## Senescence: Still an Unsolved Problem of Biology

2

3 Mark Roper\*, Pol Capdevila & Roberto Salguero-Gómez

4

## 5    Abstract

6    Peter Medawar's 'An Unsolved Problem of Biology'<sup>1</sup> was one of several formal attempts to  
7    provide an explanation for the evolution of senescence, the increasing risk of mortality and  
8    decline in reproduction with age after achieving maturity. Despite *ca.* seven decades of  
9    theoretical elaboration aiming to explain the problem since Medawar first outlined it, we  
10   argue that this fundamental problem of biology remains unsolved. Here, we utilise  
11   demographic information<sup>2,3</sup> for 308 multicellular species to derive age-based trajectories of  
12   mortality and reproduction that provide evidence against the predictions of the classical, still  
13   prevailing, theories of ageing<sup>1,4,5,6</sup>. These theories predict the inescapability of senescence<sup>1,4</sup>,  
14   or its universality at least among species with a clear germ-soma barrier<sup>5,6</sup>. The patterns of  
15   senescence in animals and plants that we report contradict both of these predictions. With the  
16   largest ageing comparative dataset of these characteristics to date, we build on recent  
17   evidence<sup>7,8</sup> to show that senescence is not the rule, and highlight the discrepancy between  
18   existing evidence and theory<sup>7,8,9</sup>. We also show that species' age patterns of mortality and  
19   reproduction often follow divergent patterns, suggesting that organisms may display  
20   senescence for one component but not the other. We propose that ageing research will benefit  
21   from widening its classical theories beyond merely individual chronological age; key life  
22   history traits such as size, the ecology of the organism, and kin selection, may together play a  
23   hidden, yet integral role in shaping senescence outcomes.

24

25     **Main**

26     The evolution of senescence has long been explained by a collation of theories defining the  
27     ‘classical evolutionary framework of ageing’. The central logic common to the theories  
28     argues that the force of natural selection weakens with age<sup>1,4,5,6</sup>. Selection becomes too weak  
29     to oppose the accumulation of genes that negatively affect older age classes<sup>1</sup>, or favours these  
30     genes if they also have beneficial effects at earlier ages in life<sup>5</sup>, when the contribution  
31     individuals make to future populations is assumed to be greater. Selection, therefore, should  
32     favour resource investment into earlier reproduction rather than late-life maintenance<sup>6</sup>.  
33     Ultimately, these theories predict, directly<sup>4</sup> or indirectly<sup>1,5</sup>, that senescence is inescapable<sup>4</sup>, or  
34     at least inevitable in organisms with clear germline-soma separation<sup>5,6</sup>.

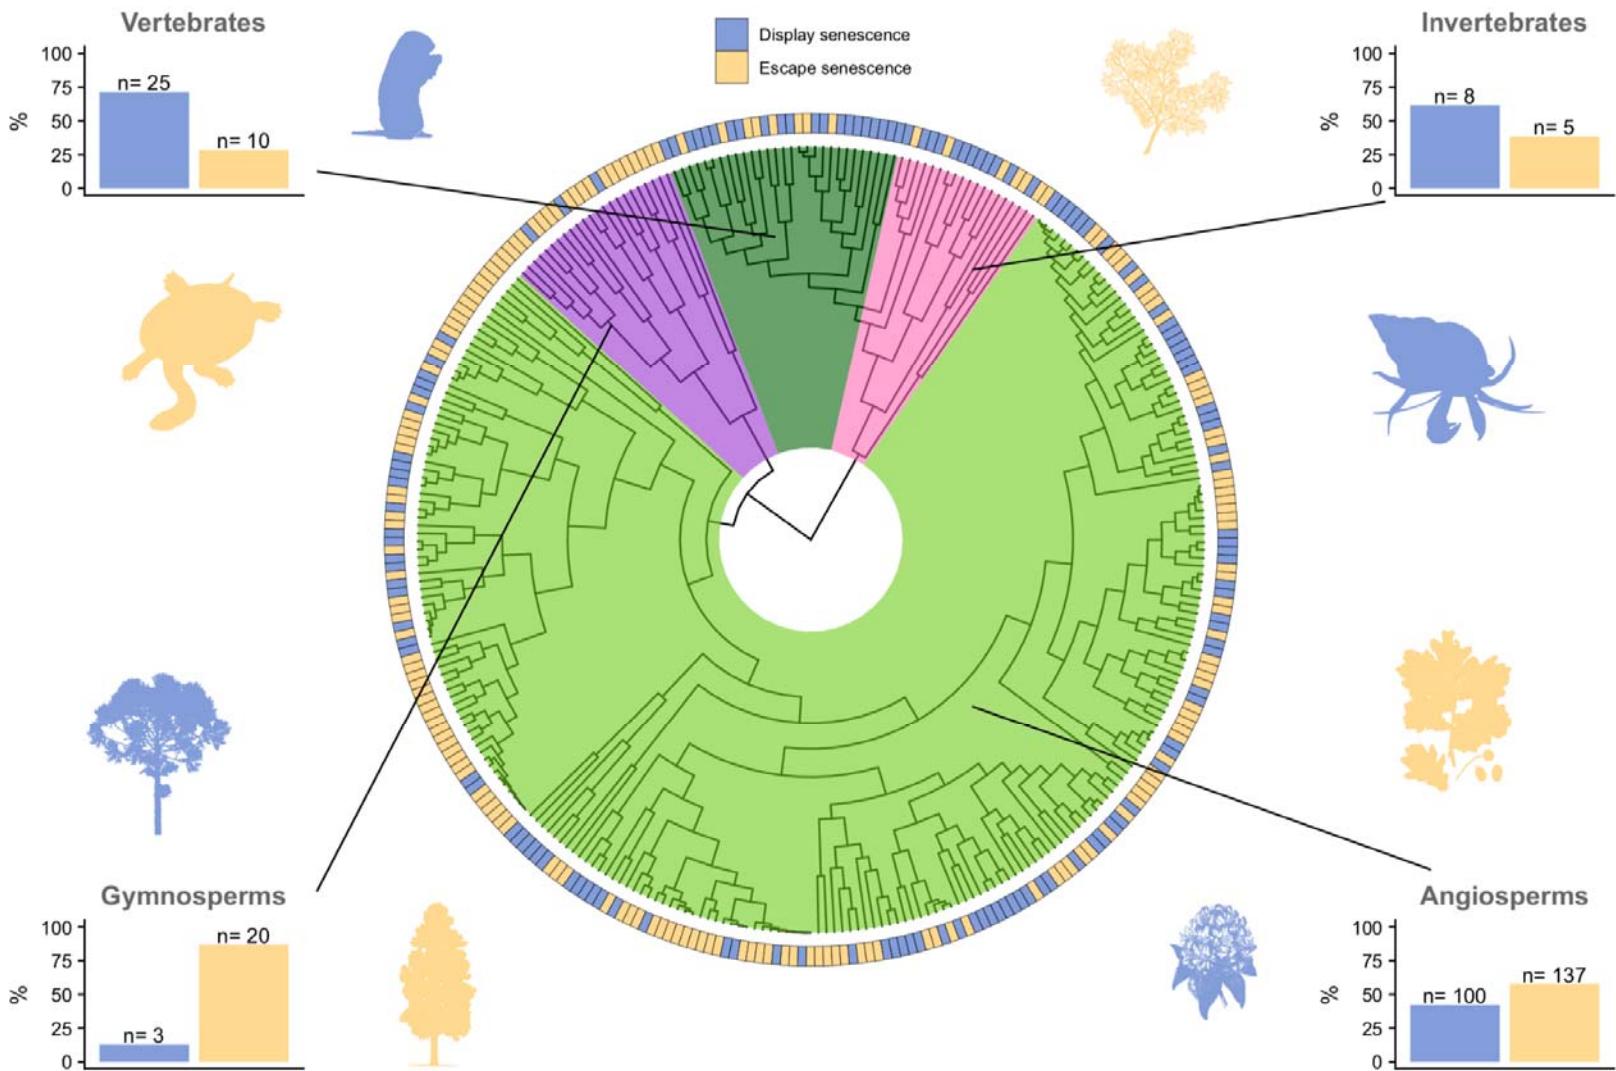

35                 It takes one example to disprove any rule. Recently, a comparative description of  
36     demographic patterns of ageing in 46 species of animals, plants, and algae<sup>8</sup> contradicted the  
37     predictions of the classical evolutionary framework. Many of the examined species displayed  
38     negligible<sup>10</sup> or even negative<sup>11</sup> senescence, where the risk of mortality remains constant or  
39     decreases with age, and reproduction remains constant or increases with age. This mismatch  
40     between observations and expectations have rendered the classical evolutionary framework  
41     insufficient to explain the evolution of senescence across the tree of life. We now need to  
42     understand mechanisms behind such variation of ageing patterns<sup>9</sup>, and how prevalent such  
43     “exceptions” are to the rule of ageing.

44                 Here, we utilise high-resolution demographic information for 48 animal<sup>2</sup> and 260  
45     plant<sup>3</sup> species worldwide to (i) provide a quantitative evaluation of the rates of actuarial  
46     senescence – the progressive age-dependent increase in mortality risk with age after  
47     maturation – across multicellular organisms, (ii) test whether the classical evolutionary  
48     framework explains the examined diversity of senescence rates, with special attention to

49 predictions from germ-soma separation, and (iii) propose how to widen the classical  
50 evolutionary framework of ageing to better encompass the tree of life.

51 First, we derived life tables<sup>12</sup> from a selection of species' matrix population models<sup>13</sup>,  
52 each of which are a summary of the population dynamics of the species in question under  
53 natural conditions (See Methods & Supplementary Information). We then quantified the rate  
54 of actuarial senescence on the survivorship trajectory of each species' life table  
55 using Keyfitz' entropy ( $H$ )<sup>14</sup>. This metric quantifies the spread and timing of mortality events  
56 in a cohort as individuals age, with  $H < 1$  indicating that most mortality occurs later in life  
57 (*i.e.* actuarial senescence), and  $H > 1$  indicating low mortality at advanced ages, whereby  
58 individuals may escape actuarial senescence (See Methods & Supplementary  
59 Information). Importantly,  $H$  is normalised by mean life expectancy, facilitating cross-species  
60 comparison to examine general patterns and plausible mechanisms.

61

5

62 **Figure 1 The evolution of and escape from senescence across multicellular life.** The  
63 classical evolutionary framework of ageing does not explain the evolution of actuarial  
64 senescence across our 308 study species. Species that escape (yellow) and display (blue)  
65 senescence, as measured by Keyfitz' entropy ( $H$ )<sup>14</sup>, are dispersed throughout the four  
66 examined clades, with the percentages of each clade either displaying or escaping actuarial  
67 senescence shown in the bar charts. Depicted around the phylogeny are eight representative  
68 species, escaping (blue) and displaying (yellow), from each clade. Clockwise, these species  
69 are *Paramuricea clavata* (Invertebrate), *Pagurus longicarpus* (Invertebrate), *Quercus rugosa*  
70 (Angiosperm), *Rhododendron maximum* (Angiosperm), *Pinus lambertiana* (Gymnosperm),  
71 *Taxus floridana* (Gymnosperm), *Marmota flaviventris* (Vertebrate) and *Chelodina expansa*  
72 (Vertebrate).

73

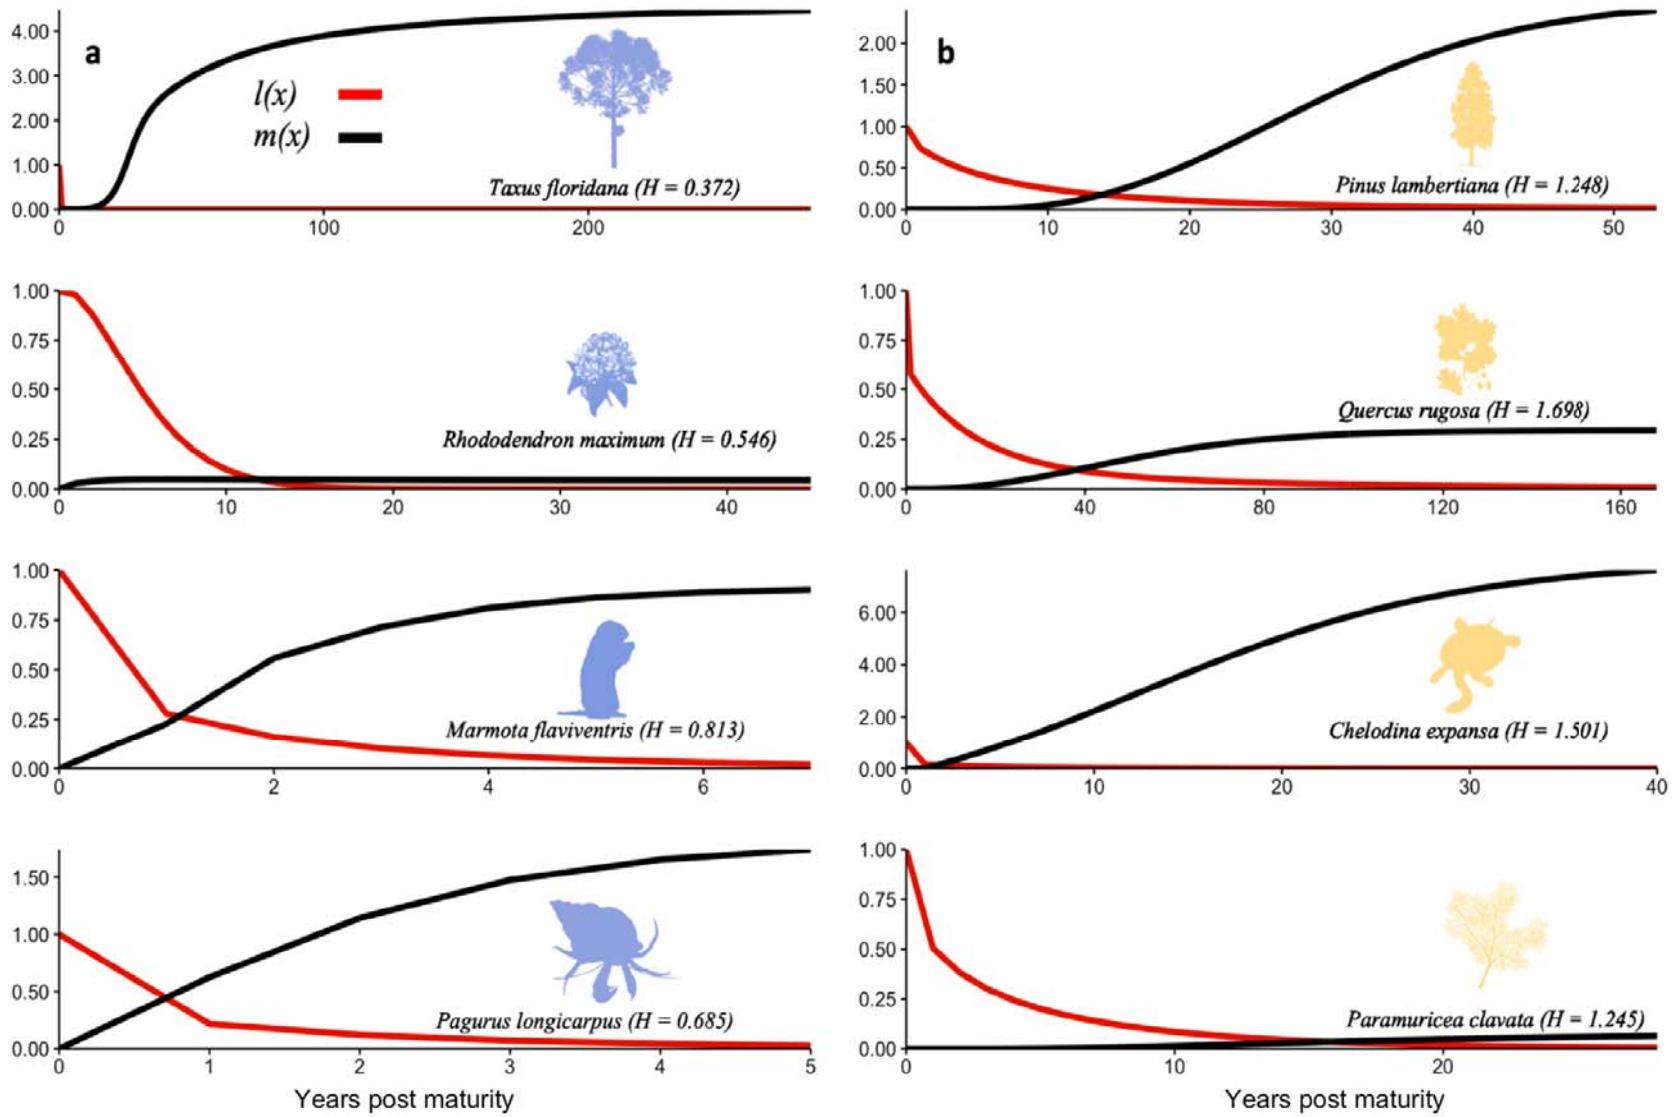

74 Most of the species in our analysis do not display senescence (Fig. 1, Supplementary  
75 Table 1). These include approximately 30% (10/35) of the studied vertebrate species, which  
76 have a clear germ-soma separation, such as the broad-shelled river turtle (*Chelodina expansa*;  
77 Fig. 1). In contrast, 42% of vascular plants (angiosperms and gymnosperms), all lacking a  
78 clear germ-soma barrier, display senescence (Fig. 1). In general, the evolutionary history of a  
79 species in our study plays a relatively weak role in constraining its ability to escape/evolve  
80 senescence. Estimates of Pagel's  $\lambda$ <sup>15</sup>, a metric that measures how well phylogenetic  
81 relatedness predicts the variation of a trait across species (See Methods and Supplementary  
82 information) are generally weak (Extended Data Table 1), with the full analysis producing a  
83 Pagel's  $\lambda = 0.38$  (0.14-0.65, 95% C.I.). Overall, the emerging senescence landscape appears  
84 (i) not inescapable, (ii) not inevitable in species with a germ-soma barrier, and (iii) prevalent  
85 in species without a clear germ-soma barrier. These findings are in direct contradiction with  
86 the predictions of the classical evolutionary framework of ageing<sup>1,4,5,6</sup>.

87 The central assumption of the classical evolutionary framework of ageing, that the  
88 force of natural selection weakens with age, rests on the assumption that older individuals  
89 contribute less to future populations<sup>1,4,5,6</sup>. This is both because fewer individuals survive to  
90 later age classes<sup>1</sup>, and individuals are expected to favour reproduction at young rather than  
91 old ages<sup>1,5,6</sup>. To observe how different age classes contribute to future populations in our

92 study species, we use the derived life tables<sup>12</sup> to quantify age-specific reproduction rates  
93 ( $m(x)$ ) for species that we previously identified to display actuarial senescence ( $H<1$ ) vs.  
94 those that do not ( $H>1$ ) (See Methods & Supplementary information). The  $m(x)$  trajectories  
95 for all the species in our dataset can be found in Extended Data Fig. 1. For practicality, here,  
96 we provide the trajectories for the eight representative species across the four clades depicted  
97 in Figure 1.

98

99

100 **Figure 2 Age-based patterns of survivorship ( $l(x)$  - red) and reproduction ( $m(x)$  - black)**  
101 **are often decoupled, as shown for a selected subset of the examined species in Figure 1.**  
102 **a)** Species quantified as displaying actuarial senescence ( $H < 1$ ) and **b)** species that escape  
103 actuarial senescence ( $H > 1$ ). Species are representative of vertebrates, invertebrates,  
104 gymnosperms, and angiosperms. Trajectories are conditional upon reaching the age of  
105 maturity, represented as 0, at which the mature cohort is defined to have entered adulthood  
106 with a survivorship of 1. The trajectories of  $l(x)$  and  $m(x)$  run from age at maturity to the age  
107 at which 5% of the mature cohort is still alive.

108

109       Classical theories of ageing predict that rates of reproduction should decline with  
110 age<sup>1,4,5,6</sup>. In our study species, however, patterns of  $m(x)$  are diverse and appear to be  
111 independent of whether the species displays or escapes actuarial senescence (Extended Data  
112 Fig. 1a-h). For instance, the long-wristed hermit crab (*Pagurus longicarpus*) displays  
113 actuarial senescence (Fig. 1), yet its reproduction increases with age (Fig. 2). Our results  
114 suggest that an individual's risk of mortality and rate of reproduction often follow different  
115 trajectories (Fig. 2, Extended Data Fig. 1a-h). For each species in our study, we only consider  
116 a single studied population, and so this decoupling cannot be an artefact of intra-specific  
117 variation across different populations. It follows that species may display actuarial  
118 senescence, but not reproductive senescence, and *vice versa*. Thus, we urge future work to  
119 consider that senescence is a two-component phenomenon of which, as displayed here, both  
120 are not destined to the same fate. To fully divulge the senescence profile of a species one  
121 must consider both mortality and reproduction.

122       Studies on reproductive senescence are sparser than their actuarial senescence  
123 counterparts. Although, important longitudinal investigations into reproductive senescence  
124 have been conducted<sup>16,17,18</sup>, and current data suggest that rates of reproduction, like mortality  
125 hazards, can also both increase or decrease with age. Our results support observations that  
126 patterns of reproduction are variable across species (Fig. 2, Extended Data Fig. 1).  
127 Developing a methodology to quantify these senescence patterns of reproduction, as done

128 here using Keyfitz' entropy<sup>14</sup> ( $H$ ) for actuarial senescence, should be a focus of future  
129 theoretical work to unearth when, where, and what mechanisms drive how tightly the two  
130 components of senescence co-vary.

131 In general, our results display the discrepancy between the predictions of the classical  
132 evolutionary framework of ageing and empirical data. We suggest that researchers must  
133 widen the framework to better encompass the biology of a more diverse range of taxa. For  
134 example, the models of the classical evolutionary framework are purely age-structured, yet,  
135 in some species, demographic patterns of survival and reproduction may be influenced  
136 equally or even more by factors besides age<sup>13</sup>. Indeed, the force of selection does not always  
137 decline with age for some species<sup>19</sup>. These organisms display demographic trajectories of  
138 survival and reproduction that are better predicted by size rather than age, such as many  
139 plants<sup>20</sup>, which is supported by the 58% of studied plant species here that escape senescence,  
140 or corals<sup>21</sup> (e.g. *Paramuricea clavata*; Fig. 1).

141 Many of the predictions made explicit from the classical framework of ageing have,  
142 until recently, long stood the test of time. Higher rates of extrinsic mortality, *i.e.* deaths due to  
143 the background environment, are expected to accelerate rates of senescence, whereas juvenile  
144 mortality is predicted not to play a role in the evolution of senescence<sup>5</sup>. Theoretical  
145 advancements, however, have shown that to have a significant effect, extrinsic mortality must  
146 be age-dependent<sup>22</sup>. Also, by biasing the stable age distribution of a population towards  
147 younger ages, high birth rate can also reduce the strength of selection with age<sup>23</sup>. The strength  
148 of selection at a given age is dependent on both the abundance of individuals in a given age  
149 class *and* the respective reproductive value of that age class<sup>4,23</sup>. Following this logic, some  
150 species that display senescence yet retain high reproduction at old ages (e.g. *Marmota*  
151 *flaviventris* or *Pagurus longicarpus*; Fig. 1, Fig. 2) may have a stable age distribution biased  
152 towards younger individuals. This outcome would render selection too weak to promote an

153 escape from senescence. Ultimately, how the environment shapes patterns of birth and deaths  
154 will dictate both the reproductive value of age classes and the stable age-distribution of the  
155 classes. In turn, the resulting dynamics of these pressures will affect the relative strengths of  
156 age-specific selection gradients<sup>24</sup> for mortality and reproduction, and therefore patterns of  
157 senescence.

158 Finally, we have only considered patterns of survival and reproduction with respect to  
159 effects on the focal individual. If an individual's survival and/or reproduction affects the  
160 fitness of others, however, and the interacting individuals are relatives, selection on the  
161 demographic age trajectories will also be weighted by these effects<sup>25</sup>. In our study, for  
162 example, the killer whale (*Orcinus orca*) experiences negligible actuarial senescence ( $H =$   
163 0.999) (Extended Data Fig. 1a). Killer whales are an exemplar where post-reproductive  
164 survival is hypothesised to have evolved due to the positive effects individuals can have on  
165 the survival and reproduction of offspring, *i.e.* ‘grandmother hypothesis’<sup>4,5,26</sup>. This is  
166 consistent with our results. Further evidence is also beginning to accrue elsewhere that  
167 sociality may have an important role in driving patterns of senescence beyond the remits of  
168 ‘grandmothering’<sup>27,28</sup>.

169 The emerging picture of senescence across multicellular organisms is at odds with the  
170 widely cited predictions of the classical evolutionary framework<sup>1,4,5,6</sup>. What drives the  
171 evolution of senescence has attracted the attention of a vast research community, but we  
172 propose that the field would benefit immensely if the attention is shifted towards the  
173 underlying mechanisms allowing species to escape from senescence. We expect the greatest  
174 progress to be made by researchers honing their focus to widening the classic evolutionary  
175 theories to a framework not solely focused on age, but instead inclusive of the  
176 aforementioned factors and with a special focus on actuarial and reproductive senescence as  
177 potentially differing trajectories. Most ageing research likely stems from human desire to

178 increase human health and life span<sup>29</sup>. This desire requires understanding the variation in  
179 patterns of senescence across the tree of life. For now, senescence remains an unsolved  
180 problem of biology.

181 **Methods**

182

183 **Data**

184 We used the COMADRE Animal Matrix Database<sup>2</sup> (v. 3.0.0) and COMPADRE Plant Matrix  
185 Database<sup>3</sup> (v. 5.0.0) to obtain age trajectories of survival and reproduction. These open-access  
186 data repositories consist of matrix population models<sup>13</sup> (MPMs) incorporating high-resolution  
187 demographic information on the survival and reproduction patterns of over 1,000 animal and  
188 plant species worldwide<sup>2,3</sup>. Both databases include information on species for which the data  
189 have been digitised and thoroughly error-checked. In addition, we contacted authors for  
190 clarifications when any doubt about the interpretation of the life cycle of the species emerged.  
191 We imposed a series of selection criteria to restrict our analyses to data of the highest quality  
192 possible.

193 (i) MPMs were parameterised with field data from non-disturbed, unmanipulated  
194 populations (*i.e.* natural populations) to best describe the species' age trajectories.

195 (ii) MPMs had dimension  $\geq 3 \times 3$  (*i.e.* rows  $\times$  columns). Generally, low dimensions  
196 MPMs lack quality for the estimation of life history traits<sup>30</sup>. This selection  
197 criterion also helps avoid problems with quick convergence to stationary  
198 equilibrium, at which point the estimates of life history trait values and rates of  
199 senescence become unreliable<sup>8,31</sup>.

200 (iii) MPMs were only used when the entire life cycle was explicitly modelled  
201 including recordings of survival, development, and reproduction for all life cycle  
202 stages.

- 203 (iv) When MPMs existed for multiple populations within a given species, we  
204 calculated the arithmetic element-by-element mean MPM to obtain a single MPM  
205 per species.
- 206 (v) When multiple studies existed for the same species, we considered only the study  
207 of greater duration to ensure the highest temporal variation in the population  
208 dynamics was captured.
- 209 (vi) Studies of annual plant species modelled using seasonal projection matrices were  
210 not included; we chose only species using an annual time step. This is due to the  
211 difficulties of converting their population dynamics to an annual basis to compare  
212 with all other species' models.
- 213 (vii) Included MPMs have stage-specific survival values  $\leq 1$ . In a small number of  
214 published models, the stage-specific survival values can exceed 1 due to clonality  
215 being hidden in the matrix, rounding errors, or other mistakes in the original  
216 model<sup>2,3</sup>.
- 217 (viii) MPMs were from species of which phylogenetic data was available, to ensure we  
218 were able to account for phylogenetic relatedness on our models.

219 The result of these criteria was a subset of 308 species of animals and plants from the  
220 initial databases, which we used for our analysis. Of these, 48 were animals, with 13  
221 invertebrates and 35 vertebrates. The remaining 260 species were plants, with 23  
222 gymnosperms and 237 angiosperms. We provide a list of all the species used, their  
223 categorisation as displaying or escaping senescence including value of  $H$ , and their relevant  
224 source study (Supplementary Table 1).

225

226 **Displaying vs escaping senescence**

227 MPMs are a summary of the population dynamics of a given species, from which we can  
228 calculate several life history traits. To do so, we first must decompose an MPM ( $\mathbf{A}$ ) into its  
229 sub-components<sup>13</sup>:

230  $\mathbf{U}$  – containing the stage-specific survival rates

231  $\mathbf{F}$  – containing the stage-specific per-capita reproduction rates

232  $\mathbf{C}$  – containing stage-specific per-capita clonality rates

233 
$$\mathbf{A} = \mathbf{U} + \mathbf{F} + \mathbf{C} \quad \text{equation 1}$$

234 This decomposition facilitates the estimation of key life history traits, including  
235 Keyfitz' entropy ( $H$ )<sup>14</sup>. Calculating  $H$  requires first obtaining the age-specific survivorship  
236 curve  $l(x)$  from  $\mathbf{U}$ . First, the definition of age requires a choice of a stage that corresponds to  
237 "birth". Following Jones *et al.*<sup>8</sup>, we defined the stage corresponding to birth as the first  
238 established non-propagule stage (e.g., not seeds or seed bank in the case of plants, nor larvae  
239 or propagules in animals) due to the estimate uncertainty of parameters involved in those  
240 stages. The calculation of  $l(x)$  was then implemented according to Caswell (p. 118-21)<sup>13</sup>.

241 
$$l(x) = e^t \mathbf{U}^x e^j \quad x = 0, 1, \dots \quad \text{equation}$$

242 2

243 We considered survivorship trajectories beginning at the age of maturity (calculated  
244 following 5.47–5.54 in Caswell<sup>13</sup>) and ending at the age at which 5% survivorship from  
245 maturity occurs. This is because a cohort modelled by iteration of the  $\mathbf{U}$  matrix eventually  
246 decays exponentially at a rate given by the dominant eigenvalue of  $\mathbf{U}$ , and converges to a  
247 quasi-stationary distribution given by the corresponding right eigenvector  $\mathbf{w}$ . Once this  
248 convergence has happened, mortality remains constant with age, and so to prevent our  
249 conclusions being overly influenced by this assumption, we calculated the age at which the  
250 cohort had converged to within a specified percentage (5%) of the quasi-stationary  
251 distribution<sup>8,31</sup>.

252         $H$  is proportional to the area under the age-specific survivorship curve and is  
253        calculated as follows

254                  
$$H = \frac{-\log(lx)lx}{\sum lx}$$
 equation 3

255        If most mortality occurs later in life,  $H < 1$ , and individuals in the population display  
256        actuarial senescence. On the contrary, if  $H > 1$ , the risk of mortality declines with age and the  
257        individuals in the population escape actuarial senescence. Here, we categorise species as  
258        either escaping or displaying senescence, however, values of  $H \sim 1$  are more likely to indicate  
259        negligible senescence, where risk of mortality remains relatively constant with age.

260

261        **Phylogenetic analyses for actuarial senescence**

262        After categorising species as displaying ( $H < 1$ ) or escaping ( $H > 1$ ) senescence, we accounted  
263        for the phylogenetic relatedness of the species studied to determine the influence of a species'  
264        evolutionary history in its likelihood of evolving or escaping senescence. To build the  
265        phylogenetic tree with the species included in this study, we used data from the Open Tree of  
266        Life<sup>32</sup> (OTL), a database that combines public available taxonomic and phylogenetic  
267        information across the tree of life. We first checked that the species names in our data were  
268        taxonomically accepted using the *taxize* R package<sup>33</sup>. Then, we obtained animal and plant  
269        phylogenetic trees form OTL for the list of species in our data using *rotl* R package<sup>34</sup>. The  
270        branch length of the resulting tree was computed using the *compute.brlen* function from the R  
271        package *ape*<sup>35</sup>, with Grafen's<sup>36</sup> arbitrary branch lengths. Polytomies (*i.e.*  $> 2$  species with the  
272        same ancestor) were resolved using the function *multi2di* from *ape* package<sup>35</sup>, which  
273        transforms polytomies into a series of random dichotomies with one or several branches of  
274        length zero.

275        To evaluate the role of phylogenetic relatedness in determining the patterns of  
276        variation of actuarial senescence we estimated Pagel's  $\lambda$ <sup>15</sup>. This metric is an index bounded

277 between zero and one, where values ~0 indicate that the evolutionary history of the species  
278 explains little about the variation of the trait measured, and values ~1 suggest that that  
279 evolutionary history mostly explains the observed variation of the trait across the studied  
280 species. To estimate Pagel's  $\lambda$  we used the R package *motmot.2.0*<sup>37</sup>. A full summary of the  
281 phylogenetic signals obtained for each of the four monophyletic groups can be found in the  
282 Extended Data and Figures (Table 1).

283 **Reproduction analysis**

284 We calculated reproductive age-trajectories for the species in our analysis to investigate  
285 whether reproductive senescence followed the same pattern as actuarial senescence in species  
286 that display *vs.* escape actuarial senescence. Age-specific reproduction ( $m(x)$ ) was calculated  
287 following Caswell (p. 118-21)<sup>13</sup>. Briefly, the proportional structure of the cohort at age  $x$  is  
288 given by

289 
$$\mathbf{p}(x) = \frac{U^x e_j}{e^T U^x e_j} \quad x = 0, 1, \dots \quad \text{equation 4}$$

290 The total sexual reproductive output per individual at age  $x$  is given by

291 
$$m(x) = \mathbf{e}^T \mathbf{F} \mathbf{p}(x) \quad \text{equation 5}$$

292

293 For two species, *Araucaria mulleri* and *Juniperus procera*,  $m(x)$  was incalculable, and  
294 so both species'  $l(x)$  and  $m(x)$  trajectories are not reported. For the remaining 306 species, the  
295  $l(x)$  and  $m(x)$  trajectories are found in the Extended Fig. 1a-h.

296

297 **Code availability**

298 Code used for analysis is available in the supplementary information.

299 **Data availability**

300 Data are available from the source data files in the supplementary information and from the

301 COMPADRE Plant Matrix Database and COMADRE Animal Matrix Database

302 ([www.compadre-db.com](http://www.compadre-db.com)).

394 **Contributions**

395 M.R. and R.S.G. conceived the project. M.R. and P.C conducted the analysis and produced

396 all visualizations. M.R drafted the first version and together with P.C. and R.S.-G., revised

397 and edited the manuscript.

398 **Competing interests**

399 The authors declare no competing interests.

402

403 **Extended data figures and tables**

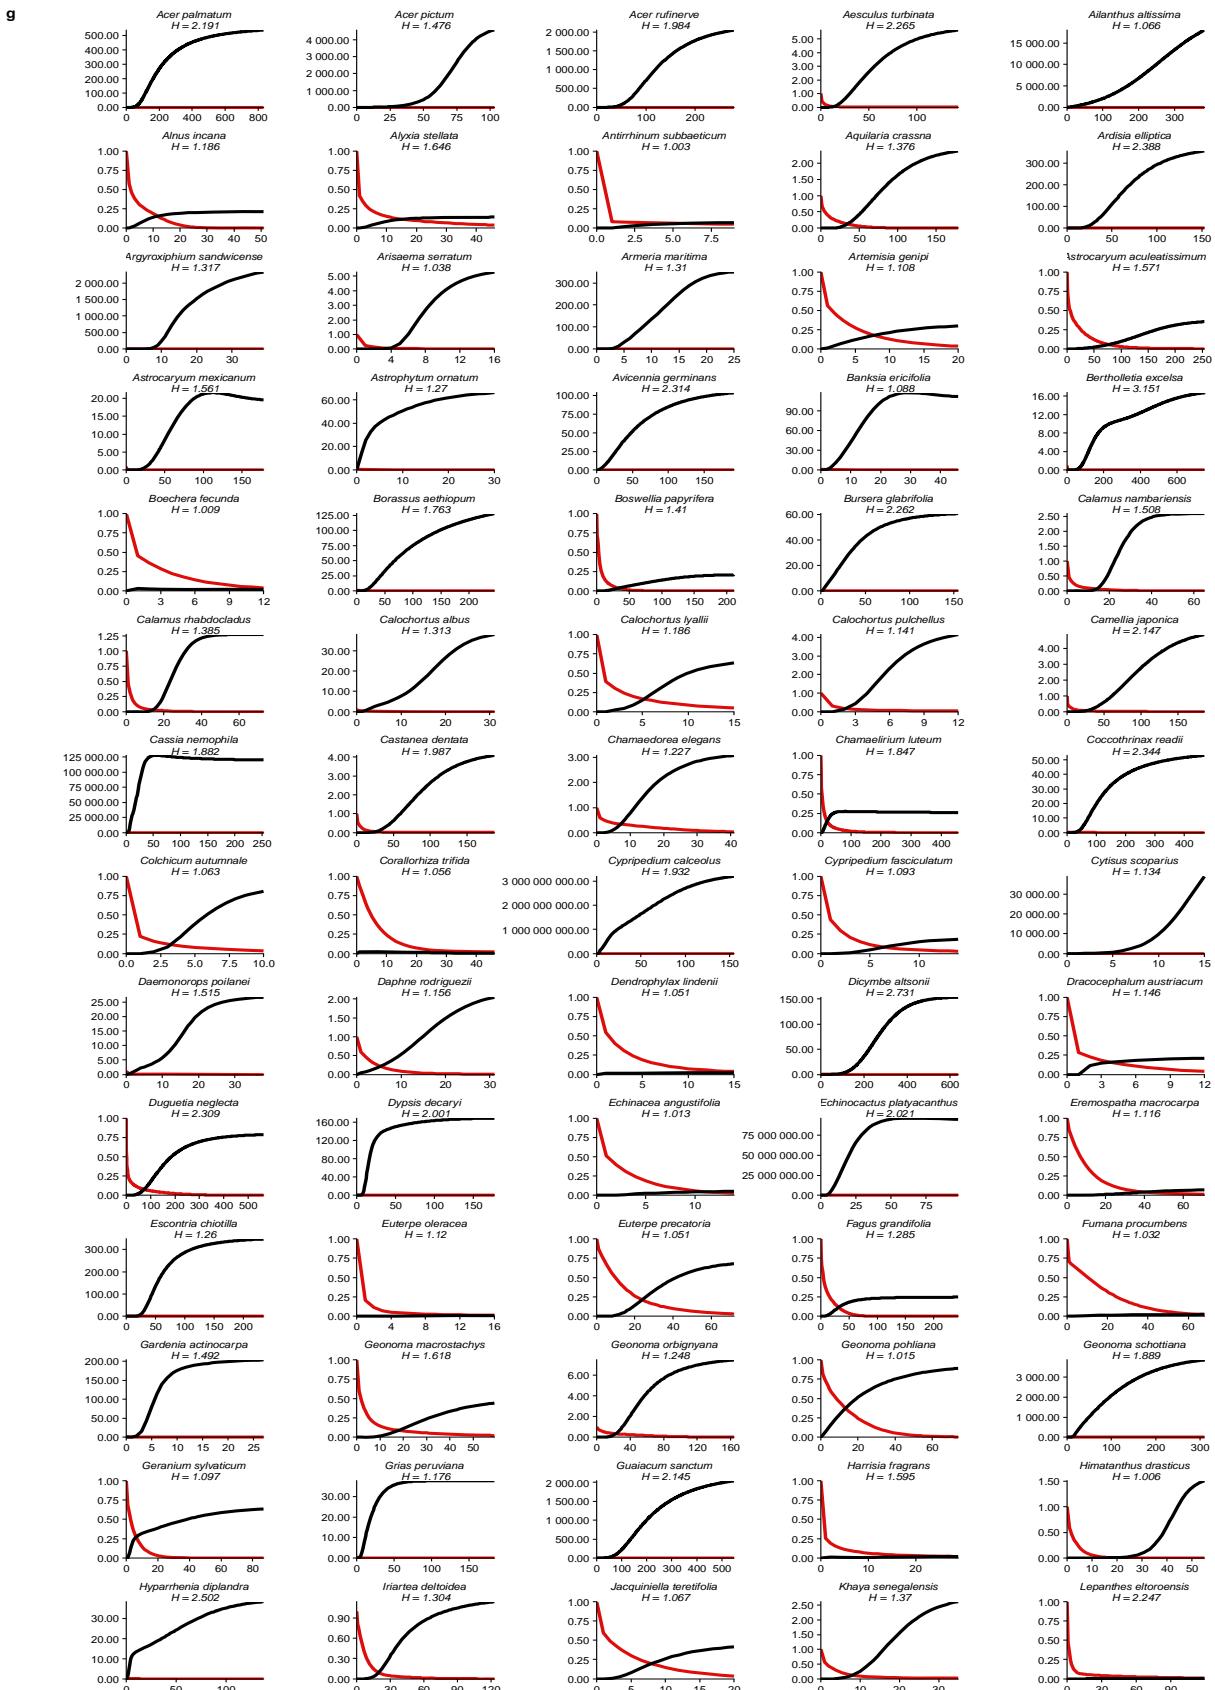

404 **Fig. 1: Survivorship (red) and reproduction (black) age-trajectories for 306 of our study**  
405 **species.** **a)** Invertebrates that escape senescence **b)** Vertebrates that escape senescence **c)**  
406 Invertebrates that display senescence **d)** Vertebrates that escape senescence **e)** Gymnosperms  
407 that escape senescence **f)** Gymnosperms that display senescence **g)** Angiosperms that escape  
408 senescence **h)** Angiosperms that display senescence. Trajectories are conditional upon  
409 reaching, and are shown from, the age of maturity, labelled as 0, to the age at which 5% of  
410 the mature cohort is still alive. The mature cohort is defined to have survivorship of 1.

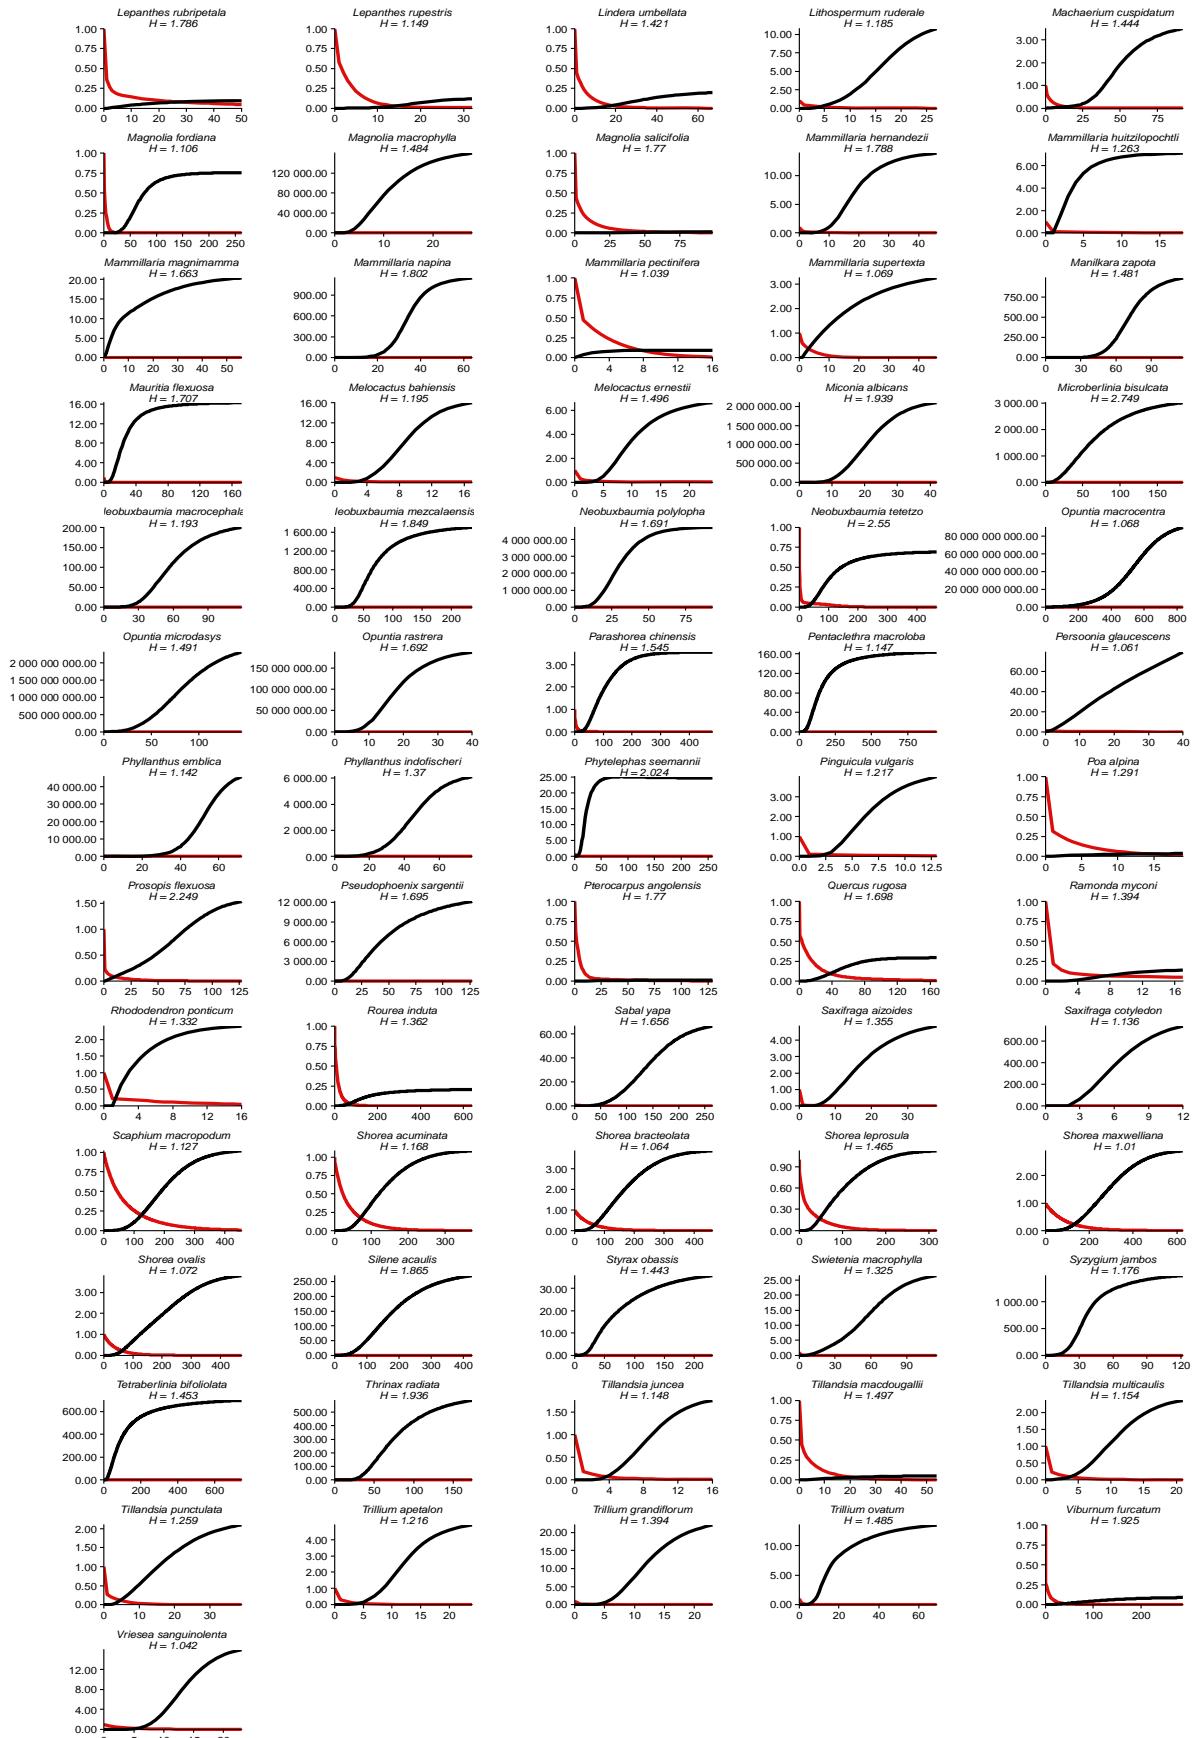

411

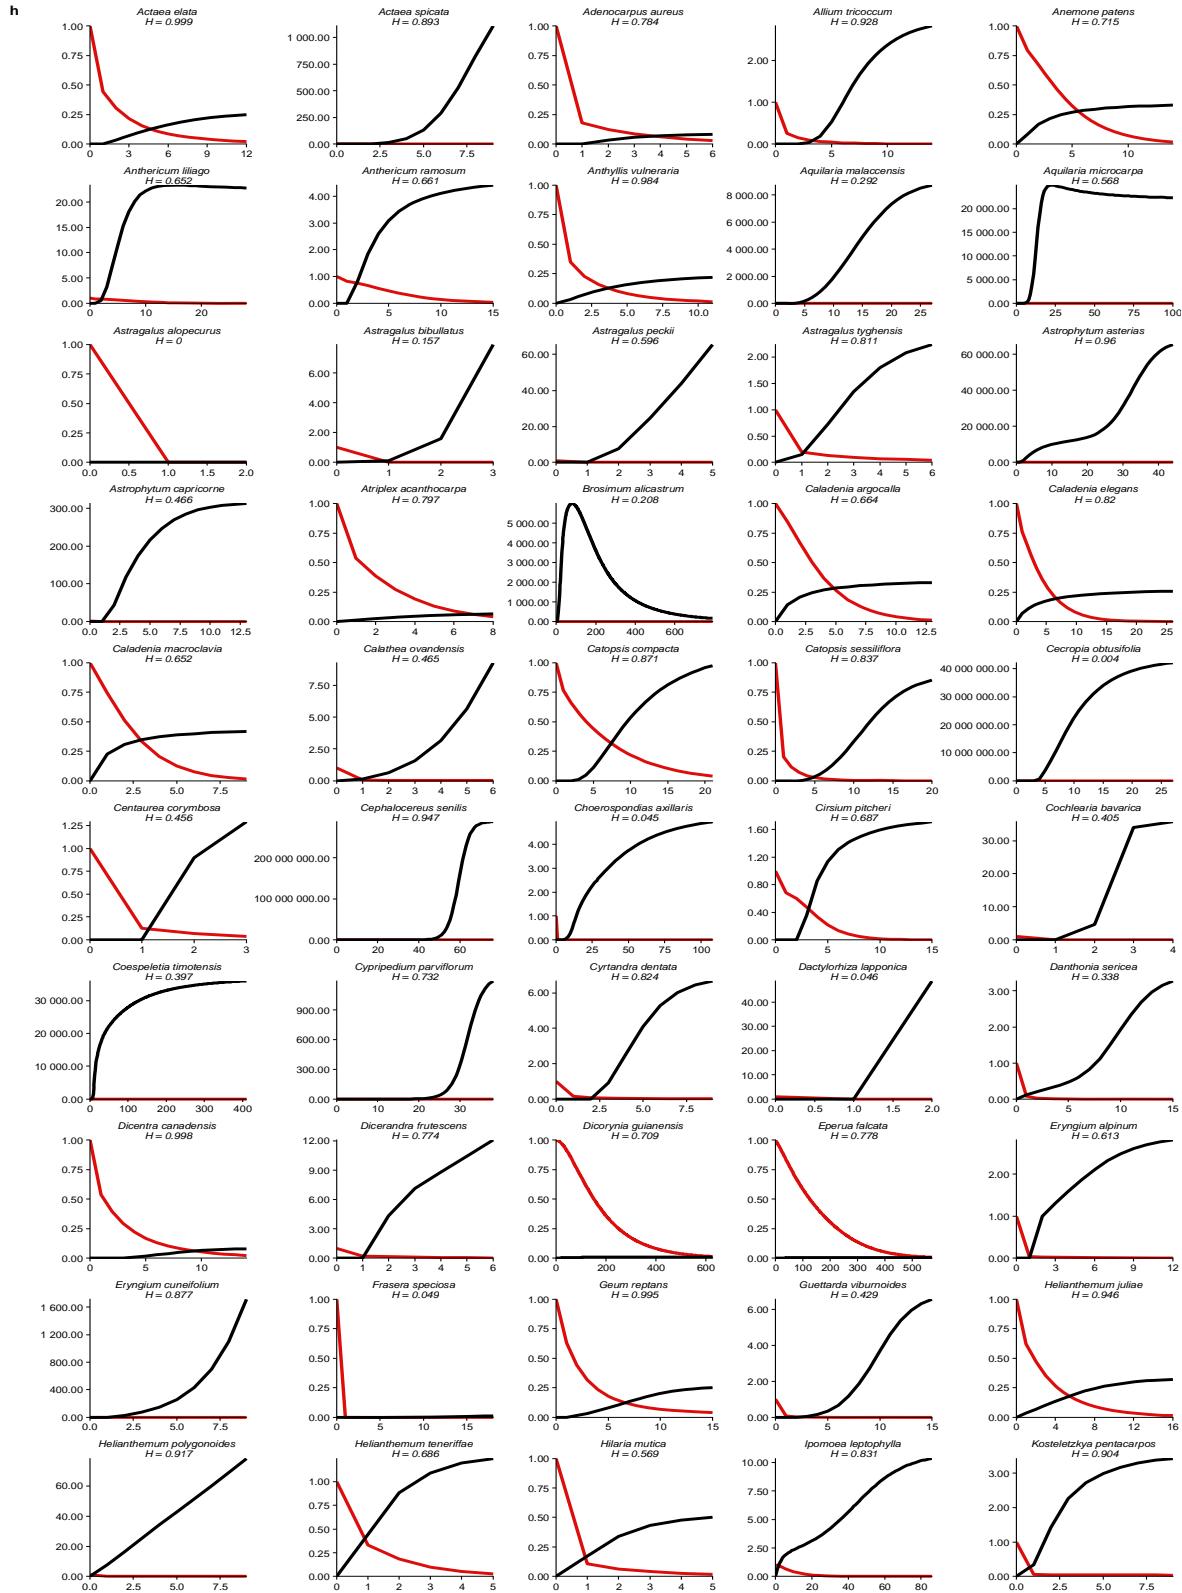

421

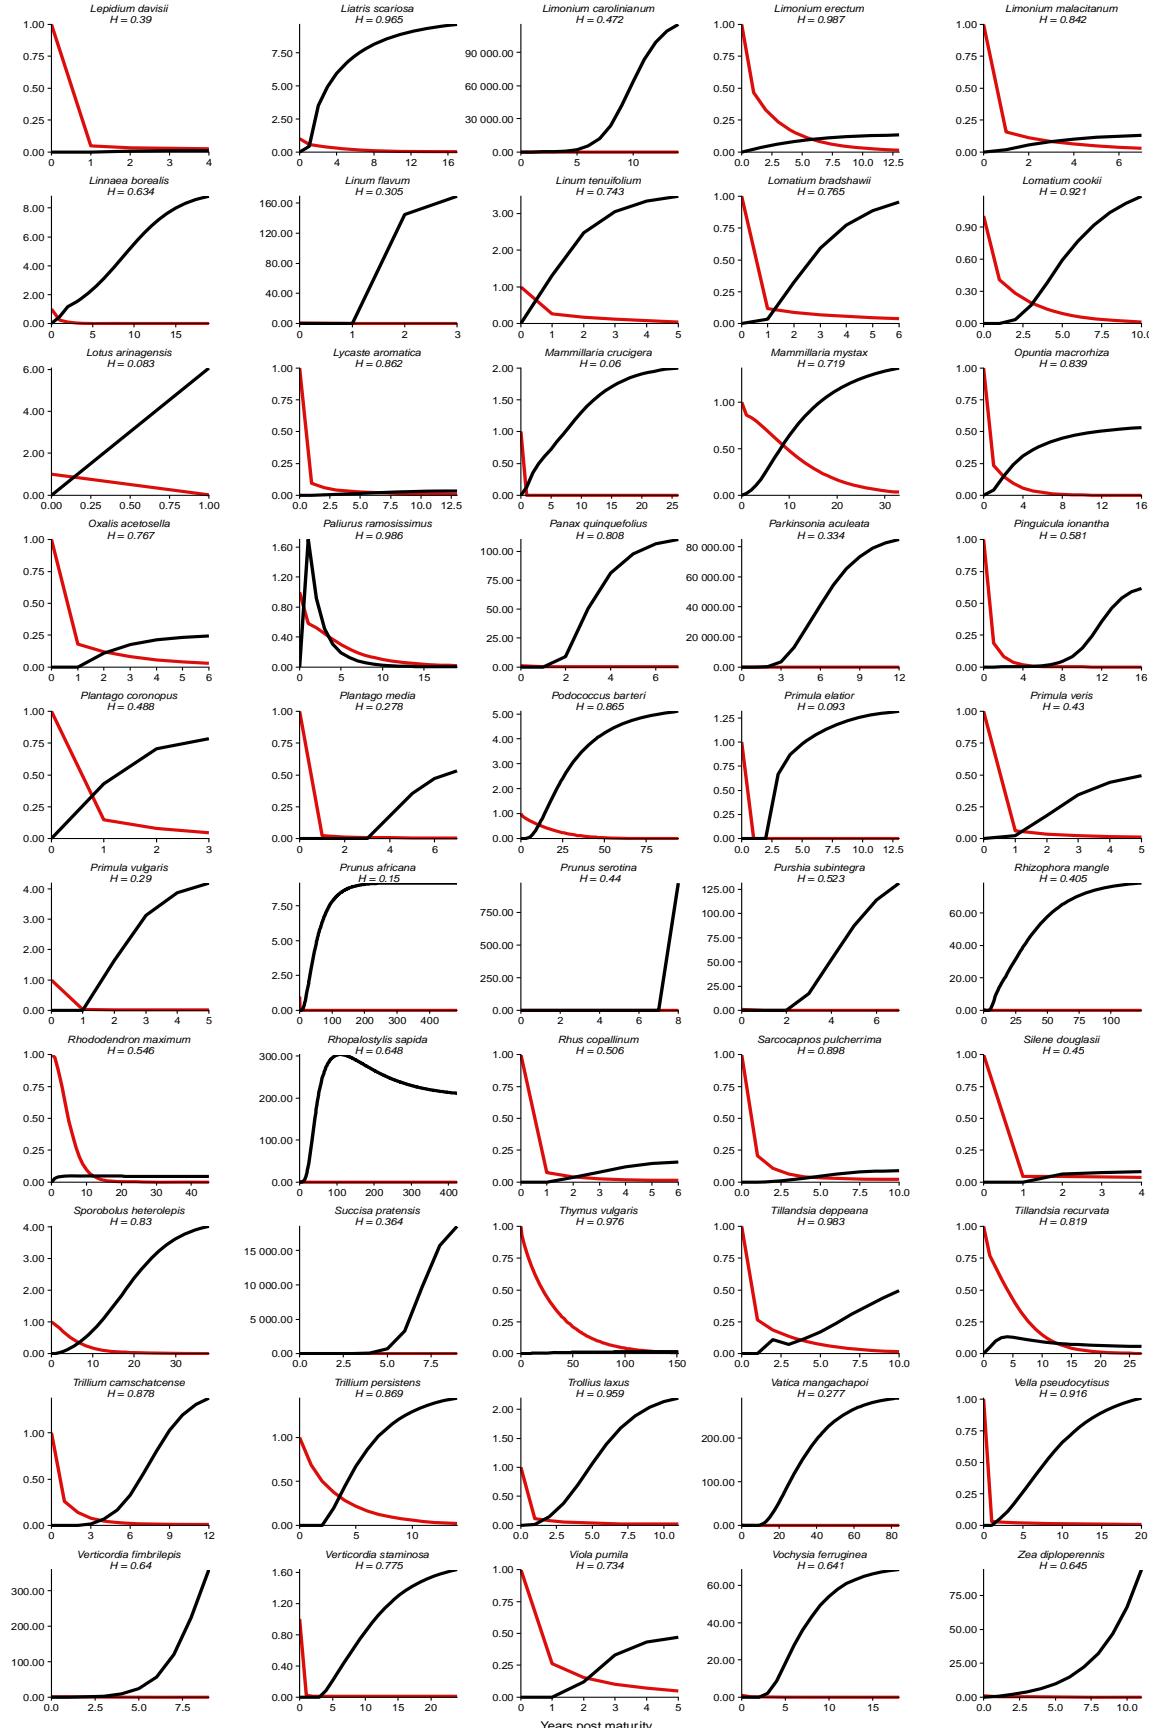

424

425

427 **Extended Data Table 1: Phylogenetic signals of actuarial senescence for each major**  
428 **taxonomic group of our 308 studied species are relatively weak.** Calculated estimates of  
429 Pagel's  $\lambda$  within the phylogenetic analysis of actuarial senescence across our study species.  
430 Pagel's  $\lambda$  is an index bounded between zero and one, where values ~0 indicate that the  
431 evolutionary history of the species explains little about the variation of the trait measured,  
432 and values ~1 suggest that that evolutionary history mostly explains the observed variation of  
433 the trait across the studied species.

434

Taxonomic breadth	Pagel's $\lambda$	5% CI	95% CI
Whole analysis	0.376	0.142	0.654
Plants	0.359	0.077	0.704
Animals	0.000	0.000	0.572
Angiosperms	0.215	0.000	0.687
Gymnosperms	0.000	0.000	0.699
Vertebrates	0.000	0.000	0.658
Invertebrates	0.291	0.000	0.845

435

436 **Supplementary information**

437 **Supplementary Table 1: Study species.** Included species in our analysis were those that  
438 fitted the selection criteria described in methods. Species names, their kingdom (Animalia or  
439 Plantae), whether they display or escape actuarial senescence according to Keyfitz' entropy<sup>14</sup>  
440 ( $H$ ), and the source study from which the data was originally compiled into COMADRE<sup>2</sup> and  
441 COMPADRE<sup>3</sup> are listed.

Species	Kingdom	Actuarial senescence	$H$	Source
<i>Clinocottus analis</i>	Animalia	Displays senescence	0.945	Davis, J., & Levin, L. Importance of pre-recruitment life-history stages to population dynamics of the woolly sculpin <i>Clinocottus analis</i> . <i>Marine Ecology Progress Series</i> . <b>234</b> , 229–246. (2002).
