Coal Vein Nature Trail

The beautiful layers of rock you see here tell a story of the 60-million-year geologic history of the badlands. From ancient swamps to recent coal fires, this landscape is constantly changing. Learn more by following the numbered trail posts.

Stay to the left to follow the posts in numerical order.

1. Layers

Each layer of rock here has its own origin story, told by its color.

Blue-grey
Bentonite clay is made of ash from distant volcanoes.

Brick-red
Clinker forms when coal veins catch fire and bake the rock above, changing it into this much harder, red rock. These fires are a natural part of the badlands, and help create this fascinating landscape.

Brown and Tan
Sandstone, **siltstone**, and **mudstone** are sediments washed down from the Rocky Mountains by rivers and streams.

Black
Coal is the remains of ancient plants and animals that lived in Everglades-like swamps.

2. Collapse

In this area there was a 12-foot-thick coal vein deep underground. In 1951 it caught fire and burned for 26 years. As it burned away, the rocks above were left unsupported and the surface collapsed, forming the depression you are about to enter. Before the fire, the land was level with the top of the stairs.

3. Bentonite

Notice the sediment on either side of the trail. Fifty-five million years ago, volcanoes in the Rockies spewed out ash that blew east. At that time, this area was a vast, tropical swamp. The ash settled in wet areas and became bentonite clay. Bentonite looks like popcorn when dry (*below*), but becomes sticky, slick mud when wet. It can absorb up to five times its weight in water. Known as the mineral of one thousand uses, it is used to seal landfills and ponds, to make cat litter, and much more.

Stay to the left to continue on the guided nature trail.
Take the cutoff trail to the right to avoid a section of trail with very steep stairs. You will rejoin the guided nature trail near post #11.

4. Caprocks

Rocks in the badlands are generally soft and easily eroded by rain and streams. Some are harder than others, and become *caprocks*. A caprock acts like a hat, shielding softer rock underneath. When the layers underneath wear away, and large pieces of caprock break off and fall. The large pieces of sandstone behind you were once caprocks at the top of the hill.

Left: An example of a caprock found elsewhere in the park.

5. Dry Climate

The dry climate of western North Dakota keeps the badlands from eroding away quickly — if rain were more common, the soft rocks would have washed away long ago. The lack of moisture allows only the hardiest plants to survive.

The trees here are Rocky Mountain juniper. They, and all the other shrubs, grasses, and wildflowers you find here, are adapted to survival in this land of extreme temperatures and little moisture.

6. Seasonal Pool

Low spots like this one formed when the ground collapsed during the coal vein fire. They fill with water in the wet springtime and after summer rains. These seasonal ponds are important habitat for western chorus frogs that must lay their eggs in standing water.

Listen for the chirping of the male chorus frogs near seasonal pools from April to June.

7. Burn Out

Just ahead and to the right is where the coal vein fire burned out after 26 years (1951-1977). Visitors could see smoke, glowing coals, and sometimes flames. They even roasted marshmallows over the fire!

Right: This photograph was taken in the 1970s as the burning coal fire crept toward its end.

Caution! Steep cliff edges ahead.

8. Hills Overlook

The trail goes to the right. To your left is an overlook. Be careful; the edge drops off sharply. From this overlook, you can see how plants are affected by the terrain. The slopes you see are north-facing. They are cool and shady and retain moisture better than sunny south-facing slopes. This allows juniper and other shrubs to thrive. South facing slopes support only hardy grasses and a few very drought-tolerant shrubs.

9. Clinker

Feel the red rock next to the post. It locally called scoria, but more correctly called clinker. It is one of the hardest rocks in the badlands. Clinker is created when a burning coal seam bakes the rock layer above it. Baking rock is like putting clay into a kiln to make pottery — the rock hardens as it bakes. Look for clinker functioning as a caprock atop buttes throughout the park.

10. Seasonal Stream

Just ahead, stairs lead to the valley of a seasonal stream. As you descend, notice the cool, moist air against your skin. This stream bed is dry most of the year. It usually runs only during spring snowmelt and summer rainstorms. Because it is protected from the sun, this area stays moist and cool. Note the plants you see here and compare them to the plants you have encountered in open grassland. What are the differences?

Continue straight ahead to follow the guided nature trail.

11. Ignition

This is the spot where the coal vein ignited during a lightning storm in 1951. Even today, these natural fires can be started by lightning, prairie fires, or even spontaneous combustion.

Caution! Steep cliff edges ahead.

12. Clinker Overlook

The small spur trail going up the hill leads to an overlook. Be careful; the edge drops sharply. When you look to the left and right you can see and feel the clinker where it forms a protective caprock. The red color of the clinker comes from iron in the rocks that oxidized (rusted) when the rock was baked by the underlying coal fire.

13. Slumping

The hill in front of you has the appearance of sliding slowly into a jumble. That is exactly what it is doing through a process called slumping. When the coal vein burned under this area, the ground became unstable, causing cracks in the hillside. Rain flowing into the cracks weakens the hill more, especially where it comes in contact with bentonite layers that become slippery when wet. As the wet bentonite slides, the hill slowly slumps away.

14. Grassland

When the underground coal fire was burning, this area looked more like a wasteland than a grassland. After the fire burned out, prairie plants reclaimed the land slowly over time.

From a distance, prairie may look plain, but it is actually one of the most diverse ecosystems in the world. An up-close look reveals many different species of grasses and other plants.

15. The Big Picture

Take in the view. The things you have observed on this trail are not unique to this one spot. They can be seen, felt, and identified throughout the badlands. Even today, coal fires shape the dynamic landscape of the badlands.

Geology is not only a study of the past; here it is an ever present process. How do these things fit into the big picture of the park? How long will these processes continue to shape this land?

16. Chimney

What is unusual about the massive piece of clinker in front of you?

Fires need oxygen, even when they are burning underground. As the coal fire burned deep into the hillside, cracks in the rock layers allowed air to be sucked down into the fire. Fire burned up the cracks and baked the rocks nearby forming vertical "chimneys." Chimneys are the hottest part of the coal fire and bake the rock inside into a very hard clinker called porcellanite which is especially resistant to erosion.

This chimney you are looking at was exposed when softer sediments around it eroded away.

There are many signs that large coal vein fires have burned throughout the park in the past. Even today, coal fires can sometimes be found shaping and changing the landscape of the badlands.

Geology is not only a study of the past; it is an ongoing process.

We hope you enjoyed your hiking experience. Please return this brochure to the box at the beginning of the trail. Thank you!
