria*) and *Gurania* based on floral syndromes. Jeffrey (1978) also argued that Cogniaux, in his 1916 treatment, recognized far too many species, and included numerous misidentifications. Nonetheless, Jeffrey (1978) made six new combinations; *P. ottonica* (Schltdl.) C. Jeffrey, *P. umbrosa* (Kunth) C. Jeffrey, *P. ovata* (Donn. Sm.) C. Jeffrey, *P. triphylla* (Miq.) C. Jeffrey, *P. warmingiana* (Cogn.) C. Jeffrey, and *P. ternata* (M. Roem.) C. Jeffrey, and described one new species, *P. racemosa* C. Jeffrey. Subsequently, four additional combinations were made in *Psiguria* as follows: *P. trifoliata* (L.) Alain (Liogier 1980), *P. dunlapii* (Standley) R. J. Hampshire (Hampshire 1992), *P. aurantiaca* (S. F. Blake) C. Nelson & Fern. Casas, and *P. diversifolia* (Cogn.) C. Nelson & Fern. Casas (Nelson Sutherland and Fernandez Casas 1998).

Phylogeny—The most recent phylogeny of Cucurbitaceae placed *Psiguria* in tribe Coniandreae, and supported the monophly of a clade including *Psiguria*, *Helmontia*, and *Gurania*, but questioned the monophly of *Psiguria* (Kocyan et al. 2007). The speciation event separating *Psiguria* and *Gurania* is estimated to be six ± three million years ago (Schaefner et al. 2009). Steele et al. (2010) found strong support for the monophly of the genus, as well as weak to strong support for only six species of *Psiguria* (Fig. 1, reproduced from Steele et al. 2010). These six, *P. pedata*, *P. ternata*, *P. umbrosa*, *P. warscewiczzii*, *P. triphylla*, and *P. racemosa*, are also recognized here.

Comparative Morphology and Geographic Distribution—The relationships between the three genera in the clade

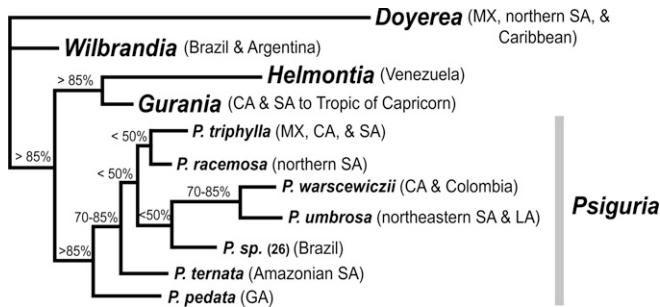

FIG. 1. Phylogeny of *Psiguria* (Cucurbitaceae) (reproduced from Steele et al. 2010, Fig. 5) inferred from a combination of eight chloroplast intergenic spacers, ITS, and the nuclear serine/threonine phosphatase gene intron. Bootstrap values are indicated above branches.

(*Psiguria*, *Gurania*, and *Helmontia*) are still unclear. In the molecular phylogeny of *Psiguria* based on plastid genes, *Gurania* and *Helmontia* form a clade sister to *Psiguria* (Fig. 1). The nuclear datasets present conflicting and poorly supported evolutionary histories. However, the molecular separation of *Psiguria* and *Gurania* supports Cogniaux's (1916) split of *Anguria* based on striking differences in flower morphology, but it does not explain the similarities between *Helmontia* and *Psiguria* flowers that differ mainly in petal color (*Psiguria*: red, pink, or orange, *Helmontia*: white). Additionally, pollen morphology would suggest that *Psiguria* and *Gurania* are sister because, although most cucurbits including *Helmontia* have single-grain pollen, *Psiguria* and *Gurania* shed pollen in tetrads (Jeffrey 1964; Roubik and Moreno 1991). All three genera consist of Neotropical vines with large leaves, and brightly colored flowers in *Psiguria* and *Gurania* distinguish them from most other cucurbits (Condon and Steck 1997). *Psiguria* is distinguished from *Gurania* by predominantly glabrous leaves and salverform flowers in which the green calyx forms a tube (see Fig. 2 for shape variations) ending in five short, green sepals, and red, pink, or orange petals spreading out beyond the throat of the tube. In contrast, *Gurania* flowers have predominantly pubescent leaves and bright orange, long, divided sepals with short, inconspicuous, yellow petals that are often mistaken for anthers. *Psiguria* and *Gurania* have geographic distributions stretching from southern Mexico to Paraguay, but only *Psiguria* extends into the Greater Antilles. *Helmontia* flowers are similar to those of *Psiguria* (other than petal color), but *Helmontia* is known only from northeastern South America.

Ecology and Natural History—Aspects of the pollination system, ecological interactions, phenology, and natural history of *Psiguria* have been studied at several field and greenhouse locations since the early 1970s (Gilbert 1972, 1975, 1977;

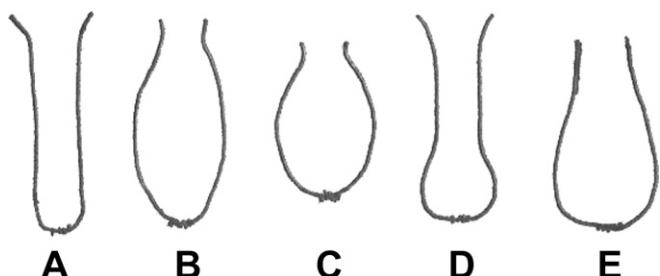

FIG. 2. Floral tube shapes. A. cylindrical, B. elliptical, C. oval, D. cylindrical with thickened base, E. flask-shaped.

Boggs et al. 1981; Gilbert 1983; Condon 1984; Murawski and Gilbert 1986; Murawski 1987; Condon and Gilbert 1988, 1990; Gilbert 1993; Condon and Norrbom 1994; Condon and Steck 1997; Condon et al. 2008). From the time of Cogniaux until these investigations, most species of *Psiguria* were thought to be dioecious. Despite the fact that several botanists before him described *Anguria* taxa under the category of monoecious (Linnaeus 1759, 1762; von Jacquin 1760; de Necker 1790), Cogniaux (1916) described the genus as having dioecious, rarely monoecious, members. This misdirected idea persisted until several long-term, detailed observations revealed that these plants were indeed monoecious with temporally and spatially separated male and female flowers (Gilbert 1983; Condon 1984; Condon and Gilbert 1988). Indeterminate, erect male inflorescences are first to emerge from leaf nodes of climbing vines, and produce flowers for three months to over a year (Gilbert 1975, 1983; Condon 1984; Condon and Gilbert 1988). Once stems reach adequate size, and after an intermediate flowerless period lasting a few days to several months, plants switch sex to produce female flowers at nodes on terminal branches, sometimes with reduced leaves and tendrils (Murawski 1987; Condon and Gilbert 1988, 1990). Some plants continue to produce male flowers when female flowers are produced, but this is rare (Murawski 1987). The time from seed germination to fruit set can be several years (Gilbert 1983). The temporal separation of male and female flowers may be an adaptation for outcrossing since artificially self-pollinated species have produced viable offspring (Condon and Gilbert 1990).

Female branches hang on other vegetation away from the main vine, and typically turn downward, dropping as much as two meters before producing the first flower (Condon and Gilbert 1990). A plant may have from one to as many as six female flowers per node, with fruits maturing about two to three weeks after pollination (Condon and Gilbert 1990). Female branches produce receptive flowers for about a week to ten days unless no fruit is set, in which case flowering may continue for an undetermined amount of time (Condon 1984; Condon and Gilbert 1988). Gilbert (1983) observed a *Psiguria triphylla* (called *Anguria pachyphylla* Donn. Sm.) individual at La Selva Biological Research Station in Costa Rica that, over an eight-year period, alternated between female flowering and fruiting until it reached 15 m in length. Additionally, large vines can alternate between flowering and vegetative states (Condon and Gilbert 1990).

Zero to three male flowers are typically open per inflorescence each day, while one to several female flowers at a node may be open at a time; however both types of flowers open only once for few to several hours before falling off or maturing into fruit (Condon 1984; Murawski 1987; Condon and Gilbert 1988). Both male and female flowers may emerge high in the canopy or in light gaps or shade at lower canopy levels, and neither has been described as having scent (Murawski 1987; Condon and Gilbert 1990).

Most *Psiguria* species can produce male flowers year-round, but the average daily number of inflorescences produced per plant varies over time, from zero to 46 (Gilbert 1977; Murawski and Gilbert 1986; Murawski 1987; Gilbert 1993). Additionally, seasonal fluctuations have been observed, with peaks often at the start of the rainy season (Condon 1984). For all species, a strongly male-biased flowering ratio (e.g. 32:1) has been observed (Gilbert 1975; Murawski and Gilbert 1986; Murawski 1987; Condon and Gilbert 1988). Extensive

flowering time, providing nearly constant pollen and nectar sources, may have influenced speciation in *Psiguria*'s major pollinators, *Heliconius* Kluk butterflies (Gilbert 1972, 1975, 1977; Boggs et al. 1981; Murawski and Gilbert 1986; Condon and Gilbert 1990; Gilbert 1993).

Psiguria plays a role in a suite of plant-animal interactions, the most-studied of which is the relationship with its pollinators. Although *Psiguria* flowers are visited by several organisms such as hummingbirds, bees, moths, and butterflies, *Heliconius* butterflies have been observed making the most visits and transferring the greatest amount of pollen to the stigmas of female flowers (Gilbert 1972, 1975, 1977; Boggs et al. 1981; Gilbert 1983; Condon 1984; Murawski and Gilbert 1986; Murawski 1987; Condon and Gilbert 1990; Gilbert 1993). Because of the morphological similarity between male and female flowers, and the similar textures of anthers and stigmatic surfaces, it is hypothesized that the butterflies may visit female flowers "accidentally" while foraging for pollen (Condon and Gilbert 1990). This interaction makes *Psiguria* (along with sister genus *Gurania*) among the few cucurbit genera that are butterfly or bird-pollinated (Gilbert 1983). However, because *Psiguria* flowers are visited by many organisms that rob pollen rather than transferring it to female flowers, gene flow in the plant population will vary with visitor composition (Murawski and Gilbert 1986; Murawski 1987).

Heliconius butterflies provide a vital service for *Psiguria*, but the benefit to the pollinator cannot be understated. In fact, most species of *Heliconius* butterflies rely heavily on nutrients obtained from the pollen of *Psiguria* flowers. Unlike other lepidopterans that, during larval feeding, obtain nitrogenous compounds necessary for egg production, *Heliconius* butterflies as adults (both male and female) assimilate amino acids and proteins obtained from pollen of *Psiguria* and a few *Gurania* species (Gilbert 1972, 1975, 1977; Boggs et al. 1981). *Psiguria* and *Gurania* are preferred over other sources due to the large size of the pollen tetrads (Gilbert 1975; Boggs et al. 1981). Although most of the *Heliconius*-collected pollen produced by *Psiguria* is actually destroyed by the butterflies, a sufficient portion is transferred to female flowers fulfilling the butterfly's role as the primary pollen vector (Condon 1984; Murawski and Gilbert 1986). *Psiguria* flowers also provide nectar to *Heliconius* feeders. Butterflies scrape pollen from the anthers, combine it with nectar, and then massage the mixture with their proboscis. The butterflies then absorb amino acids from the pollen into their system. Female butterflies feed early in the morning, gathering pollen for its nutritional value, while males feed later in the morning on nectar, keeping both sexes nearby for times of breeding (Gilbert 1975; Condon 1984; Murawski and Gilbert 1986; Murawski 1987; Gilbert 1993). Not only does this system provide a pollination vector for the widely-spaced plants, but the steady food source contributes to the nearly constant egg-laying success of the long-lived (up to six months) butterflies (Gilbert 1977; Murawski 1987).

Several other plant-animal interactions involving *Psiguria* have been observed or studied. Bats are believed to be the primary fruit dispersal agents (Gilbert 1983; Condon 1984; Condon and Gilbert 1990). Parrots, squirrels, mice, and monkeys destroy the seeds or prey on immature fruits (Gilbert 1975, 1983; Condon and Gilbert 1990). Several insect parasites are associated with *Psiguria*, including pickleworm, *Diaphania nitidalis* Stoll (Pyralidae), and fruit flies, *Blepharoneura* Loew (Tephritidae) (Condon 1984; Condon and Gilbert 1990;

Condon and Norrbom 1994; Condon and Steck 1997; Condon et al. 2008). The latter of these two infest both male and female flowers, repelling butterfly pollinators, and feeding on seeds causing predispersal seed mortality (Gilbert 1983; Condon 1984; Murawski 1987; Condon and Gilbert 1990). Most recently it has been discovered that several morphologically similar, sympatric species of *Blepharoneura* feed on separate parts of *Psiguria* and *Gurania* plants that can host as many as 13 different *Blepharoneura* species (Condon and Norrbom 1994; Condon and Steck 1997; Condon et al. 2008).

MATERIALS AND METHODS

The present treatment is based on both herbarium and personal collections covering the geographic and morphological ranges of *Psiguria*. Personal collections are deposited in TEX and countries of collection, and specimens were borrowed from five additional herbaria; MO, NY, F, GH, and US. The examined collections totaled 758, and included representatives from each of the six species of *Psiguria* as follows (number in parentheses is number of collections): *P. pedata* (77), *P. racemosa* (18), *P. ternata* (73), *P. triphylla* (297), *P. umbrosa* (43), and *P. warscewiczii* (250). Type specimens were examined where possible, some of which included photographs or copies of type drawings. Preserved flowers were rehydrated by soaking them in diluted Aerosol OT surfactant for a maximum of 24 hr. Several flowers from plants growing in greenhouses at The University of Texas at Austin were collected and fixed in FAA before measuring. On 178 individuals from herbaria or living material, 43 quantitative characters were measured using either a metric ruler with millimeter divisions (for measurements greater than 10 mm), or the reticule of an Olympus SZ61 light microscope (for measurements less than 10 mm). Figure 3 shows a diagram of two measurements (leaf base depth and lobe depth), which may not be obvious. The number of specimens measured was determined by the geographic and morphological variability of each species. This included 25-*P. pedata*, 11-*P. racemosa*, 19-*P. ternata*, 65-*P. triphylla*, 23-*P. umbrosa*, and 35-*P. warscewiczii*. These data served as the basis for the species descriptions and keys.

Species Concept—Species are distinguished by their evolutionary history. Toward that end, components of both morphological and phylogenetic species concepts are incorporated by aligning the molecular phylogenetic results of Steele et al. (2010) with the current morphological observations and measurements from field, greenhouse, and herbarium specimens. A species is defined as the smallest monophyletic group

having weak to strong bootstrap support and consistently sharing one or more morphological character traits. These criteria exclude forms or races which have not been distinguished genetically, and the natural history, reproductive biology, and phenology are considered such that semaphorants are not confused as different species. Species are described such that, whenever possible, researchers can identify organisms using keys based on characters observed in the field and/or by comparing them with type specimens. When this is not possible, DNA barcodes are provided for species delineation.

TAXONOMIC TREATMENT

PSIGURIA Arn., Hook. Jour. Bot. 3: 247. 1841.—LECTOTYPE:
Psiguria pedata (L.) R. A. Howard.

Monoeious, perennial, vines with simple tendrils, herbaceous but some becoming woody with greater stem size and age; stems, minutely sulcate, glabrous or puberulent, solid or light green with darker, linear splotches, 0.9–7.0 mm in diameter; tendrils glabrous or puberulent, solid or light green with darker speckles, 0.2–3.1 mm in diameter. Leaves petiolate, the blades membranous or coriaceous, upper surface darker green, lighter green below, and both surfaces glabrous with veins and margins sometimes puberulent, venation reticulate, main veins flush or prominent, margins entire or irregular, sometimes with irregularly-spaced veins extending beyond blade, simple, trifoliolate, pedate, or a combination of these; petioles glabrous or pubescent, 0.5–5.3 mm in diameter, 3–96 mm long; simple leaves lanceolate, elliptic, or trilobed, base auriculate, truncate, rounded, and/or acute, bases 5–33(–40) mm deep, apices acuminate, 39–219 mm long, 22–122(–178) mm wide, lobe depth average 62.5% of total length; petiolules glabrous or puberulent, sometimes winged, 0.6–3.6 mm in diameter, 0–48 mm long; compound leaves with center leaflet elliptic to oblanceolate, side leaflets lanceolate to oblanceolate, apices acuminate or cuspidate; bases of center leaflets acute or attenuate, 40–305 mm long, 17–132(–150) mm wide; bases of side leaflets acute, attenuate, truncate, sometimes oblique, 25–225 mm long, 13–124 mm wide; bases of outer leaflets on pedate leaves oblique, adaxial bases acute-attenuate and abaxial bases acute-truncate, 18–115(–145) mm long. Inflorescences pedunculate racemes or corymbs; peduncles glabrous or puberulent, solid green or light green with darker splotches, 0.5–4.6(–8.0) mm in diameter, (8–)21–395 mm long; pedicels absent or, if present, then pubescent, 0–19 mm long, with 0.24–1.2 flowers per mm. Staminate flowers axillary, first 2–3 flowers sometimes much larger than subsequent flowers, receptacle with trichomes; calyx salverform, glabrous or puberulent, solid green or light green with darker speckles, 4–17.0(–21.0) mm long, 1.0–7.0 mm wide, adaxial surface glabrous or puberulent with or without trichomes at throat; sepals 5, thin or thick, triangular or linear, color same as or darker than calyx, 0.5–8.5 mm long; corolla rotate, adnate to calyx tube, lobes 5, free, orange, pink, or red, ovate to obovate, venation reticulate, pubescent internally and externally, apex rounded to acuminate, 2.0–62.0 mm long, 2.0–40.0 mm wide, length-to-width ratio 1.2–2.1; anthers 2, free, filamentous and dorsifixated inside floral tube, bilocular, straight or folded backwards, (1.0–)3.4–11.0 mm long, anther appendage round or triangular, glabrous or papillose, 0.1–1.2 mm long, folded portion (if applicable) (0.7–)1.0–1.5 mm long. Pistillate flowers 2–5 per node, axillary or terminal; calyx salverform, cylindrical or various flask shapes, glabrous or puberulent, striped or solid, (4.9–)11.0–41.0 mm long, 0.9–10.0 mm wide, adaxial surface glabrous or puberulent, with or without trichomes at

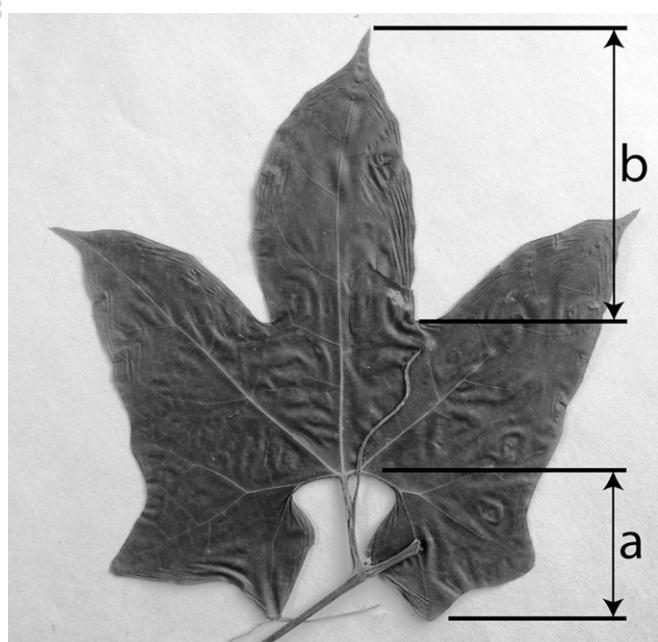

FIG. 3. Diagram of two leaf measurements. a. base depth, b. lobe depth.

throat; sepals 5, thin or thick, triangular or linear, color same as or darker than calyx, 0.5–3.7 mm long; corolla rotate, adnate to calyx tube, lobes 5, free, orange, pink, or red, elliptic to obovate, venation reticulate, both sides pubescent, apex rounded to acuminate, 4.5–16.0 mm long, 2.4–9.5 mm wide, length-to-width ratio 1.3–3.5; gynoecium 1, bilocular, ovary elliptic-oblong, 6.5–22.0 mm long, 1.9–7.0 mm wide, ovules numerous,

horizontal, style 1, 2.3–9.0 mm long, stigmas twice branched, stigmatic surfaces papillose, stigma 3.5–10.2(–12.0) mm long. Fruit a pepo, oblong, indehiscent, solid green or with lighter green or white stripes, 18–80 mm long, 10–24 mm wide, wall 0.7–3.0 mm thick. Seeds 30–88, ovate-oblong, flattened, without a distinct margin, whitish-gray, 5.0–10.0 mm long, 2.8–5.9 mm wide, 1.5–3.8 mm thick.

KEY TO SPECIES OF *PSIGURIA*

Two keys are provided: Key 1 for specimens with staminate flowers, and Key 2 for sterile or carpellate specimens. Because vines in tropical forests are often seen without flowers, it may be necessary to identify sterile specimens. However, because the leaf morphology of a *Psiguria* individual can change over its lifetime, morphological characters may not be enough for accurate identification. In this case, it will be necessary to narrow the identification down to two or three species with a few consistent stem and leaf characters plus geographic location, and then utilize DNA barcodes for exact identification as described in Steele et al. (2010), which contains a list of chloroplast DNA markers for distinguishing the six species of *Psiguria*. The second key below refers to markers and reference sequences from Table 4 in that publication.

KEY 1 TO SPECIES OF *PSIGURIA*

(specimens with staminate flowers)

1. Anther folded backwards
1. Anther straight

 2. Flowers > 0.75 per mm; pedicels absent or < 0.3 mm long
 2. Flowers < or = to 0.75 per mm; pedicels present and > 0.5 mm long

 3. Pedicels > or = 2.0 mm long; petal apex acuminate
 4. Calyx and peduncle color solid; sepals same color as calyx; petals pink
 4. Calyx and peduncle color speckled/splotched; sepal color darker than calyx; petals orange
 3. Pedicels < 2.0 mm long; petal apex rounded or rounded-acute
 5. Petals orange-red; sepal thick, triangular; sepal 0.5–1.5 mm long; sepal color darker than calyx, first 2–3 flowers not much larger than later flowers; geographic distribution N of equator
 5. Petals pink; sepal thin, linear; sepal > 1.5 mm long; sepal color same as calyx, first 2–3 flowers much larger than later flowers; geographic distribution S of equator

KEY 2 TO SPECIES OF *PSIGURIA*

(sterile or carpellate specimens)

1. Leaves simple, trilobed or 5-lobed, sometimes deeply, but never trifoliolate
2. Chloroplast DNA region *rpoB-trnC* matches *P. racemosa* reference sequence and geographic distribution in Colombia or Venezuela
2. Chloroplast DNA regions *rpoB-trnC* and/or *psbZ-trnM* match *P. umbrosa* reference sequences and geographic distribution in Venezuela, Brazil, or Lesser Antilles
1. Leaves bifid, trifoliolate, or pedate, with immature leaves often simple and lobed, or sometimes a combination of shapes
3. Stem surface light green with darker green splotches, leaves trifoliolate, pedate, or seldom simple and trilobed, large lobes on outside of side leaflets, and chloroplast DNA region *ndhF-rpL32* matches *P. umbrosa* reference sequence, but not matching regions *rpoB-trnC* and/or *psbZ-trnM* with *P. umbrosa* reference sequences
3. Stem surface solid green, leaves bifid, trifoliolate, pedate, with immature leaves often simple and lobed, or sometimes a combination of complexities
4. Leaf margins with veins extending beyond the margins of the leaves, chloroplast DNA region *ndhC-trnV* matches *P. pedata* reference sequence, and geographic distribution in Greater Antilles or rarely Costa Rica
4. Leaf margins seldom with veins extending beyond the margins of the leaves
5. Leaves trifoliolate, or rarely pedate, and main vein in side leaflets strongly off-center, typically with small lobes on outside base of side leaflets, chloroplast DNA region *3rps16-trnQ* matches *P. ternata* reference sequence, and geographic distribution in Peru, Brazil, Bolivia, or Paraguay
5. Leaves simple and elliptic, 2-lobed, trilobed, trifoliolate, or mixed complexities; main vein in side leaflets not strongly off-center, typically without lobes on outside base of side leaflets, chloroplast DNA regions *ndhC-trnV*, *ndhF-rpL32*, and/or *3rps16-trnQ* match *P. triphylla* reference sequences, and geographic distribution in Mexico, Central America, or South America

Anguria cookiana Britton Britt & Wils., Sci. Surv. Puerto Rico & Virgin Islands 6: 267. 1925.—TYPE: PUERTO RICO. 20 Nov 1899, Goll 627 (holotype: NY!).

Stems glabrous or puberulent, solid green, 0.9–2.0 mm in diameter; tendrils glabrous, solid green, 0.3–1.0 mm in diameter. Leaves immature membranous, mature coriaceous, both surfaces glabrous with veins and margins sometimes puberulent, 3–5 main veins, flush, margins entire-irregular-crisped, often with irregularly-spaced veins extending beyond blade, simple, trifoliolate, pedate (sometimes with outer leaflets further divided into 2 parts), or a combination of these; petioles puberulent, 0.5–2.2 mm in diameter, 9–45 mm long; simple leaves trilobed, base auriculate, base 12–20 mm deep, apex acuminate, 39–98 mm long, 40–79 mm wide, average lobe depth 44.6% of total length; petiolules winged and glabrous or puberulent, 0.6–1.3 mm in diameter, 0–12 mm long; complex leaves with center leaflet elliptic-rhombic-ob lanceolate and side leaflets lanceolate-elliptic-ob lanceolate, apices acuminate-cuspidate; center leaflet base acute-attenuate, 40–91(–128) mm long, (12)–21–43 mm wide; side leaflets base acute-attenuate, 45–93 mm long, (13)–20–40 mm wide; outer leaflets on pedate leaves base oblique, adaxial base acute-attenuate and abaxial base acute-truncate, (18)–24–78 mm long. Inflorescence a raceme; peduncles glabrous, solid green or rarely light green with darker splotches, 0.6–1.9 mm in diameter, (8)–21–105 mm long; pedicels puberulent, 1–16 mm long, with 0.27–0.56 flowers per mm. Staminate flowers, first 2–3 flowers not much larger than subsequent flowers; calyx salverform, oval, puberulent, solid green, 4–9.3 mm long, 1.0–6.0 mm wide, adaxial surface glabrous with trichomes at throat; sepals thin, triangular-linear, color same as calyx, 0.8–2.5 mm long; petals orange, ovate-rhombic, apex cuspidate, 4.0–15.0 mm long, 3.2–7.0 mm wide, length-to-width ratio 1.9; anthers folded backwards, 3.4–6.0 mm long, anther appendage round-triangular, glabrous-papillose, 0.1–0.7 mm long, folded portion (0.7)–1.0–1.5 mm long. Pistillate flowers 2–3 per node, axillary; calyx salverform, cylindrical-elliptical-elongated, glabrous, striped color, 17.0–30.0 mm long, 0.9–10.0 mm wide, adaxial surface glabrous or puberulent with trichomes at throat; sepals thin, linear, color same as calyx, 1.6–1.8 mm long; petals orange, elliptic, apex acute, length unknown, width unknown; ovary elliptic-oblong, 10–10.5 mm long, 3.0–3.5 mm wide, style 7.0–7.5 mm long, stigma 4.5–4.8 mm long. Fruits, green with lighter green stripes, 18–36 mm long, 10–18 mm wide, wall 0.7–1.3 mm thick. Seeds 44–46, 6.3–6.5 mm long, 3.9–4.1 mm wide, 2.0–2.4 mm thick.

Phenology—Flowering throughout the year. Of the 77 specimens examined, 70.1% had male flowers, 10.4% had female flowers or fruits, and the remainder were sterile.

Distribution and Habitat—Throughout the Greater Antilles and the Bahamas (Fig. 4), with one collection from Costa Rica with label stating “cloud forest exposed to Atlantic trade winds, Continental Divide.” Found at elevations from sea level to 1,200 m, in secondary, evergreen or deciduous, moist or dry forests, on rocky, limestone, or clay soils, in dense forest shade or on slopes, riverbanks, or ravines.

Discussion—The leaves of an individual *Psiguria pedata* change greatly over its life, and can take on various forms in adjacent positions along the stem (Fig. 5A–C). Because of this variability, the species has historically been split into several taxa.

The folded anther (Fig. 6A) most easily distinguishes *Psiguria pedata* from all other *Psiguria* species, which have straight anthers (Fig. 6B). Additionally, *P. pedata* is found predominantly in the Greater Antilles, with one exception, one herbarium specimen from Costa Rica, which grouped with other *P. pedata* samples in the molecular phylogeny (Steele et al. 2010). The collection did not contain male flowers, so the folded anther characteristic could not be confirmed in this sample. However, because of the special notation on the herbarium sheet label (quoted in the “Distribution and Habitat” section above), it is not unreasonable to think that seeds of the Greater Antilles *P. pedata* were carried to the continent in a hurricane or by means of the Atlantic trade winds.

Representative Specimens Examined—(collections marked with an asterisk were measured for species descriptions)

2. *PSIGURIA RACEMOSA* C. Jeffrey, Kew Bulletin 33(2): 347. 1978.—TYPE: VENEZUELA. Aragua: Guamitas, Williams 10130 (holotype: VEN fide Jeffrey (1978)).

Stems glabrous or puberulent, solid green, 1.3–4.7 mm in diameter; tendrils glabrous, solid green, 0.5–1.6 mm in diameter. Leaves membranous, both surfaces glabrous with veins sometimes puberulent, 3–5 main veins, flush, margins entire-irregular-wavy, with irregularly-spaced veins extending beyond blade, simple; petioles glabrous or pubescent, 1.2–3.0 mm in diameter, (3)–22–58 mm long; simple leaves trilobed, base auriculate-truncate-rounded-acute, base 7–30 mm deep, apex acuminate, 115–219 mm long, 32–70 mm wide, lobe depth average 67.3% of total length. Inflorescence an indeterminate corymb; peduncles glabrous or puberulent, solid green, 1.1–2.0 mm in diameter, 90–225 mm long; pedicels pubescent, 2.0–13.5 mm long, with 0.5–0.74(–0.83) flowers per mm. Staminate flowers, first 2–3 flowers not much larger than subsequent flowers; calyx salverform flask-shaped, glabrous or puberulent, solid green, 5.0–9.5 mm long, 1.4–5.5(–7.0) mm wide, adaxial surface glabrous with sparse to dense trichomes at throat; sepals thin, linear, color same as calyx, 1.5–4.0 mm long; petals pink with orange or yellow center, elliptic-rhombic, apex acuminate, 4.5–13.0 mm long, 2.2–7.0 mm wide, length-to-width ratio 2.1; anthers straight, 4.4–7.0 mm long, anther appendage triangular, papillose, 0.4–1.0 mm long. Pistillate flowers 3 per node, axillary; calyx salverform elongated ellipse, glabrous, solid green, 11.0 mm long, 3.3 mm wide, adaxial surface unknown; sepals thin, triangular, color same as calyx, 2.5 mm long; petals unknown, elliptic, apex acuminate, 8.8 mm long, 2.5 mm wide, length-to-width ratio 3.5; ovary elliptic-oblong, 6.5 mm long, 3.3 mm wide, style length unknown, stigma length unknown. Fruits, exocarp color unknown, 19.0 mm long, 12.0 mm wide, wall thickness unknown. Seeds not seen.

Phenology—Flowering April through July, and perhaps other times of the year. A few flowering individuals have also been collected in November and January. Of the 18 specimens examined, 66.7% had male flowers, 16.7% had female flowers or fruits, and the remainder were sterile.

Distribution and Habitat—Continental Colombia and Venezuela (Fig. 7). Found at elevations from 15 m to 1,750 m in tropical moist or dry broadleaf forests, and on slopes, in ravines, or climbing over rocks and shrubs.

Discussion—Compared to other species of *Psiguria*, the leaf morphology of *P. racemosa* is fairly consistent, trilobed and

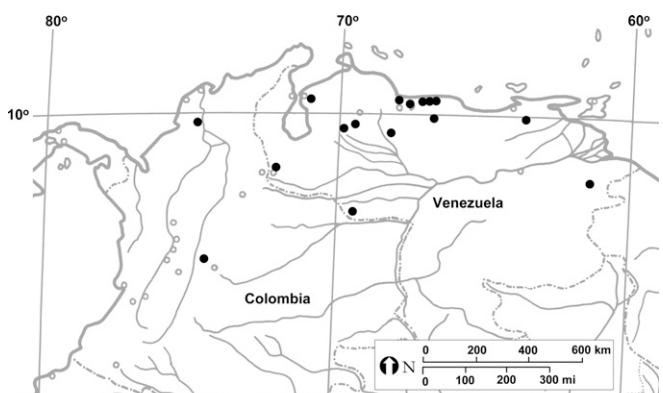

FIG. 7. Geographic distribution of *Psiguria racemosa*. Open circles are part of the base map image.

membranous, but with variable depth of lobes (Fig. 5 D, E). The geographic range of *P. racemosa* overlaps with *P. umbrosa* and *P. warszewiczzii* in Venezuela, and all three have, or may have, simple, trilobed leaves. The characters that separate *P. racemosa* from the other two are its distinctive pink flower petals, and peduncles and calyx tubes that are solid green, as opposed to the orange or orange-red flower petals, and peduncles and calyx tubes that are light green with darker speckles in *P. umbrosa* and *P. warszewiczzii*.

The geographic range of *Psiguria racemosa* also overlaps with *P. triphylla*; however, in this area, the simple, trilobed leaf morphs of *P. triphylla* have not been seen. Additional characteristics that distinguish these two species include male petal color (*P. racemosa* = pink; *P. triphylla* = deep red, typically with a yellow base), male flower pedicel average length (*P. racemosa* = 5.6 mm; *P. triphylla* = absent), and density of flowers along the peduncle (*P. racemosa* = < 0.75 flowers per mm; *P. triphylla* = > 0.75 flowers per mm). Despite these fairly obvious morphological differences, the molecular phylogeny did not strongly support the distinction of *P. racemosa* from *P. triphylla* (Steele et al. 2010). There have been few individuals of *P. racemosa* collected (only 18 examined in this study, and only five included in the molecular phylogeny). With more collections and molecular study, the lines between these two species may become better defined.

Representative Specimens Examined—(collections marked with an asterisk were measured for species descriptions)

Stems glabrous, solid green or light green with darker, linear splotches, 2.0–5.6 mm long; tendrils glabrous, solid green, 0.8–1.7 mm in diameter. Leaves coriaceous, both surfaces glabrous, veins flush or seldom abaxial main veins prominent, margins entire-irregular-wavy, with infrequent irregularly-

spaced veins extending beyond blade; trifoliolate (or rarely bifid or pedate); petioles glabrous, 1.3–3.3 mm in diameter, 14–80 mm long; petiolules glabrous or puberulent, 1.2–2.0 mm in diameter, 2–35 mm long; complex leaves with center leaflet rhombic-ob lanceolate-spatulate and side leaflets ovate-elliptic, oblique, and sometimes with small, lateral lobe, apices acuminate; center leaflet base acute-attenuate, 95–200 mm long, 45–115 mm wide; side leaflets base oblique, adaxial base acute-attenuate and abaxial base acute-truncate, 80–172 mm long, 29–97 mm wide. Inflorescence a compact raceme; peduncles glabrous or puberulent, solid green or light green with darker splotches, 1.5–3.0 mm in diameter, (78–)155–293 mm long; pedicels pubescent, (0.1–)0.5–1.6(–4.0) mm long, with 0.25–1.00 flowers per mm. Staminate flowers, first 2–3 flowers much larger than subsequent flowers; calyx salverform, cylindrical-elliptical, glabrous or puberulent, solid green or light green with darker speckles, 5.0–13.0 mm long, 2.0–6.4 mm wide, adaxial surface glabrous with trichomes at throat; sepals thin, linear, color same as calyx, 1.0–8.5 mm long; petals pink, rose, salmon-rose, or deep-rose, orbicular-ovate, apex rounded, 3.0–10.5 mm long (average first 3 flowers 62.0, 48.0, and 22.0 mm long), 2.4–7.2 mm wide (average first 3 flowers 40.0, 25.0, and 11.0 mm wide), length-to-width ratio 1.2; anthers straight, 4.4–8.0 mm long, anther appendage round-triangular, glabrous-papillose, 0.2–1.0 mm long. Pistillate flowers 2–4 per node, axillary, but at the ends of branches with reduced leaves; calyx salverform, cylindrical-elliptical, glabrous, solid green, 19.0–32.0 mm long, 2.5–5.2 mm wide, adaxial surface glabrous or puberulent with trichomes at throat; sepals thin, linear, color same as calyx, 2.3–3.7 mm long; petals pink, obovate, apex rounded or rarely cuspidate, 8.0–16.0 mm long, 3.5–9.0 mm wide, length-to-width ratio 2.1; ovary elliptic-oblong, 12.0–20.0 mm long, 4.2–7.0 mm wide, style 3.3–5.0 mm long, stigma 5.0–7.0(–12.0) mm long. Fruits, green, sometimes speckled with lighter green, 22–44 mm long, 10–18 mm wide, wall 0.7–2.0 mm thick. Seeds 44–54, 6.5–7.9 mm long, 4.5–4.9 mm wide, 1.9–3.0 mm thick.

Phenology—Flowering throughout the year with flowering peak from October through February. Of the 73 specimens examined, 71.2% had male flowers, 19.2% had female flowers or fruits, and the remainder were sterile.

Distribution and Habitat—Bolivia, Brazil, Perú, and Paraguay (Fig. 8). Found at elevations from 170 m to 1,800 m

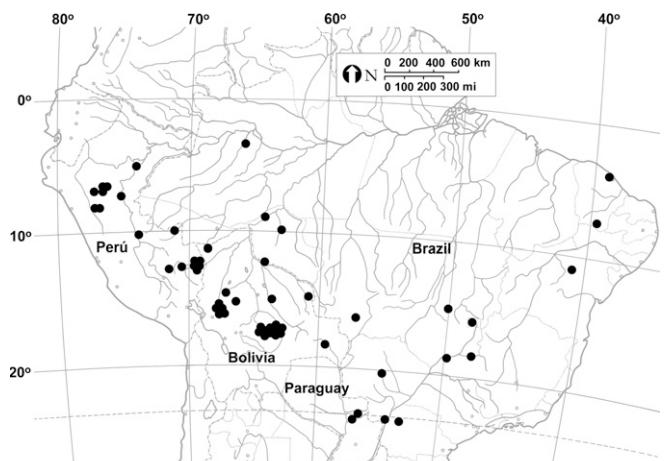

FIG. 8. Geographic distribution of *Psiguria ternata*. Open circles are part of the base map image.

FIG. 9. Comparison of the first two flowers of *Psiguria ternata* (large) with three subsequent flowers on the same inflorescence (small).

in tropical evergreen, deciduous, or semideciduous, moist or dry broadleaf forests, flooded grasslands, and xeric shrublands. May be found in disturbed or secondary forests, in dense shade or light gaps, on roadsides, riverbanks, or slopes, climbing over other vegetation, and on sandy or clay soils.

Discussion—The most distinctive characteristic of *Psiguria ternata* is the large size of the first two or three male flowers on the inflorescence, which can be six to seven times larger than subsequent flowers (Fig. 9). This characteristic is hypothesized to be an adaptation for attracting and training the pollinating butterflies to the locations of these widely separated plants (L. E. Gilbert, pers. comm.). Once the pollinator knows where to find the flowers, the plant no longer needs to allocate great resources to making a giant display.

The geographic distribution of *Psiguria ternata* overlaps with *P. triphylla* and a few *P. umbrosa*. Consistent trifoliolate (rarely pedate), coriaceous leaves and pink flowers easily distinguish *P. ternata* from *P. umbrosa*, which has simple 3- to 5-lobed, membranous leaves and orange flowers. Distinguishing *P. ternata* from *P. triphylla* is not quite as straightforward. Both have predominantly trifoliolate, coriaceous leaves, although more often in *P. ternata*, the midveins of the side leaflets are off-center (Fig. 5F–H), whereas midveins in *P. triphylla* side leaflets are typically centered, though not always (Fig. 5P–S). Also, male inflorescences of *P. ternata* are racemose, and the flower cluster has a triangular shape (Fig. 10A) with loosely spaced flowers and pink petals. Male inflorescences of

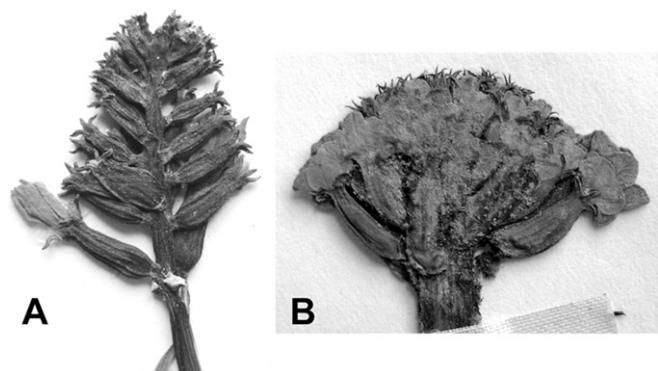

FIG. 10. Comparison of the flower clusters on *Psiguria ternata* (A. triangular) and *P. triphylla* (B. horizontal ellipse).

P. triphylla are spicate, and the flower cluster is shaped like a horizontal ellipse (Fig. 10B) with tightly clustered flowers and petals that are deep red, typically with a yellow base.

The molecular phylogeny strongly supported the clade of *Psiguria ternata* samples (Steele et al. 2010). Within this clade, two subclades were strongly supported. One clade included three samples from the tropical, moist forests of Perú, Brazil, and northern Bolivia, and the other included samples from the tropical, dry forests of south-central Bolivia. However, no morphological characteristics were identified to support a split into two taxa. Perhaps additional collections and molecular study will support a split of these clades into two species or subspecies in the future.

Stems puberulent at nodes, otherwise glabrous, flaking on older, woody stems, solid green or brown, 1.1–7.0(–32.0) mm in diameter; tendrils glabrous, solid green, 0.3–3.1 mm in diameter. Leaves coriaceous, both surfaces glabrous, veins flush or seldom abaxial and adaxial main veins prominent, margins entire-irregular-crisped-revolute, seldom with irregularly-spaced veins extending beyond blade, simple, trifoliolate, or a combination of these; petioles glabrous, 1.0–5.3 mm in diameter, 8–75 mm long; simple leaves lanceolate, elliptic, or trilobed, base auriculate-rounded-acute, base 5–30 mm deep, apex acuminate, 75–184 mm long, (22–)40–76(–178) mm wide, lobe depth average 53.2% of total length; petiolules glabrous, 0.9–3.6 mm in diameter, 2–48 mm long; complex leaves with center leaflet elliptic-obovate-oblanceolate and side leaflets ovate-elliptic-obovate, apices acuminate-cuspidate; center leaflet base acute-attenuate, 71–305 mm long, 22–132(–177) mm wide; side leaflets base cuneate-acute, rarely oblique, 55–225 mm long, 18–124 mm wide. Inflorescence an apedicellate, indeterminate corymb; peduncles glabrous, solid green, (0.6–)1.1–4.6(–8.0) mm in diameter, 63–395 mm long; pedicels absent or length less than 0.3 mm, with greater than 0.75 flowers per mm. Staminate flowers, first 2–3 flowers not much larger than subsequent flowers; calyx salverform cylindrical, often with a thickened base, rarely cylindrical, glabrous or puberulent, solid green, 5.5–15.0 mm long, 1.0–4.8 mm wide, adaxial surface glabrous with sparse to dense trichomes at throat; sepals thin, triangular-linear, color typically same as calyx, but sometimes darker, 0.6–2.7(–4.8) mm long; petals red with yellow center, orange-red, strong red, or scarlet, orbicular-rhombic-flask-shaped, apex cuspidate, 2.0–12.0 mm long, 2.0–10.0 mm wide, length-to-width ratio 1.6; anthers straight, 3.4–8.5 mm long, anther appendage round-triangular, glabrous-papillose, 0.1–1.2 mm long. Pistillate flowers 2–5 per node, terminal; calyx salverform, cylindrical, glabrous, solid green, 11.0–41.0 mm long, 1.4–6.5 mm wide, adaxial surface glabrous with trichomes at throat; sepals thin, triangular-linear, color typically same as calyx, but sometimes darker, 1.0–2.3 mm long; petals red, orange-red, or scarlet, orbicular-rhombic-oblanceolate, apex cuspidate, 4.5–9.5 mm long, 2.5–9.5 mm wide, length-to-width ratio 1.6; ovary elliptic-oblong, 14.0–22.0 mm long, 3.0–5.8 mm wide, style 4.6–9.0 mm long, stigma 6.1–10.2 mm long. Fruits, green with lighter green stripes, some turning yellow with age, 30–45 mm long, 15–24 mm wide, wall 0.7–3.0 mm thick. Seeds 32–46, 7.7–10.0 mm long, 4.2–5.9 mm wide, 1.8–3.8 mm thick.

Phenology—Flowering throughout the year. Of the 297 specimens examined, 75.0% had male flowers, 9.1% had female flowers or fruits, and the remainder were sterile.

Distribution and Habitat—Throughout the Continental range of *Psiguria*, from southern Mexico to northern Bolivia (Fig. 11). Found at elevations from sea level to 2,100 m in tropical and subtropical evergreen, deciduous, or semideciduous, moist or dry forests, cloud forests, and flooded grasslands, in the upper canopies or clearings of both primary and secondary forests. May be found in dense shade or light gaps, on roadsides, riverbanks, or slopes, climbing over other vegetation, and on limestone, sandy, or clay soils.

Discussion—Of the *Psiguria* species, *P. triphylla* has the most variable leaf morphology (Fig. 5I–S). Mature leaves range from simple and elliptic to various trilobed shapes and sizes to an assortment of trifoliolate profiles. It is also the most widely distributed geographically (Fig. 11). For characters used to distinguish *P. triphylla* from the other species, see the

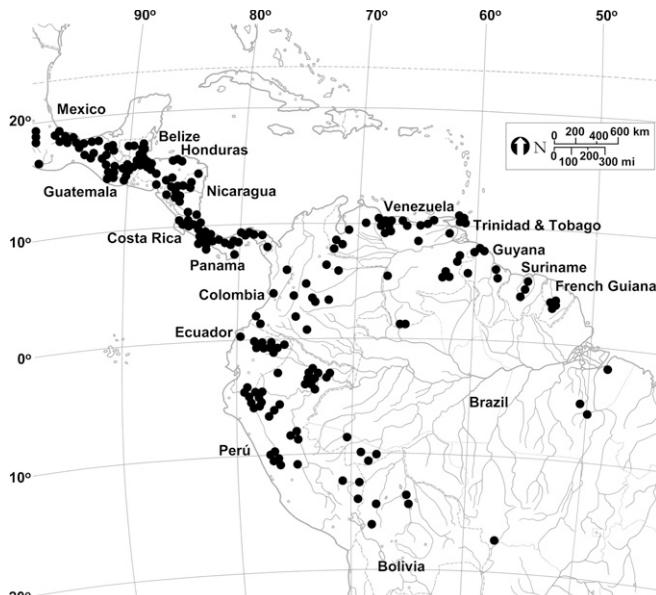

FIG. 11. Geographic distribution of *Psiguria triphylla*. Open circles are part of the base map image.

discussions under those taxonomic descriptions or the keys. *Psiguria triphylla* is most easily identified by flowers that lack pedicels, and a high density of flowers on an inflorescence (as many as three per millimeter). Figure 12 shows a typical *P. triphylla* inflorescence with flower scars covering the peduncle. Typically only one or two flowers open per day implying that this inflorescence (with approximately 383 flower scars) had been flowering for 7–13 mo at the time it was collected.

In the molecular phylogeny (Steele et al. 2010), all but one of the 28 *Psiguria triphylla* samples formed a moderately well-supported clade. Within this clade were several groupings of samples and some long branches. The lack of morphological variation in male flowers, and the great variation in leaf morphology do not help to explain these molecular groups. One exception may be the specimens from Los Tuxtlas and Catemaco, Veracruz, Mexico. Although four of the six samples included in the molecular phylogeny are clones of one another, artificially increasing the bootstrap support for the clade, it does not explain the rather long branch leading to it. The leaves of these specimens are simple, trilobed, and wide, but the lobing is much more shallow, and lobe tips are more rounded (Fig. 5K) than seen in the other trilobed *P. triphylla* leaf morphs. Additionally, although rarely seen in the field, the female corollas are typically reflexed downward rather than rotate (L. E. Gilbert pers. comm.). Additional collections undergoing molecular and morphological study may lead to

FIG. 12. Inflorescence of *Psiguria triphylla*, nearly 14 cm long, and containing approximately 383 flower scars.

the designation of a variety or subspecies containing these samples.

Psiguria triphylla also includes individuals that are different in stem size and overall robustness. Some mature, flowering individuals have small stems (1.0 mm) and almost delicate leaves, whereas others have robust, sturdy stems (up to 32 mm). Collections of widely varying sizes have been made throughout the geographic range. However, a notable exception is in northeastern Venezuela and in Trinidad where only the small-stemmed form is found.

Anguria warmingiana Cogn. Diagn. Cucurb. I: 21. 1876. *Psiguria warmingiana* (Cogn.) C. Jeffrey, Kew Bull. 33(2): 354. 1978.—TYPE: BRAZIL. 1860, *Peckolt* 512 (holotype: online photograph BR!).

Stems glabrous or puberulent, solid green, 1.2–3.9 mm in diameter; tendrils glabrous or puberulent, solid green or light green with darker, speckles, 0.2–1.5 mm in diameter. Leaves membranous, both surfaces glabrous with veins seldom puberulent, 3–5 main veins, flush, margins entire, with irregularly-spaced veins extending beyond blade, simple; petioles puberulent or rarely glabrous, 0.7–2.0 mm in diameter, 12–75 mm long; simple leaves 3–to 5-lobed, base auriculate, base (5–)10–33(–40) mm deep, apex acuminate, 55–180 mm long, (23–)31–70 mm wide, lobe depth average 73.8% of total length. Inflorescence an indeterminate corymb; peduncles glabrous or rarely puberulent, light green with darker splotches, 0.5–1.6 mm in diameter, 70–205 mm long; pedicels puberulent, (0.5–)1.0–19 mm long, with 0.24–0.7 flowers per mm. Staminate flowers, first 2–3 flowers not much larger than subsequent flowers; calyx salverform flask, puberulent, light green with darker speckles, 5.5–12.0(–21.0) mm long, 1.5–6.5 mm wide, adaxial surface glabrous with trichomes at throat; sepals thin, linear, color darker than calyx, 1.0–3.5 mm long; petals orange, ovate-elliptic-rhombic, apex acuminate, 5.5–16.0 mm long, 2.5–7.3 mm wide, length-to-width ratio 2.0; anthers straight, 4.8–11 mm long, anther appendage round, minutely papillose, 0.3–0.8 mm long. Pistillate flowers 2–3 per node, axillary; calyx salverform, cylindrical, puberulent, solid green, 20.0–27.5 mm long, 1.3–6.5 mm wide, adaxial surface glabrous; sepals thin, linear, color same as or darker than calyx, 1.0–2.0 mm long; petals orange, oblong-elliptic-rhombic, apex acuminate, 4.5–6.5 mm long, 2.4–2.9 mm wide, length-to-width ratio 2.1; ovary elliptic-oblong, 10.0–15.0 mm long, 2.3–6.5 mm wide, style 4.5–5.5 mm long, stigma 3.5–5.0 mm long. Fruits, green, sometimes with lighter green stripes, 21–39 mm long, 12.5–18.0 mm wide, wall thickness unknown. Seeds 30–78, 5.0–6.0 mm long, 2.8–3.0 mm wide, 1.5–1.7 mm thick.

Phenology—Flowering throughout the year with flowering peak January through June. Of the 43 specimens examined, 74.4% had male flowers, 23.3% had female flowers or fruits, and the remainder were sterile.

Distribution and Habitat—Predominantly in northern South America and the Lesser Antilles, with a few individuals in eastern Brazil (Fig. 13). Found at elevations from 15–850 m, almost exclusively in tropical dry forests (with few individuals in moist tropical forests), along roadsides, riverbanks, slopes, or ravines, in shade or along forest edges, climbing over rocks, shrubs, or fallen trees.

Discussion—The distribution of *Psiguria umbrosa* overlaps with *P. racemosa*, *P. ternata*, and *P. triphylla*, and possibly comes into contact with *P. warscewiczii* in the southeastern-most edge of the *P. warscewiczii* range. Characteristics used to distinguish *P. umbrosa* from *P. racemosa* and *P. ternata* can be found under descriptions of those taxa or the keys. Typically, the trifoliolate leaf morphology of *P. triphylla* differentiates it from the simple, 3- to 5-lobed leaves of *P. umbrosa* (Fig. 5T, U), but there are simple, trilobed leaf morphs of *P. triphylla* (Fig. 5K–O) that can confuse identification. In those individuals, flowers are needed to distinguish the species. Male inflorescences of *P. umbrosa* are racemose (pedicel average length = 4.3 mm), peduncles and calices are light green with darker speckles, and petals are light orange. In *P. triphylla*, male inflorescences are spicate (pedicels absent), peduncles and calices are solid green, and petals are deep red, typically with a yellow base.

The molecular phylogeny of *Psiguria* resulted in a strongly supported clade of *P. umbrosa* samples that was sister to *P. warscewiczii* with moderate bootstrap support (Steele et al. 2010). However, if found in the small region of overlap, *P. umbrosa* can be difficult to distinguish from the trilobed morph of *P. warscewiczii*. Differences may exist such as male petal color and apex (*P. umbrosa* = light orange, acuminate; *P. warscewiczii* = dark orange, rounded-acute), and the outer margins of trilobed leaves (*P. umbrosa* = small indentation and lateral lobe; *P. warscewiczii* = larger indentation and lateral lobe), but variation in these characteristics can confound identification. The most consistent characters include the average lengths of pedicels on male flowers (*P. umbrosa* = 4.3 mm;

P. warscewiczii = 1.0 mm) and sepal characters (*P. umbrosa* = thin and linear; *P. warscewiczii* = thick and triangular).

Representative Specimens Examined—(collections marked with an asterisk were measured for species descriptions)

Stems glabrous or puberulent, light green with darker, linear splotches, 1.5–5.0 mm in diameter; tendrils glabrous or puberulent, light green with darker, speckles, 0.4–1.8 mm in diameter. Leaves immature membranous, mature coriaceous, both surfaces glabrous with veins and margins seldom puberulent, veins flush or seldom abaxial and adaxial main veins

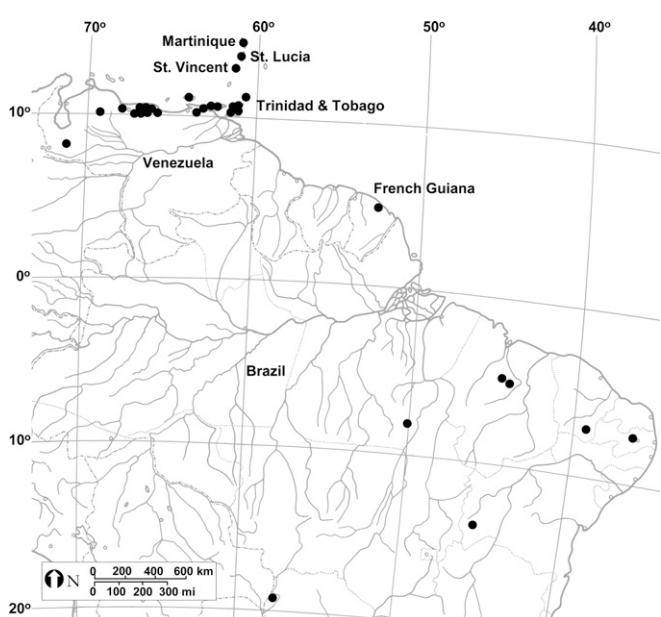

FIG. 13. Geographic distribution of *Psiguria umbrosa*. Open circles are part of the base map image.

prominent, margins entire-irregular-lobed, with irregularly-spaced veins extending beyond blade, simple, trifoliolate, or seldom pedate; petioles puberulent or rarely glabrous, 0.8–2.7 mm in diameter, 12–96 mm long; simple leaves trilobed, base auriculate, base 10–25 mm deep, apex acuminate, 86–183 mm long, 30–90(–122) mm wide, lobe depth average 73.5% of total length; petiolules winged and puberulent, 0.6–1.5(–2.1) mm in diameter, 0–20 mm long; complex leaves with center leaflet elliptic-rhombic-ob lanceolate and side leaflets ovate-elliptic with lateral lobe, sometimes large, apices acuminate; center leaflet base acute-attenuate, 52–206 mm long, 17–75(–150) mm wide; side leaflets base oblique, adaxial base acute-attenuate and abaxial base acute-truncate, 25–169 mm long, 14–69 mm wide; outer leaflets on pedate leaves base oblique, adaxial base acute-attenuate and abaxial base acute-truncate, 40–115(–145) mm long. Inflorescence a compact raceme; peduncles glabrous, light green with darker splotches, 1.0–1.9 mm in diameter, (36–)130–285 mm long; pedicels puberulent, (0.1–)0.5–1.9 mm long, with 0.25–0.75(–1.2) flowers per mm. Staminate flowers, first 2–3 flowers not much larger than subsequent flowers; calyx salverform, cylindrical, rarely flask-shaped, glabrous, light green with darker speckles, 7.0–17.0 mm long, 1.0–4.6 mm wide, adaxial surface glabrous or puberulent with sparse trichomes at throat; sepals thick, triangular, color darker than calyx, 0.5–2.1 mm long; petals intense orange or orange-red, ovate-elliptic-orbicular, apex rounded-acute, 4.0–10.0 mm long, 3.0–7.0 mm wide, length-to-width ratio 1.6; anthers straight, (1.0–)6.0–10.9 mm long, anther appendage round or rarely triangular, glabrous or rarely papillose, 0.1–0.5(–0.7) mm long. Pistillate flowers 2 per node, axillary, but at the ends of branches with reduced leaves; calyx salverform, cylindrical, glabrous or puberulent, striped green, (4.9–)18.0–25.0 mm long, 1.0–3.6 mm wide, adaxial surface puberulent with sparse trichomes at throat; sepals thick, triangular-linear, color darker than calyx, 0.5–1.6 mm long; petals bright orange or orange-red, elliptic-orbicular, apex cuspidate, 4.5–9.2 mm long, 3.3–6.9 mm wide, length-to-width ratio 1.3; ovary elliptic-oblong, 10.0–15.0 mm long, 1.9–3.5 mm wide, style 2.3–4.5 mm long, stigma 5.5–7.2 mm long. Fruits, green with lighter green or white stripes, 34–80 mm long, 14–22 mm wide, wall 0.7–2.2 mm thick. Seeds 56–88, 6.4–8.7 mm long, 3.8–4.8 mm wide, 1.9–2.7 mm thick.

Phenology—Flowering throughout the year. Of the 250 specimens examined, 76.8% had male flowers, 9.6% had female flowers or fruits, and the remainder were sterile.

Distribution and Habitat—Continental from southern Mexico to northwestern Colombia and Venezuela (Fig. 14). Found at elevations from sea level to 1,600 m in tropical and subtropical evergreen or semideciduous, moist (but can extend into dry areas along riverbanks), primary or secondary forests, cloud forests, and flooded grasslands. May be found in dense shade or light gaps, on roadsides, riverbanks, or slopes, climbing over other vegetation, and on limestone, sandy, or clay soils.

Discussion—The geographic range of *Psiguria warszewiczii* overlaps with those of *P. racemosa*, *P. triphylla*, and one collection of *P. pedata* (in Costa Rica), and possibly comes into contact with *P. umbrosa* in the southeastern-most edge of the *P. warszewiczii* range. For characteristics used to distinguish *P. warszewiczii* from *P. racemosa* and *P. umbrosa*, see the discussion under each of their taxonomic descriptions or the keys. Leaf morphology in *P. warszewiczii* (Fig. 5V–BB) can take as many forms as that in *P. pedata*; therefore, the best way to distin-

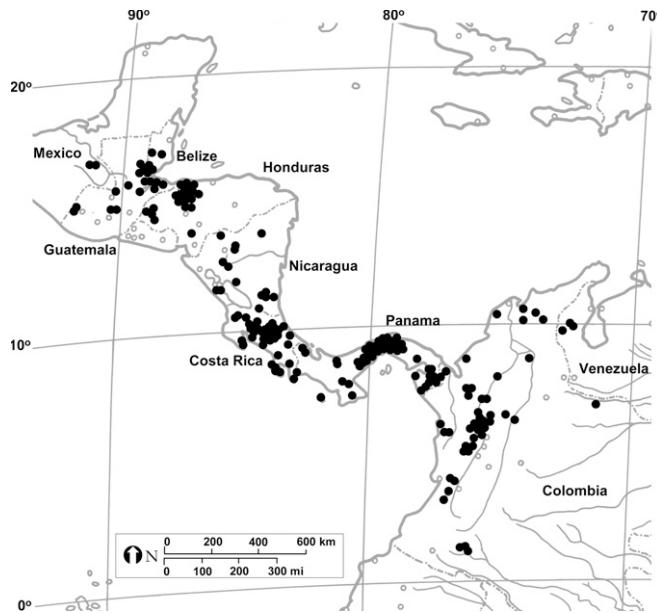

FIG. 14. Geographic distribution of *Psiguria warszewiczii*. Open circles are part of the base map image.

guish the two is with male flowers. They differ in anther shape (*P. warszewiczii* = straight; *P. pedata* = folded backwards), average pedicel length (*P. warszewiczii* = 1.0 mm; *P. pedata* = 5.2 mm), and calyx color and shape (*P. warszewiczii* = light green with darker speckles, cylinder or elongated flask; *P. pedata* = solid green, oval). The best characters to distinguish *P. warszewiczii* from *P. triphylla* include stem, peduncle, and calyx color (*P. warszewiczii* = light green with darker speckles; *P. triphylla* = solid green) and the density of flowers along the peduncle (*P. warszewiczii* = < 0.75 flowers per mm; *P. triphylla* = > 0.75 flowers per mm).

Morphological variation in *Psiguria warszewiczii* includes simple, trilobed leaves of varying depths (found in the southern end of the range), pedate leaves (found at the northern end of the range), and trifoliolate leaves with variable margins and lateral lobe sizes (found throughout the range) (Fig. 5V–BB). The molecular phylogeny revealed a weakly supported, monophyletic clade of *P. warszewiczii* samples, and this clade was split into two weakly supported clades (Steele et al. 2010). Although the trifoliolate morph is found in both clades, since the inner clades split predominantly along geographic lines (a northern clade and a southern clade), additional molecular and/or morphological characters may support a split of these clades into two species in the future.

Representative Specimens Examined—(collections marked with an asterisk were measured for species descriptions)

ACKNOWLEDGMENTS. The author thanks R. K. Jansen and two anonymous reviewers for valuable comments on the manuscript, and B. B. Simpson, L. E. Gilbert, C. R. Linder, and M. Mehdy on earlier versions. The author acknowledges the following research grants: NSF Doctoral Dissertation Improvement Grant DEB 0808294, the Plant Biology Program at The University of Texas at Austin, the American Society of Plant Taxonomy, and the Botanical Society of America. I also thank MO, NY, F, GH, US, and TEX herbaria for loaned specimens, R. Fernández and P. Protte (Costa Rica), F. Axelrod (University of Puerto Rico-Río Piedras), T. Clase (Jardín Botánico Nacional Dominican Republic), O. Plata (Herbario Nacional de Bolivia), and K. Meza (Perú) for field assistance and collecting plants, M. Timaná (Pontificia Universidad Católica del Perú) for help with plant-collecting permits, UT Austin's Brackenridge Field Laboratory for providing facilities and staff assistance that maintained living collections used in the work, and Wayt Thomas, Ph. D., Institute of Systematic Botany, The New York Botanical Garden for supplying the Neotropical base map.
